The domestic mining industry is faced with a need to determine the nature and quantity of reserves and potential resources and to develop more efficient techniques and equipment for exploitation of the available ore deposits in competition with foreign suppliers.

A problem facing domestic smelters, and one that will probably become more serious in the future, is the maintenance of or establishment of a dependable and economic supply of primary raw material for existing plants in competition with foreign smelters. The nationalistic trend toward refining in the country of origin of the ores will diminish availability of ores for export and refining elsewhere.

The lead industry is influenced predominately by gasoline powered transportation as storage batteries and as gasoline additives. A continuing problem exists in the maintenance of lead superiority in these fields by research and technologic improvement and, also, in the other historic uses of lead constantly vulnerable to substitution by competitive materials. A need exists to determine and to develop other potential and advantageous applications of lead in construction and allied industrial fields.

Problems exist in many areas of utilization. The temperature requirements for lead-based solders, especially in automobile radiators, are increasing and improved mechanical properties and corrosion resistance at these elevated temperatures is needed. Difficulties are encountered in obtaining a strong bond and an impervious coating in using lead to clad other metals. Existing methods of joining lead pipe and cable are expensive and inefficient, and high-pressure lead calking methods require improvement for modern use. A number of lead compounds have properties peculiarly suited to use in protective and decorative coatings; however, the lead industry's growth in this area has not paralleled the growth of the coatings industry. Toxicity to humans is a problem of continuing concern and research study, especially in the area of atmospheric pollution control of highway and industrial plant fume.

LIGNITE

By Eugene T. Sheridan [1]

LIGNITE is a soft and porous carbonaceous material that is the intermediate stage between peat and subbituminous coal. Lignite is brownish-black in color and is referred to sometimes as brown coal.

There are known deposits of lignite in 15 States, and recoverable reserves have been estimated at 224 billion short tons. The bulk of the reserves occur in central and western North Dakota, northwestern South Dakota, and eastern Montana. There are also important deposits in Texas.

The lignite industry is concentrated in North Dakota which had 30 of the 35 active mines and about 90 percent of the total production in 1963. Virtually all of the remaining output was produced in Montana. Lignite in both States is restricted for the most part to local areas of production where it is used principally for electric-power generation and residential and industrial heating.

World production of lignite for 1963 was estimated at 760 million short tons. East Germany was the largest producer, followed by the U.S.S.R. and West Germany.

BACKGROUND

Lignite was used as domestic fuel in local areas from the time of settlement, but the lignite industry was not established until the latter part of the 19th century when mines were reported operating in California, Montana, North Dakota, South Dakota, and Texas. Data on production before 1930 are incomplete, but the U.S. Geological Survey reported in its annual report of the mineral resources of the United States for 1900 that production in North Dakota and Texas, the leading producing States at this time, totaled 382,795 tons.

The industry in Texas climbed from an annual output of 252,912 tons in 1900 to 1.4 million tons in 1914, then averaged about 1 million tons per year for the next two decades. Production began to decline in the late 1930's, however, as natural gas and petroleum took over fuel markets held by lignite, and by 1950, less than 20,000 tons of lignite was produced in Texas annually. Currently, lignite is mined at Rockdale in Milam County and at Darco, Harrison County. It is used principally for generating electric power, as a source of activated carbon, and as an oil well drilling-mud additive.

Production in California in 1900 was reported to be about 70,000 tons. California reserves are small and restricted to one area, and lignite has not been able to compete successfully as a fuel in this State. Only one mine is known to have been in operation in California in the past decade and the output from this mine has been processed for the recovery of montan wax.

Although still relatively small, the industry in Montana has expanded within the past decade with the use of lignite as fuel for generating electric power. From an output of only 25,572 tons in 1957 when virtually all was used for space heating, production increased to 289,532 tons in 1963. One power-generating plant in eastern Montana presently is using lignite for fuel.

Virtually all lignite produced in South Dakota is used for domestic fuel. The industry in this State has always been small and annual output has never exceeded 100,000 tons. Production in 1963 was only 16,561 tons.

Output in North Dakota, the leading producer since the 1920's, increased from 1.3 million tons in 1925 to 3.3 million tons in 1950, then gradually decreased to 2.3 million tons in 1958. Production since then has remained roughly at this level. North Dakota's lignite reserves are huge, and lignite always has been the major fuel used within the State. The industry has

[1] Supervisory mineral specialist.

been restricted in development, however, because the low calorific value and high moisture content of lignite confine its use to a relatively small marketing area. Most of the lignite produced in North Dakota is used for residential and industrial heating, and for electric-power generation.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Compared with the bituminous coal industry where active mines exceed 8,000, the lignite-mining industry is small; only 35 mines in 3 States were active in 1963. This number does not include mines with production of less than 1,000 tons, nor does it include the two active operations in Texas. Most of the industry is concentrated in North Dakota, which had 30 of the 35 active mining operations in 1963. Montana had four active mines and South Dakota had one.

The size of operations varied greatly, but most were small, with tonnages of less than 50,000 tons. Of the 30 mines operating in North Dakota in 1963, only 6 had outputs ranging between 100,000 and 500,000 tons, and only 1 had an output that exceeded 500,000 tons. Of Montana's four active operations, only one produced more than 50,000 tons in 1963.

The relative size of lignite mines in the United States in 1963 is shown in table 1.

TABLE 1.—*Relative size of lignite mines in the United States in 1963* [1]

Size	Number of plants	Production (short tons)
Under 50,000 tons	26	246,853
50,000–99,999 tons	1	58,172
100,000–199,999 tons	3	495,764
200,000–500,000 tons	4	1,192,366
Over 500,000 tons	1	711,926
Total	35	2,705,081

[1] Mines with production over 1,000 tons but exclusive of Texas.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Coals are separated into four general classes according to rank or degree of coalification—(1) Anthracite, (2) bituminous, (3) subbituminous, and (4) lignite.

The great variation in the composition of coals can be seen from the following analyses, on an ash-free basis, of a typical lignite and an anthracite:

	Lignite (percent)	*Anthracite (percent)*
Fixed carbon	33	92
Volatile matter	26	5
Moisture	41	3
Total	100	100

For the higher rank coals, rank is determined by the amount of fixed carbon and volatile matter in the coal as determined by proximate analysis. For lower rank coals, heating value and agglomerating properties denote rank. Lignite is our lowest rank of coal and, according to the American Society for Testing Materials (ASTM) classification, all coals with a calorific value of less than 8,300 B.t.u. per pound (moist, mineral-matter-free basis) are termed lignite. The class lignite is subdivided into two groups—Lignite A, which includes coals with calorific values between 6,300 and 8,300 B.t.u. per pound, and lignite B, which denotes coals with heating values of less than 6,300 B.t.u. per pound.

Most of the lignite reserves of the United States fall into the "A" grouping, and all lignite presently produced is of this type. Lignite B is similar to most of the brown coals that occur in Germany and other European countries.

As lignite production in the United States is relatively small and virtually all is used locally for heating and electric-power generation, lignite is not sold by grades and specifications, except that it is sold to powerplants on the basis of calorific value and ash and moisture content. It usually is subjected also to freezeproofing methods prior to shipment.

Although a standard size classification system has not been adopted by the industry, lignite is sold by certain designated sizes in common use, as shown in table 2. Generally speaking, lignite, as mined, that passes through a 2-inch mesh or smaller screen is called screenings or industrial size. To this may be added a 2-inch or smaller top size produced in the crushing and screening of other sizes. Stoker size prepared by crushing lump lignite is designated by the word "crushed" as it has a more uniform size distribution than the regular screened size. Nut sizes of 2 by 1 inch, or 2 by 1½ inches, may be screened from the crushed product. Large-size double-screened coals used in domestic heating and cooking equipment are described by their use, as plus 8- or plus 6-inch lump, or 8- by 4-inch furnace size.

Leonardite, a coal-like substance associated with lignitic outcrops, is thought to be derived from lignite by the process of natural oxidation. The significant difference between leonardite and lignite is the oxygen content; leonardite contains 28 to 29 percent oxygen and lignite, 19 to 20 percent. Leonardite is little known out-

side lignite-producing areas and deposits have been developed commercially only to a minor extent.

TABLE 2.—*Common designation for lignite sizes, as produced*

Designation	Size (inches)
Lump	plus 8
	plus 6
Furnace	8 by 4
	6 by 3
Stove	4 by 2
	3 by 2
Nut	2 by 1
	2 by 1½
Stoker, crushed	2 by 0
Industrial or screenings	2 by 0
Industrial stoker or rescreened screenings	2 by ¼ or 1¼ by ¼

TECHNOLOGY

Geology

Although coal commonly is thought of as a mineral, it differs from minerals, such as stone and iron ore, in that it is of organic origin. Coal was formed from the remains of living vegetation—trees, shrubs, roots, herbs, and vines—that grew many millions of years ago in swamps and bogs. Century after century, the dead vegetation accumulated to a gradually increasing depth, and only after a series of transformations, usually by movements of the earth's crust accompanied by heat and pressure, these deposits were gradually converted to coal. Varieties of coal, which represent different degrees of conversion, are known as ranks. Anthracite, which represents the greatest degree of conversion, is the highest rank of coal; lignite is the lowest.

Peat is the initial stage in the formation of lignite and other coals. When plant materials fall upon dry ground, they are attacked by fungi and bacteria and decompose rapidly. However, when the plant material falls into water or on soil saturated with moisture, atmospheric oxygen, which controls bacterial activity, is excluded and decomposition is retarded. Plant debris accumulated under such conditions results in the formation of peat, and an accumulation of many layers of plant materials forms a peat deposit.

The changes involved in the conversion of peat into coal are not completely known, but it is thought that the transformation is due largely to pressures exerted by overlying strata laid down on a peat deposit, and by mountain building and earth disturbances. Changes in elevation are constantly occurring in the earth's crust, and the subsidence of a peat deposit followed by an accumulation of overburden appears to have been the initial change. In the course of time subsidence of the surface may have been reversed and the deposit elevated, sometimes above its original level, to form one of the convolutions of strata of hills or mountains. The combination of heat and pressure accompanying such a movement plus the continued exertion of these forces over very long periods, greatly altered the chemical and physical properties of the original plant structures, and the resulting material, which varies in degree of transformation, is called coal.

Coalification is extremely slow when it depends mainly upon pressure generated by overlying rock. For this reason many coal deposits are still of low rank, that is, in an early stage of coalification, although they may have been buried millions of years. The advanced state of coalification typified by Pennsylvania anthracite probably is due to the enormous pressures to which deposits were subjected when the Appalachian mountains were formed. The anthracite seams are thought to be extensions of the bituminous seams of central and western Pennsylvania that were subjected to greater pressures and temperatures during the mountain-building era.

Seams or bands of coal, separated by layers of clay, shale, and other organic material, apparently represent the effects of alternate depressions and elevations during which succeeding layers of peat were formed. Inorganic materials within the coal probably were deposited as suspended particles in the water in which the peat was formed, or may have evolved from the organic materials of the coal itself.

Mining, Preparation, and Storage

Virtually all lignite is produced by strip mining, but most stripping operations are small and production is concentrated at a relatively small number of large operations. Of the 31 strip mines active in 1963, 8 produced almost 90 percent of the total output of the industry. There were only four active underground mines in 1963, and their combined production was less than 1 percent of the total lignite output.

One factor of major importance in a stripping operation is the thickness of the overburden in relation to the thickness of the seam being mined. Individual beds of lignite vary substantially in thickness, ranging from about 3 feet to 25 feet. The depth of overburden also varies, and in some instances it is necessary to remove overburden up to 70 feet thick and place it in a position where it will not interfere with subsequent operations. Overburden in the lignite areas, however, usually is composed of unconsolidated clays with occasional shale or

sandstone, which can easily be removed by stripping shovels, draglines, or bulldozers.

Lignite operations generally employ about the same stripping methods as bituminous coal stripping mines. Stripping consists of removing the overburden in successive uniform cuts and placing it in a previous adjacent cut from which lignite has been removed. The equipment used depends chiefly upon the depth of the overburden and the financial resources of the producing company.

A newly designed strip-mining machine called a wheel excavator was being installed in 1964 at Truax-Traer Coal Co.'s Glenharold mine in North Dakota. This machine has an expected advantage over conventional equipment in that it will provide for the simultaneous mining of four beds of lignite. The discharge end of the machine can be manipulated in a 105° arc. When refuse is being mined, the discharge boom is over the spoil pile; when lignite is being mined, the discharge boom is rotated to a stockpile in the pit.

Preparation processes in the lignite industry consist principally of crushing and screening, and in some instances, treating with oil to improve handling characteristics by reducing dust, and freezeproofing. Other processes common to the coal industry, such as mechanical cleaning or washing, are not practiced with lignite because ash content usually is low, and lignite is unresponsive to such forms of beneficiation. Lignite as shipped generally has an ash content of 5 to 8 percent. Removing the weathered layer on top of the uncovered bed before loading and leaving the bottom of the bed for the loading shovel reduce the inclusion of extraneous matter, and quality for a given mine is quite uniform. In general, the mineral matter of lignite is largely composed of finely divided particles that are difficult to separate.

As the market for lignite is largely for stoker and industrial sizes for power generation, most lignite is crushed and, at the larger mines, is passed through a primary breaker, then over a shaker screen where the various lump sizes are separated for sale or additional crushing. Double-roll crushers are used for secondary crushing in many instances, but other types of equipment such as hammermills also are used for size reduction.

Lignite normally is not dried prior to shipment, but a few large companies dry a small portion of their production and mix it with natural lignite for freezeproofing purposes. One method used is pneumatic or entrained drying, which is applicable only to fine materials. In this process moisture is removed from fine-sized lignite suspended in a cyclone separator by a rapidly moving stream of hot gases. The equipment includes a heat source such as a firebox and stoker, a duct into which the lignite is dispersed in the hot gas stream, a cyclone separator equipped with an air lock, and an exhauster which pulls the gases and fine solids through the system.

In steam drying, which has been used commercially in Europe, lignite is placed in an autoclave and heated with saturated steam at from 250 to 400 pounds per square inch, gage. During a period of heating, followed by a period of steaming under pressure, some of the moisture in the lignite is expelled and drained off as liquid water. The residual heat in the lignite causes additional moisture to be removed during the pressure-release period. Since part of the water is removed as a liquid, the thermal requirement for steam drying per unit quantity of moisture removed is less than for processes in which all moisture is removed by vaporization.

Lignite must be stored under strict storage procedures to avoid spontaneous combustion and slacking, or degradation of the product. Where the amounts stored are small and removal is continuous, lignite is stored in bins or silos. If stored for long periods, airtight covers must be used on the bins or silos. For large tonnages, lignite usually is stored in compacted piles according to special stockpiling procedures. These usually consist of constructing the piles in layers, 1 foot or less in thickness, and crushing, leveling, and compacting each layer with rollers.

Combustion

Lignite can be burned at heat-release rates and efficiencies nearly comparable to those of higher rank coals, and large quantities are consumed each year in firing boilers for electric-power generation. Because of its high moisture content, however, the heating value of a pound of lignite is only about one-half that of many eastern coals. Therefore, when lignite is burned for power generation, the fuel-handling and preparation equipment must be increased proportionately in size, and the power required for operating this equipment must be increased accordingly. Boiler efficiencies also are about 5 percent less than those of boilers burning other fuels because of the heat required for moisture evaporation. To obtain maximum efficiency, lignite furnaces generally are built higher and have somewhat greater volume per unit capacity than furnaces burning higher rank fuels.

As with bituminous coal, lignite can be burned successfully in powerplant boilers using underfeed stokers, traveling-grate stokers, spreader stokers, pulverized burning equipment, and cyclone burners. The first really successful

equipment suitable for lignite was the forced-draft, traveling-grate stoker, which was used extensively for a number of years until it was replaced by the more efficient spreader stoker. Spreader stokers used in conjunction with traveling grates are used at most of the smaller plants, but larger installations use the unit-pulverizer method of firing because spreader stokers have boiler-size limitations.

The most recent development in coal-burning equipment is the cyclone burner, which was developed to obtain higher efficiencies and improved performance in burning high-ash coals with low-ash fusion temperatures. This burner has a refractory-lined, water-cooled, combustion chamber into which pulverized coal and air are introduced tangentially at one end so that the air and fuel are given a whirling motion. The fuel is burned at high temperatures as it travels through the burner, leaving most of the molten ash adhering to the cylinder wall, from which it flows by gravity to a slag tank. As with any unit designed for liquid ash removal, this furnace must operate well above the fusion temperature of the ash for satisfactory tapping of the slag.

Carbonization

Carbonization is the thermal processing of coal in ovens or retorts in the absence of air. Such processing yields a liquid fraction containing tar and other basic chemicals; a relatively low B.t.u. gas; and a solid residue called char or coke. Carbonization of lignite in the United States has been limited because the carbonization products are different from those of bituminous coal and are in small demand. Lignite, when carbonized, forms a char rather than coke and is not satisfactory for metallurgical applications. The small quantity of char currently produced is used principally for manufacturing briquets.

In the briquet plant at Dickinson, N. Dak., of the Husky Oil Co. of Cody, Wyo., lignite is crushed to 4 inches or less and carbonized in Lurgi-Spülgas retorts. After carbonization, the char residue settles at the bottom of the retort where it is cooled by recycled carbonization gas and discharged. A gas mixture containing tars and other products of combustion is drawn off at the top of the carbonizer and, after processing for the removal of dust and tars, the gas is recycled to the carbonizer to supply heat for the process. The tars and light oils, after separation from the water condensate, are distilled into a liquid fraction and a pitch residue. The distillate is used as a wood preservative, and the pitch, supplemented by petroleum asphalt, as a binder for manufacturing briquets suitable for residential heating.

The Husky briquetting plant also manufactures a smokeless barbecue briquet. In this process, sulfur-laden pyrites are removed from the char, which then is mixed with a starch binder and compacted at 5,000 to 10,000 pounds per square inch. After drying to 4 percent moisture, the briquets are cooled for 72 hours, packaged in small bags, and sold as fuel for barbecue grills, ovens, and broilers.

Gasification and Hydrogenation

The gasification products of lignite generally are defined as synthesis gas and producer gas. Producer gas is made by blowing air through a solid-fuel bed with or without the addition of steam. The resulting product is a relatively inexpensive gas containing a high percentage of nitrogen. Because of its low heating value, producer gas is not suitable for utility distribution and normally is used at or near the point of production. Gasification of lignite or brown coal is done on a commercial basis in several foreign countries, but lignite is not processed in this manner in the United States.

Lignite can be converted also into liquid products having potential use as chemicals or fuel by a process called hydrogenation. This is a type of processing in which the complex compounds of the coal are split and partially broken down into lower molecular weight products by the direct addition of hydrogen under pressure.

USES

Lignite is used in the United States principally as fuel for residential and industrial heating and for generating electric power. Approximately two-thirds of the total consumed in 1963 was used in powerplants, and most of the remainder, for space heating. Small quantities were used for several other purposes.

One plant carbonized lignite in a Lurgi gasifier and produced a char which was then briquetted. This plant produced two types of briquets: (1) a conventional fuel briquet that was sold for space heating, and (2) a smokeless briquet that was sold as fuel for outdoor grills.

Some lignite deposits yield montan wax and the output of a small mine at Ione, Calif., is operated for this purpose. Wax is recovered by a solvent-extraction process and used in polishes, phonograph records, candles, carbon paper, and crayons.

Lignite can be used as a source of activated carbons, and one plant in Texas processes lignite for this purpose. Activated carbons derived from lignite are used for decolorizing solutions, water treatment, recovery of solvents, gas absorption, recovery of gold, and extraction of iodine.

Leonardite, a form of oxidized lignite, is used as a dispersant, for viscosity control in oil-well drilling muds, as a stabilizer for iron-exchange resins in water treatment, and as a source of water-soluble brown stain for wood finishing. Leonardite is also a source of humic acids and a plant in Wyoming has been reported to be producing limited quantities of lignite-based fertilizer having a humic-acid content of 50 percent.

Lignite is used also in a number of foreign countries as a primary raw material for the production of chemicals, heating gases, and liquid fuels.

RESERVES

The potential recoverable reserves of lignite in the United States are estimated to total 224 billion short tons, approximately one-quarter of the total reserve of all ranks on a tonnage basis. However, the calorific value of lignite is lower than that of other coals, and, on the basis of equivalent heating values, the lignite reserve represents about one-sixth of our total coal resource.

Lignite occurs in three general areas—The northern Great Plains, the gulf, and the Pacific coast. The northern Great Plains region includes the western half of North Dakota, eastern Montana, northeastern Wyoming, and northwestern South Dakota. Deposits in this region are in extensive blanket-like beds, and the recoverable reserve is estimated at 220 billion tons, about 98 percent of the U.S. total. North Dakota has the most extensive deposits, with recoverable reserves estimated to total 175 billion tons, nearly four-fifths of the U.S. total.

Gulf region deposits, which are in the lower Mississippi Valley, occur in Alabama, Arkansas, Kansas, Louisiana, Oklahoma, and Texas. The principal deposits in this region are in Texas where the recoverable reserve is estimated to be 3.4 billion tons, somewhat less than 2 percent of the U.S. total.

Reserves of the Pacific coast are in the central and western parts of California and in the western parts of Oregon and Washington. There are also small deposits of lignite in Idaho and Nevada. Unlike the extensive blanket-like beds of the northern plains, these deposits, as those of the gulf region, are discontinuous and relatively small. Reserves in these States constitute less than 1 percent of the total lignite resource of the United States.

Table 3 shows the geographic distribution of reserves, and table 4 shows lignite reserves in relation to reserves of all other ranks of coal.

TABLE 3.—*Potential recoverable reserves of lignite [1] by States, as of Jan. 1, 1964*

State	Million short tons
North Dakota	175,352
Montana	43,766
Texas	3,440
South Dakota	1,017
Arkansas	175
Alabama	10
Other States [2]	25
Total	223,785

[1] Estimated on the basis of 50-percent recovery of the total estimated reserve.
[2] Includes Alaska, California, Idaho, Kansas, Louisiana, Nevada, Oklahoma, Washington, and Wyoming.

TABLE 4.—*Potential recoverable reserves of various ranks of coal,[1] based on bituminous coal equivalent, as of Jan. 1, 1964*

	Million short tons	Equivalent million short tons of bituminous coal [2]	Percent of total coal reserves on B.t.u. basis	Calorific values used for conversion (B.t.u.'s)
Anthracite	8,000	8,000	1	12,700
Bituminous	378,000	378,000	57	13,100
Subbituminous	218,000	158,000	24	9,500
Lignite	224,000	115,000	18	6,700
Total	828,000	659,000	100	

[1] Estimated on the basis of 50-percent recovery of the total estimated reserve.
[2] Based upon a calorific value of 13,100 B.t.u. per pound.

SOURCES OF STATISTICAL INFORMATION

The sources of data on lignite are the same as those outlined for coal in the annual chapter on bituminous coal in the Bureau of Mines Minerals Yearbook, volume II. Most of the statistical information was based upon detailed annual reports of production, mine operations, and product distribution, furnished by producers to the Bureau. For production not reported to the Bureau (chiefly that of small mines), data were obtained from various State mine departments and, in a few instances, from railroad carloadings. Thus, complete coverage of all mines producing 1,000 tons or more per year was included in this report.

PRODUCTION AND CONSUMPTION

Production of lignite in the United States in 1963 was 2.7 million tons. This quantity does not include the production of lignite by two companies in Texas, for which data are confidential, nor the production of mines with an output of less than 1,000 tons. North Dakota

was the largest producer, with about nine-tenths of the total output. Montana produced virtually all of the remainder, but one mine in South Dakota produced 17,000 tons.

Production in North Dakota was centered in Mercer County in the west-central part of the State, and in Burke and Ward Counties in the northwest. The largest producers were the Truax-Traer Coal Co., the Knife River Coal Mining Co., and Baukol-Noonan, Inc. Montana's output was produced principally in Richland County in the northeastern section of the State. The Knife River Coal Mining Co. is the principal producer of lignite in Montana.

Virtually all lignite was produced by strip mining. Except for a small decrease in 1963, caused principally by the relocation of one large operation and the adoption of more selective mining practices at others, lignite production has increased moderately each year since 1958. Compared with average production for 1957–59, output in 1963 increased 6 percent.

World production of lignite for 1963 was estimated to total 796 million tons. U.S. production was less than 1 percent of the world total.

Lignite production in the United States, by States and counties, in 1963, is shown in table 5.

TABLE 5.—*Lignite production in the United States in 1963* [1]

State and county	Number of mines	Production (short tons)
Montana:		
Powder River	1	(2)
Richland	2	(2)
Sheridan	1	2,653
Undistributed		286,879
Total	4	289,532

[1] Mines with production over 1,000 tons but exclusive of Texas.
[2] Included with "Undistributed."

Consumption of lignite in 1963, as shown in table 6, was 2.6 million tons. Of this quantity, consumption by powerplants, according to data compiled by the National Coal Association from records of the Federal Power Commission, was 1.7 million tons, nearly two-thirds of the total lignite used by utilities and shipped by producers to other consumers. Of the total used for electric-power generation, 58 percent was consumed at plants in North Dakota and South Dakota, and 24 percent in Minnesota. These three States also used a combined total of nearly 1 million tons of lignite for heating purposes.

TABLE 6.—*Consumption by electric utilities, and shipments by producers to retail dealers and other consumers, of lignite in the United States in 1963*

[Short tons]

State	Utility plants [1]	Retail dealers [2]	All other uses [2]	Total
Minnesota	406,000	6,000	241,000	653,000
North Dakota and South Dakota	963,000	407,000	299,000	1,669,000
Montana and Wyoming [3]	304,000	----------	6,000	310,000
Total	1,673,000	413,000	546,000	2,632,000

[2] Shipments of lignite as reported by producers to the Bureau of Mines.
[3] Does not include Texas.

PRICES

The average value per ton of all lignite produced in the United States in 1963, f.o.b. plant, was $2.17. Prices of lignite have steadily decreased as a result of increased productivity, and the average price was $0.15 per ton less than that in 1957–59. An indication of the relative costs of producing lignite by strip mining and underground mining is shown in table 7. The average value per ton of all lignite produced at underground mines in 1963 was $4.63, compared with only $2.17 for lignite at strip mines.

TABLE 7.—*Summary of data on lignite mines in the United States operating in 1963* [1]

	Underground	Strip	Total
Number of mines	4	31	35
Production ---------- short tons	7,048	2,698,033	2,705,081
Average value per ton	$4.63	$2.17	$2.17
Average number of men working daily	12	332	344
Average number of days worked	113	209	206
Number of man-days worked	1,360	69,350	70,710
Average tons per man per day	5.18	38.90	38.26

[1] Mines with production over 1,000 tons but exclusive of lignite produced in Texas.

EMPLOYMENT AND PRODUCTIVITY

Employment at lignite mines has declined steadily because of increased mechanization and the continued change from underground to strip-mining operations. Compared with 1957–59 when the average number of men working daily was 384, there was an average of 344 men

employed by the industry in 1963. Of this number, 12 were employed at 4 underground mines and 332 at 31 strip mines. Peak employment was in 1939 when a total of 2,130 men were employed at lignite mines.

Productivity during the past decade, as measured in tons of output per man-day, has ranged from a low of 32.68 tons in 1956 to a high of 42.46 tons in 1962. The trend was steadily upward from 1958 until 1963 when output decreased because of more selective mining practices at some stripping operations and the movement of one large strip mine to another location. Productivity at strip mines far exceeded that of underground mines; output at stripping operations in 1963 was 38.9 tons per man-day, compared with only 5.18 tons per man-day for underground operations.

Statistical data on employment and productivity are shown in tables 7 and 8.

TABLE 8.—*Production, value, men working daily, days active, man-days, and output per man per day at lignite mines in the United States* [1]

Year	Production (short tons)			Average value per ton f.o.b. mines	Average number of men working daily	Average number of days worked	Number of man-days worked	Average tons per man per day
	Underground	Strip	Total					
1957–59 (average)	18,550	2,535,421	2,553,971	$2.32	384	197	75,471	33.83
1960	13,669	2,732,399	2,746,068	2.29	384	197	75,662	36.29

[1] Excludes lignite produced in Texas.

RESEARCH

Although the use of lignite in the United States is relatively small, the potential of the resource has tremendous magnitude, and a large amount of effort has been devoted to the improvement of technology relative to using lignite as a fuel and as a source of raw materials for the production of gas and chemicals, and to the development of new product uses. Because of the small size of the industry, much of the research has been conducted by the Federal Government, principally the Department of the Interior through the Bureau of Mines. Industry, however, has become increasingly aware of the fruits of research and is expending effort along these lines, contracting for most of the work with commercial laboratories. In implementing its responsibilities for conserving and developing the Nation's mineral-fuel resources, the Bureau of Mines has conducted a large-scale research program on lignite for many years at its Lignite Research Laboratory at Grand Forks, N. Dak. Investigative studies have been widespread, ranging from fundamental and basic research to applied research and development. Current work has been concerned principally with the use of lignite as fuel in steam-generating units and as a solid reductant for iron ore; storage techniques; burning characteristics; preparation, pulverizing characteristics, and pneumatic drying; extraction of humic acids; and the hydrocracking of low-temperature lignite tar.

Emphasis has been placed on the upgrading of lignite for fuel. Because the use of lignite has been somewhat limited by its inherently high moisture content, methods have been developed for removing some of the moisture, particularly to keep it from freezing when shipped. Relatively recent studies by the Bureau have shown that the addition of 15 percent by weight of dried lignite fines to as-mined lignite before shipment is superior to the conventional oil-treatment method of freezeproofing, a nd one large producer has adopted this process for all lignite shipments. Another producer partially dries all of his product as a method of freezeproofing.

Another area of study is carbonization. In addition to char, the carbonization of lignite results in the production of tar and other chemical materials that normally must be sold to carbonize lignite economically. The Bureau has devoted substantial attention to the characterization of such products with the view of developing methods for upgrading so that these products can be sold in established markets.

The production of gas by total gasification procedures offers the potential for a large tonnage outlet for lignite, and the Bureau has made numerous investigations in this area. Synthesis gas consists chiefly of carbon monoxide and hydrogen, chemicals which after suitable purification and modification, can be used for the production of ammonia, synthetic liquid fuels, and various organic chemicals. Synthesis gas also can be burned as a reducing gas in metallurgical applications. Experiments on fixed-bed gasification are being continued by the Bureau, and a pilot-scale slagging gasification plant for evaluating the German Lurgi process has been erected at the Grand Forks Laboratory.

OUTLOOK

The short-range future for lignite appears to be one of moderately increased production with the bulk of the output being consumed in present markets, namely residential and industrial heating and electric-power generation. An increase in production, however, will result principally from an increased demand for powerplant fuel because heating markets that have been lost to oil and gas probably will not be recaptured. The inroads made by oil and gas into lignite heating markets in recent years appear to have reached a peak, and the lignite industry should be able to retain present heating markets. New discoveries of natural gas, however, could present another threat. It is expected that lignite will continue as the principal fuel of electric-utility plants in lignite-producing areas and that electric power requirements in the next few years will increase at a rate more or less consistent with population growth. Further expansion of utilities will be tied to the expansion of existing local industries or the establishment of new ones.

The long-range future for lignite is more difficult to forecast. Fuel and energy markets undoubtedly will continue to increase, but the extent of the increase will depend upon technological developments and other factors, such as the attraction of new industries to the lignite-producing areas, or the development of new product uses. Fuel marketing areas probably will be extended in the future, by removing moisture from the lignite and shipping an upgraded product. There is also the possibility of onsite powerplants producing electric power for long-distance transmission.

Markets for barbecue briquets made from lignite char should continue to expand, and leonardite should find increased usage as a conditioning agent for oil-well drilling muds. The key to lignite development, however, will be the establishment of new use markets that will consume large tonnages. Markets that appear to show the most promise would use lignite as a raw material for the production of chemicals or synthesis gas, as a fuel for the production of prereduced taconite pellets, or as a source of humic acids for the preparation of fertilizers.

PROBLEMS

The lignite industry has been limited in expansion by a number of interrelated factors, but the principal limiting factor is the nature of the product. Being a low-rank fuel with a high moisture content, lignite can compete with other higher rank fuels only in local fuel markets because transportation costs restrict its movement. The present marketing area for lignite extends about 300 miles east and southeast from the areas of production. The eastern market extends to the area where the price of lignite is equaled by that of eastern coals delivered at northern Lake ports; the southeastern market extends to where prices are equal to those of coal barged up the Mississippi River. North and west of the lignite deposits, markets are limited by the lack of population and the availability of higher-rank coals. The marketing area for lignite, therefore, is very small. But this disadvantage is compounded by the small population and limited industrial markets within the area where lignite is competitive.

A major problem encountered in burning lignite in power stations is boiler fouling. This is a condition that occurs when deposits of ash form on the convection surfaces of boilers, gradually decreasing efficiency to the point where the boilers must be taken out of service for manual cleaning. Although the problem is complex and not fully understood, it is suspected that some of the causes of fouling are due, not only to impurities in the lignite, but also to compounds appearing in the ash. Some of the problems of ash deposition can be solved by using a suitable boiler design and modern cleaning devices. More information is needed, however, on the various impurities in lignite ash, such as alkalies, that are thought to be responsible for fouling, and the relationship between certain other factors, such as ash particle size and exit-gas temperatures, that are associated with ash deposition.

A continuing problem of the industry is storage. Lignite "weathers" or "slacks" badly upon drying, and lump sizes deteriorate when lignite is stockpiled. It is subject also to spontaneous heating and can be stored only under controlled conditions.

Because of its high moisture content, lignite becomes severely agglomerated when shipped in cold weather, and unloading railroad cars containing frozen lignite presents a serious problem. A number of freezeproofing methods have been developed, however, and the problem usually is eliminated if lignite is processed prior to shipment.

The industry is hampered by the lack of detailed information on specific lignite deposits. Data on the size and extent of reserves in in-

dividual deposits are very limited, and only meager information is available on seams and the impurities that exist in various seams and strata. The development of such basic information on reserves would, undoubtedly, promote a more extensive utilization of lignite resources.

Another basic problem is that most lignite-producing companies are of relatively small size and have a limited capacity for individual research and engineering. The lignite industry is very cognizant of its problems, however, and actively participates in the work of the Lignite Advisory Committee, a group appointed by the Secretary of the Interior in 1960 to consider current problems of the lignite industry as an aid in the programing of research.

LIME AND CALCIUM

By Perry G. Cotter [1]

CALCINATION of limestone, marble, chalk, calcareous marl, shell, and dolomite at moderately high temperatures releases carbon dioxide gas and leaves behind a solid residue of quicklime, which is usually calcium oxide but may be calcium-magnesium oxide as well. Addition of water to quicklime causes rapid hydration to calcium hydroxide, $Ca(OH)_2$, or hydrated lime.

Manufacture and use of quicklime and hydrated lime is almost as old as recorded history, and the importance of these commonplace, time-tested, construction and chemical materials has not diminished at all. More quicklime and hydrated lime than ever before is required to satisfy the growing needs of modern civilization. To the few, original, primary uses in building and agriculture have been added thousands of chemical and industrial uses in modern times. Most quicklime and hydrated lime enter into chemical and industrial applications. Smaller quantities are employed in construction in mortar and plaster and in soil stabilization and in agriculture as a soil neutralizer and conditioner. Being economical as well as essential, lime has virtually no substitutes in most of its many, varied chemical and industrial uses. There has been some significant competition from other materials in construction and agriculture. Quicklime is also the principal raw material in calcium production.

Lime is so reactive to water and carbon dioxide that it never occurs naturally and is very perishable. Accordingly, it is manufactured as it is needed, and the supply ordinarily equals the demand. Although there are many kinds of calciners, most quicklime is manufactured in two types of kilns: Vertical kilns and rotary kilns. In the United States rotary kilns produce most of the quicklime, but abroad vertical kilns are responsible for most lime manufactured. Even in the United States, vertical kilns predominated in lime output until recent years. There are two classes of hydrators, continuous and batch hydrators; the continuous hydrator is preferred.

Many problems are encountered in quarrying, calcining, hydrating, storing, handling, and transporting. Problems at some operations include collecting and utilizing comminuted limestone waste, using byproduct carbon dioxide, and recovering or disposing of lime sludge. Particular attention is being directed continually toward the improvement of kiln design and operation, and basic research is also being conducted into the fundamental nature and properties of lime itself. So far as calcium is concerned, research deals with new methods of extraction that increase purity at lower cost; new ways of fabricating, working, and machining the unusual metal; and finding new uses for it, its alloys, and its compounds (*4*).[2]

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1963, 210 lime and dead-burned dolomite plants in 38 States and Puerto Rico produced 14.5 million tons of lime valued at $199 million at the plant. Next to sulfuric acid lime is the largest tonnage chemical produced in the United States.

There has been a steady reduction in the number of lime plants in the United States for the past 60 years. In 1963 the 67 plants, or 30 percent of the total plants reporting, had an annual output of less than 10,000 tons each. The 19 plants reporting production of 200,000

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to the items in the list of references at the end of this chapter.

tons or more accounted for 49 percent of total lime. Ohio, Michigan, and Missouri, in descending order, are the principal lime producing States, while the three largest consumers of lime also in descending order are Ohio, Michigan, and Texas. Most of the lime produced in the United States is high-calcium lime derived from limestone containing over 95 percent calcium carbonate, from marble waste and from shell. Most Ohio lime is dolomitic. Dolomitic lime also comes from Massachusetts, Eastern Pennsylvania, Illinois, Wisconsin, Utah, Nevada, and California. In Texas and Louisiana much high-calcium lime is derived from shell. Less than 5 percent of the total crushed limestone or 21.5 million tons produced in 1963 was used for making lime and dead-burned dolomite.

DEFINITION OF TERMS, GRADES, TESTS, AND SPECIFICATIONS

The calcination of limestone, shells, or other calcium carbonates produces *quicklime*. *Lump lime*, in pieces 5 to 12 inches in size, is a product of stationary or shaft kilns. The calcination process does not change the shape or size of the original limestone charge, but the porosity of the lumps is considerably increased by voids left by the removal of carbon dioxide. The reaction involved in calcining is: $CaCO_3$ + heat = CaO (lime) + CO_2 (carbon dioxide). Lump lime may be crushed or ground to customers specifications. A smaller sized product, resulting from the calcination of ½ to 2½ inch size limestone, is obtained from rotary kilns and is known as *pebble lime*. *Hydrated lime* is produced from ground quicklime by the addition of carefully controlled amounts of water in intermittent or continuous mechanical hydrators. This hydration process gives a stable, finely divided dry material, 95 percent of which passes through a 200 mesh screen. For many uses hydrated lime is more satisfactory than lump lime and is easier to store and transport. A paste of slaked lime and water is termed *lime putty*, and a suspension of slaked lime in water is called *milk of lime*.

Dolomite, calcined at a high temperature, with the addition of a stabilizing agent such as iron oxide or mill scale, becomes relatively inert to the action of atmospheric moisture and carbon dioxide and is known as *dead-burned dolomite* (*5*). This refractory material is granular and can be shipped in bulk. Dead-burned dolomite statistics have been included with the lime statistics by the Federal Bureau of Mines. A semiburned dolomite produced at temperatures below 1,900° F is used for water treatment.

The general term *lime* is often misconstrued to include materials other than the oxides and hydroxides of calcium and magnesium and is applied without discrimination to limestone, marls, shell, and gypsum. "Agricultural liming material", according to the Association of Official Agricultural Chemists is "material whose calcium and magnesium content is capable of neutralizing soil acidity." In industry the term lime is used to denote calcium carbonate, calcium sucrate, and calcium acetate. *Hydraulic lime* is produced by calcination of limestone containing enough aluminous and siliceous material, such as clay minerals, to form a substance that will slake and set or harden under water. Feeble hydraulic limes contain 5 to 10 percent argilaceous material, and highly hydraulic limes contain 15 to 30 percent. The slow rate of setting and low strength of hydraulic limes make them inferior to the conventional portland cements for most construction uses. *Hydraulic limestone* contains the proper amounts of silica and alumina so that a hydraulic lime, which will slake and set or harden under water, will be produced on calcining. Specifications for different uses of lime are given in a report by the National Lime Association (*3*), and periodically in reports of the American Society for Testing and Materials (*1*).

Commercial limes include such impurities as alumina, silica, and iron oxide. Alumina and silica in lime often indicate the presence of clay and less often mica and feldspar in the original limestone. Also the presence of silica may indicate these silicates, or admixed quartz, chalcedony, or calcium and magnesium silicates. The presence of over 5 percent silica in a limestone renders it unsuitable for limemaking. To be used to manufacture chemical or metallurgical lime, the limestone should contain less than 1 percent alumina and less than 2 percent silica. Iron oxide in lime is derived from limonite, pyrite, or siderite in the limestone, and their presence may result in off color lime. Organic or carbonaceous impurities are less objectionable, because they are removed as carbon dioxide during calcination. Sulfur from pyrite and phosphorous from apatite and collophane, on the other hand, are undesirable contaminants in chemical and metallurgical lime and should not exceed 0.05 and 0.02 percent respectively. The inherent dangers to public health because of the presence of lead, zinc, and other metals or minerals in some agricultural lime is under investigation.

TECHNOLOGY

Calcium is the fifth most abundant element in the earth's crust and constitutes 3.4 percent

of it by weight. Calcium oxide is the fourth most abundant oxide in the earth's crust, amounting to 4.8 percent. Lime and calcium chloride are the principal sources of elemental calcium or calcium metal, its alloys, and its compounds used for metallurgical purposes. Calcium is a silvery-white, soft, light bivalent metal of the alkaline-earth group. It has a Rockwell B hardness of 36 to 40. On exposure to air, it tarnishes quickly, acquiring a thin bluish film. The metal oxidizes rapidly in the presence of moisture or at a temperature above 570° F. Calcium imparts a brilliant yellowish-red light to the test flame. Its atomic number is 20, atomic weight is 40.08, specific gravity at 70° F, 1.55, it melts at 1,560° F, and boils at 2,625° F. At 840° F, calcium changes from the face-centered cubic system to the body-centered cubic or hexagonal close-packed crystal system.

Although calcium is much too unstable to occur naturally, its compounds are very common in nature. It occurs as carbonates (limestone, marble, chalk, calcareous marl, shell, calcite, aragonite, dolomite, and ankerite); sulfates (gypsum and anhydrite); phosphate (apatite); fluoride (fluorspar or fluorite); and in many silicate minerals. Virtually all natural waters carry dissolved calcium compounds. Calcium is usually the most abundant nonaqueous element in fresh water. On the average it constituted 20.3 percent of the solid mineral residue of fresh water, having an average salinity of 146 parts per million, in a recent worldwide study. Compounds of calcium are essential constituents in the bodies of most animals and plants. Bones, teeth, and shells are calcium compounds, and on the average, calcium amounts to 0.5 percent of the dry weight of terrestrial plants and 20 percent of their ash.

Mining and Milling

Limestone and dolomite used in manufacturing limes are obtained from open pits and underground mines. Mining and quarrying are discussed in the "Stone" chapter. Elimination of impurities, careful sizing, and careful selection of stone are required in mining and quarrying to produce lime of uniform composition and size or of special composition. Crushers are used to break the quarried limestone and screen to size it (*14*).

Lime Processing

Crushed stone composed of calcium carbonate yields carbon dioxide gas when heated to the dissociation temperature of about 1,400° to 1,700° F, and highly basic calcium oxide, or quicklime, remains. When treated with water the quicklime slakes, giving off heat and increasing in volume to form calcium hydroxide or hydrated lime. Both quicklime and hydrated lime react slowly with water vapor and carbon dioxide in the air to return to the original, more stable, calcium carbonate.

Limestone is calcined in shaft and rotary kilns. Quicklime is the immediate product of calcination. Theoretically, 1,000 pounds of limestone will produce 560 pounds of quicklime. In many modern lime plants, a significant proportion of the quicklime output is converted to hydrated lime by processing it one step further in a batch or a continuous hydrator. The 560 pounds of quicklime require 180 pounds of water to be completely hydrated; thus 1,000 pounds of limestone will theoretically yield 740 pounds of dry hydrated lime. These theoretical yields of quicklime and hydrated lime represent the ideal maximum that is never realized, and smaller quantities are always produced under the less than ideal conditions of actual manufacturing. Over one-fifth of the lime produced in the United States is hydrated. Modern methods of lime manufacture, including quarrying or mining, preparing, calcining, and hydrating, have been published. Carefully classified, crushed limestone, ranging from ¼ inch to 2½ inches in size, is fed into the higher end of the rotary kiln and pebble quicklime is taken from the lower end. Rotary kilns vary from 6 to 11½ feet in diameter and from 60 to 400 feet in length, although 150 feet is the most common length. To reduce fuel costs, most rotary kilns have preheaters at the feed end and coolers at the discharge end. The rotary kiln is considered to have the highest capacity of all limekilns. Rotary kilns produce the greatest lime tonnage per man-hour of all limekilns, are the most completely automatic and instrumented kilns, permit the highest degree of quality control, and produce the most uniform quicklime. On the other hand, they require a larger capital investment and have higher unit fuel costs than efficient vertical kilns.

Vertical or shaft kilns, into which crushed and broken limestone (usually 4- to 8-inch size, but sometimes up to 100 pounds, or "1-man" size) is fed at the top and lump quicklime is removed from the bottom, are constructed in many forms and modifications. Many are 35- to 75-foot-high, steel-covered, refractory-lined, cylindrical structures with 10- to 24-foot cross-sectional diameters. Others have a square or rectangular cross section. The most complete vertical kiln has five sections or zones from top to bottom: Preheating, calcining, finishing, cooling, and storage. Into a mixed-feed vertical kiln, both crushed limestone and coal are fed at the top, either in alternate layers or thoroughly mixed. A mixed-feed vertical kiln has the economical advantage of more complete

780–887 O—65——34

combustion of fuel, but its quicklime is contaminated with ash. Captive-lime plants in the alkali and sugar industries, where ash contamination of quicklime is unobjectionable, have mixed-feed vertical kiln. Modern, large-capacity vertical kilns produce 80 to 160 tons of quicklime a day. Vertical kilns have a lower fuel cost, smaller capital investment and greater flexibility in operation than rotary kilns (*2*).

Two new types of kilns have come into use since World War II: The FluoSolids kiln and the Ellernan kiln. The FluoSolids kiln is a vertical kiln that uses limestone reduced to 10-mesh or smaller, which is preheated in stages. This kiln has three compartments from top to bottom—preheating, calcining, and cooling. It is advantageous to use wherever limestone and lime granulate or crumble, and it combines a high capacity with economical fuel requirements. The calcining chamber of the Ellernan kiln has horizontal tunnel beams that stir the downward-moving limestone feed to insure uniform calcination. It is a continuous kiln and produces a pebble lime ¼ inch to 1½ inches in size.

At first limekilns were fired with wood; then coal supplanted wood; and now natural gas and fuel oil are displacing coal. Limestone does not freely release carbon dioxide until the kiln temperature is 1,800° F, which is well above the dissociation temperature. Actual temperature in lime-burning is usually at least 2,000° F, and may reach 2,500° F, to reduce the time required for complete calcination.

Refractory lime or dead-burned dolomite is usually calcined in rotary kilns, but the calcining temperature is higher (over 2,800° F) and the burning time is longer. Only true dolomite is used because more calcic stone, even when dead-burned, is still too reactive to moisture.

Hydrated lime is manufactured by slowly adding water to ground quicklime in a hydrator or slaker. Both batch and continuous hydrators are used. The quicklime-water mixture is mechanically agitated to insure thorough mixing. To produce a dry hydrated lime, the theoretical water to quicklime ratio of 18 : 56, or about 1 : 3, is closely followed, although some excess water is needed to offset water lost as steam formed by the heat of hydration. An air separator eliminates the uncalcined material and most of the silica after hydration.

Normally hydrated dolomitic lime consists of calcium hydroxide and magnesium oxide with little, if any, magnesium hydroxide. About 1940, actually hydrated dolomitic lime was introduced and called highly hydrated dolomitic lime. It is produced by hydrating dolomitic quicklime in an autoclave at the necessary pressure. Some soft dolomitic limes have been completely hydrated by adding water to quicklime in silos or retention bins. Highly hydrated dolomitic lime is usually milled and bagged.

Calcium Extraction

The metal calcium was first isolated by Sir Humphry Davy in 1808 by the electrolysis of a mercury-lime mixture followed by distillation of the mercury from the resulting amalgam (*7*). At a later date H. Moissan prepared the metal by reducing calcium iodide with sodium.

Metallic calcium is prepared industrially by the electrolysis of fused calcium choride, although the earlier Pidgeon process, in which lime (CaO) is reduced by aluminum under vacuum by the application of heat, is still used as a standby method.

The calcium initially recovered by these methods may be of only 85 percent purity. It is brought up to 95 to 97 percent purity by repeated melting, skimming, and casting in an inert atmosphere, usually argon. Calcium is distilled in an argon atmosphere when extra high purity above 99 percent is required.

The major impurities in calcium metal are calcium oxide, sodium chloride, and magnesium. Calcium is separated from sodium, when they are mixed together in an electrolytic sludge, by treating the mixture with an excess of a lower aliphatic alcohol, which reacts preferentially with sodium, dissolves the reaction product, and releases hydrogen. After the sodium has been dissolved, the calcium settles and is removed before any appreciable amount of calcium has reacted with the alcohol solution to release more hydrogen. A crystalline calcium of 94 to 97 percent purity and in 50 to 400 mesh sizes is produced which is much more reactive than ordinary grades (*10*).

To produce calcium hydride, on an industrial scale, lumps of calcium metal are heated to 750° F in a hydrogen atmosphere until all the calcium is transformed to the hydride.

USES

Although for centuries lime was used primarily for mortar, plaster, and as a disinfectant, these uses have been relegated to minor importance. Lime is now regarded as a basic industrial chemical and the starting material for a wide variety of chemicals, as well as for use in the neutralization of industrial and agricultural wastes, in high-temperature and dehydration processes, as a causticizing agent in the sulfate process of papermaking, in water softening and purification, and in the manufacture of petrochemicals and insecticides. In the iron and steel industry it is used in increasing quantities in the production of self-fluxing ores, in basic oxygen converters, and in electric furnaces. Lime

is also used for the removal of silica from bauxite ores, for the production of alumina, and in processes for the reduction of magnesium. Smaller quantities are used in the manufacture of sugar, soaps and greases, glue and gelatines, and in the leather industry for removing hair and plumping skins. In construction it is used in masonry mortars, plasters, sand-lime brick, stuccos, cement, and in solid stabilization of roads, runways, and similar projects. Table 3 indicates the tonnages produced for a variety of uses.

Calcium is a lightweight silvery-white metal. It is harder than sodium but softer than aluminum. It may be cast, extruded, machined, rolled into sheets, and drawn into wires. Its principal use is as a reductant for the refractory metals such as chromium, titanium, zirconium, hafnium and uranium (*8*). It is also alloyed with other light metals and is used to remove bismuth from lead and as a nodulizer for cast iron. It is also used as a deoxidizer during the pouring of steel ingots and as a gas absorber in the manufacture of vacuum tubes. It is used to separate argon from nitrogen by the liquid gas industry and to remove sulfur from crude oil. Calcium silicide, an electric furnace product from the reaction between lime, silica, and carbon is used as a steel deoxidizer, and calcium carbide, which upon hydrolysis yields acetylene, the basic material for a wide variety of industrial chemicals. The hydride of calcium (CaH_2), stable in oxygen to 400–500° C, is an excellent reducing agent for the conversion of acetone to mesitylene and is also used as a source of hydrogen for meteorological balloons.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Carbon dioxide, produced during calcination of limestone, is of basic importance in the carbonation of beet sugar syrup, and other lime plants recover it for sale or use in processing sodium chemicals (*9*). Excess limestone production is sold by some lime producers for use in concrete construction and for road building.

ALTERNATE MATERIALS

In its use as an alkaline reagent in the manufacture of chemicals and for many industrial uses there are no alternate materials to replace lime within a comparable price range. Finely ground limestone has largely replaced lime in agricultural uses because it lasts longer in the soil and requires less frequent application. In 1911 the use of lime for masonry mortars began declining, and utilization of cement for mortar increased. Furthermore, in building construction, gypsum plaster and gypsum wallboard and lath have largely replaced the older type of lime-sand plastered walls because of lower costs of installation. In the Southern States gypsum and anhydrite compete with lime for use in soil conditioning. Sodium, magnesium, potassium, and aluminum metals can be substituted for calcium in some uses.

SECONDARY SOURCES AND RECOVERY

Reuse of lime is customary in the paper pulp, calcium carbide, and beet sugar industries. Reclamation plants recarbonate the used lime sludge, dewater it, and recalcine (*12*). This regenerated lime accounts for approximately 26 percent of the total lime used, but including regenerated lime produced at water treatment plants, the amount entering the open market is less than 1 percent.

RESERVES

The sedimentary calcareous rocks, used in the manufacture of lime, are widespread in the United States, but occur in many degrees of purity. The high-grade limestones desired by manufacturers of pharmaceuticals, and the various chemical industries which are fundamentally based upon lime, are not as plentiful as the lower grades which may contain a wide variety of undesirable impurities. The high-grade beds, to which access is easy, are being depleted and lime-burners must go further afield for raw materials, or treat the lower grade more plentiful limestones by methods which are costly to remove these impurities (*11*). Because of the abundance of limestone deposits, no official estimates of reserves suitable for the manufacture of lime have been made. At the present time the question of reserves is not a limiting factor to the growth of the lime industry in the United States.

SOURCES OF STATISTICAL INFORMATION

Comprehensive statistics of the open-market and captive-lime industry are compiled annually by the Bureau of Mines. A less detailed, but indicative, monthly canvass is conducted of all domestic plants that produce over 10,000 tons of lime a year. This monthly survey permits observing and following national trends in lime during the interval between the annual statistics that embrace the entire industry. Lime import and export figures are published annually by the Bureau of Mines from data collected by the U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

In the lime industry stocks are kept low and fairly constant. Production can be increased quickly with existing facilities, and established plants are competent to supply anticipated needs.

Table 1 shows the annual lime tonnage sold or used in the United States, and table 2 shows breakdown by use and value. Ohio, Michigan, Texas, Pennsylvania, and Louisiana in descending order were the leading lime consuming States in 1963.

Because of the relatively low price of lime, foreign trade is of minor importance. In 1963, 87 percent of exported lime went to Western Hemisphere countries, which in order of decreasing quantities were, Canada, Mexico and Bahamas, and Nicaragua.

Duties on lime were unchanged from 1959; 3 cents per hundred pounds for hydrated lime, including the weight of the container, and 2½ cents per hundred pounds, including the weight of the container, on other types of lime.

STRATEGIC CONSIDERATIONS

The United States has ample supplies of limestone, shell, calcareous marl, marble, dolomite, and fuel for manufacturing whatever lime tonnage is needed. It is entirely self-sufficient in this commodity.

Lime is the lowest priced alkali obtainable and is therefore of fundamental importance in the manufacture of thousands of industrial chemicals as well as in many metallurgical processes and the more common uses for various types of construction. Metallic calcium is important as a deoxidizer and dehydrator and for its ability to form alloys with a number of other metals. However, it may be replaced, for most of these uses, by alternate alkali metals. The United States is independent of foreign lime and stockpiling for unanticipated needs is not required. Furthermore, stockpiling is impractical because of perishability, danger of fire, and expense of storage. Only by expansion of production facilities can unexpected demands be met.

TABLE 1.—*Salient lime statistics in the United States*

[Thousand short tons and thousand dollars]

	1954–58 (average)	1959	1960	1961	1962	1963
Active plants	150	154	157	220	215	208
Sold or used by producers:

Total [2]	4,949,000	5,461,000	10,411,000	5,477,000	5,484,000	10,961,000
Refractory lime	1,787,000	71,000	1,858,000	1,880,000	69,000	1,949,000
Grand total [2]	8,145,000	5,608,000	13,753,000	8,889,000	5,632,000	14,521,000

[1] Included with open-market agriculture lime to avoid disclosing confidential data.
[2] Data may not add to totals shown because of rounding.
[3] Includes alcohol, calcium carbonate (precipitated), coke and gas, food and food byproducts, insecticides, medicine and drugs, explosives, oil-well drilling, paint, petrochemicals, petroleum refining, rubber, tanning, salt, miscellaneous and unspecified uses.
[4] Includes flotation, cyanidation, bauxite purification, and magnesia manufacture.
[5] Includes wiredrawing, and various metallurgical uses.

PRICES

Prices for lime fluctuate according to demand, type, and source of supply. The average price of $13.73 per ton reported in 1963 represents an increase of only 18 percent over 1953. Prices of many other commodities rose much more in this period; however, the relatively stable price of lime does not reflect a lessening of demand but rather increased efficiencies in production and distribution. Output of open-market lime, exclusive of refractory lime, during the period 1953–63 increased 22 percent, although production of lime for agricultural uses declined considerably. Comparative figures for the production of captive and regenerated lime are not available. Prices are quoted for lime with or without containers, both at the plants and when delivered at metropolitan centers. In 1964 prices for common hydrated lime varied from a high of $44.00 per ton in Denver to a low of $2.70 per ton in Birmingham.

The price for calcium metal, of 98 percent purity, was quoted in 1964 at $0.95 per pound in lots of over 1 ton. For calcium of 99.9 percent purity it was available in small lots for $2.60 per pound f.o.b. plant. Imports of calcium in 1963 were 43 percent lower than in 1962.

TAXES

The depletion allowance on limestone and dolomite used in manufacturing lime is 15 percent. There has been no depletion allowance on lime, but recent court cases have, in some instances, upheld depletion allowances based on the selling price of finished product.

TRANSPORTATION AND STORAGE

Risk of fire, perishability, and storage expense are foremost objections to maintaining large stocks. Quicklime must be stored in multiwalled, water-proofed bags, or in watertight tanks to prevent the dangerous consequences of uncontrolled hydration, and even hydrated lime should be stored in airtight containers if gradual deterioration by air-slaking is to be prevented. Accidental contact of stored quicklime with water must be avoided. Even exposure to dampness results in slaking, and enough heat may be generated to start a fire if quicklime is stored in contact with combustible materials.

Quicklime must be kept away from open doors and all flammable materials, and its dust can cause severe burns (*6*). In general, quicklime should not be stored longer than 3 months and hydrated lime not more than 1 year (*18*).

Since quick and hydrated lime are relatively inexpensive, perishable, bulk commodities, proper transportation is costly and discourages foreign and long-distance domestic movement. Quicklime is shipped in sizes ranging from pulverized to 8 inches in diameter. Some lump and pebble quicklime is pulverized and bagged for shipment, but most lump and pebble lime is sorted as it is taken from the kiln and shipped in bulk in covered hopper cars, box cars, and container cars. Hydrated lime is always pulverized and is usually shipped in bags. The shipping of lime in self-unloading bulk trailers is becoming increasingly important, and in some localities lime slurries are conveyed by pipeline to the point of use. Forty- to 50-pound natural kraft paper is used by manufacturers and distributors for lining freight cars and trucks. This paper reduces chaffing of bags and assures delivery of a clean product. More expensive flame-resistant paper is used where a fire is a danger (*18*). To retard slaking dead-burned dolomite is frequently sprayed with oil before shipment (*4*). The principal hazard in handling and shipping calcium metal is the risk of fire from hydrogen formed by the reaction of the metal with moisture. To counteract this, metallic calcium is shipped in lump form under an argon atmosphere within special containers (*13*), and when finely divided, in a nitrogen atmosphere within special containers. For long storage calcium lumps of 1 to 130 pounds may be carefully freed from fines and packed in iron drums with seams and lids soldered.

RESEARCH

Three types of research that benefit the lime industry are conducted by private industry and universities: (1) finding new uses for lime (*17*); (2) improving methods of manufacturing lime (*16*); (3) basic lime research. Every year brings forth new patented processes for burning lime and for methods by which lime may be used in making new basic chemical products. These advances do not ordinarily come from within the lime industry itself but they are extremely important because they augment the national demand for lime. Although most new lime uses are chemical and industrial, some research is related to construction (*3*).

The lime industry is most directly involved in research on methods of production and improvements in quality. Producers of captive lime conduct research, within their own laboratories, to develop more efficient methods of lime burning and to promote efficiencies in the use of lime for their particular products. Continuing efforts are made to lower fuel ratios, extend refractory life, and to extend automation to many branches of the lime-burning process. Dust control, cleaning of kiln-exhaust gases, recovery of byproduct carbon dioxide, and improving efficiency of hydration processes are all subjects for research by the lime industry and by manufacturers of equipment. Basic lime research is conducted by the National Lime Association, the lime industry's central organization. The Association has no research laboratory of its own but supports research at some university laboratories, reports results of research accomplished by other organizations, and conducts training classes for certain users of lime.

OUTLOOK

No drastic increases are anticipated in the quantity of lime produced for its multitude of uses, and although prices may continue their upward trend, competition should act to stabilize them. Present capacity of plants to produce lime is ample, both for the present and for some few years to come. Based upon general national trends, production of primary open-market lime should amount to 11 million tons by 1980. The estimated production of lime for all uses in 1980 is 30 million tons.

Improved methods for autoclaving sand-lime brick have resulted in production of bricks greatly superior to those produced 40 years ago and should increase sales of lime for this purpose. Growing insistence on control of stream pollution should increase the market for lime used to reduce acidity of mine water and as a coagulant for precipitating industrial wastes. The use of hydrated lime to stabilize subgrades of roads and in preparing footings for buildings may be expected to increase in areas in which the soil consists largely of plastic clays. Demand for lime in production of steel, by the various basic-oxygen processes, should grow as the older open hearths are replaced by converters.

Technological changes in industrial and chemical processes, which use lime, may drastically affect some producers. The once firmly established use of calcium carbide for production of acetylene, on which many chemical processes was based, may decline because of substitution of propylene and ethylene for acetylene.

Substitution of gypsum wallboard and gypsum plasters for construction in place of lime mortars, plasters, and stuccos, appears likely to continue.

Demand for calcium metal for use in purification of gases, as a getter in high-vacuum technology, and as a reductant in metallurgy of rare metals is not expected to increase greatly.

PROBLEMS

The search for new markets for lime with the accompanying need for research to satisfy the type and grade requirements of the new lime consumers is an ever-present problem. The rapidly changing technology, in many consumer industries, may eliminate some well established uses for lime. New developments in kilns, giving lower fuel consumption, reduced maintenance costs, better products, or which are more easily adapted to automation, may cause some older plants to be less competitive. The continuing problems of rate of kiln feed, heat control removal of dust, storage, hydration, and transportation, are all matters for intensive and continuing research. Increased use of alternate materials such as gypsum and other substitutes for plastering and wallboard reduces demand for certain types of lime. The regeneration and sale of lime from miscellaneous chemical processes offers competition to some producers of open-market lime. The storage and disposal of regenerated lime is a problem to the paper pulp, sugar, and chemical industries. With the exception of a few producers of exceptionally high-purity lime, sales are limited to areas in which transportation costs are moderate.

The demand for calcium metal, used in pyrometallurgy, and for many other purposes, is accompanied by problems in production, use, and storage (*5*, *19*). Costs are high because of the discontinuous nature of production and the need for high-purity salts used in electrolytic processes. In addition, electrolytic processes for producing calcium are critically affected by contamination from refractories and the alloys used to make the cells. The cells used in the electrolytic reduction of calcium fail because of burnthroughs, cracking, and corrosion. Metallothermic methods for the production of calcium are complicated by the necessity of using both high temperatures (to 1,700° C) and extremely high vacuum.

LITHIUM

By Donald E. Eilertsen [1]

LITHIUM is the lightest of all metals, but is used mainly in compounds for varied applications such as multipurpose greases, batteries, welding, ceramics, air conditioning, bleaching, and generation of hydrogen for buoyancy purposes. Nevertheless, extremely lightweight lithium-magnesium alloys are promising aerospace and industrial structural materials.

Spodumene from pegmatites and dilithium-sodium-phosphate from brines are the current raw materials used to make lithium and its compounds.

Foreign lithium minerals are recovered by hand-sorting methods while domestic spodumene is obtained by mechanized mining and milling methods. Spodumene is converted to lithium compounds by either an acid or an alkali method. The processors of lithium mineral source materials to lithium primary products in the United States are Foote Mineral Co., at Sunbright, Va., and Exton, Pa.; Lithium Corp. of America, Inc., at Bessemer City, N.C.; and American Potash & Chemical Corp., at Trona, Calif.

Lithium compounds are used in multipurpose greases, nuclear energy, air conditioning, storage and dry cell batteries, welding and brazing, ceramics, glass, bleaches, catalysis, and preparing hydrogen.

Lithium metal's principal uses are in alloying, preparation of compounds, purification of steels, copper, and copper alloys, and production of synthetic rubber. Various lithium minerals also have ceramic applications.

Moderate growth of the lithium industry is anticipated. Problems of the industry include development of new uses and markets and further development of the technology.

BACKGROUND

Germany was the first producer of lithium minerals and remained the largest producer until 1886. The leadership was then held by France until the early 1900's. The United States led from 1900 until 1953, and since then Southern Rhodesia has been the leader.

The first commercial production of lithium minerals in the United States took place in 1898 when 30 tons of spodumene was shipped from the Etta Mine in the Black Hills, S. Dak. Other mines began to produce lithium minerals, and by 1910 the U.S. output, all from South Dakota, reached 238 tons.

Dilithium-sodium-phosphate, from Searles Lake, Calif. brines in 1938, and spodumene flotation concentrate from Kings Mountain, N.C. pegmatites in 1953 became important commercial sources of lithium.

European production of lithium compounds dates back before 1900 whereas U.S. production was started in 1901 by two firms in New Jersey. Three firms in the United States process lithium minerals to lithium compounds at the present time.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Foote Mineral Co. mines spodumene ore from pegmatite and produces spodumene flotation concentrate at Kings Mountain, N.C.; and American Potash & Chemical Corp. recovers crude dilithium-sodium phosphate from Searles Lake brines at Trona, Calif. In addition to this some amblygonite has been produced in South Dakota.

Currently, three firms in the United States process lithium minerals to lithium compounds. They are Foote Mineral Co. at Sunbright, Va.

[1] Commodity specialist.

and Exton, Pa.; Lithium Corp. of America, Inc., at Bessemer City, N.C.; and American Potash & Chemical Corp. at Trona, Calif.

Elsewhere in the free world in recent years, lithium compounds have been produced in the United Kingdom, France, West Germany, Southern Rhodesia, Brazil (*8*),[1] Italy, and Quebec.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Lithium is soft, silver-white, and the lightest of all metals 0.534 g./cm.^{3} at 20° C. Some of its other properties as follows (*6*) :

Atomic number	3
Atomic weight	6.94
Melting point, °C	179
Boiling point, °C	1,317
Heat of fusion, calorie per gram, (179° C)	103.2
Heat of vaporization, calorie per gram (1,317° C)	4,680
Heat capacity, calories per gram per degree C. (0° C)	0.784
Coefficient of linear thermal expansion per degree C, (20° C)	56×10^{-6}

Lithium metal reacts violently with water to form hydrogen and lithium hydroxide, but the heat involved is not sufficient to ignite the hydrogen.

The chemical composition and lithia (Li_2O) contents of five sources of lithium are shown in table 1.

TABLE 1.—*Lithium source materials*

Mineral	Chemical composition	Theoretical Li_2O content (percent)	Approximate range of Li_2O in commercial mineral (percent)
Spodumene	$LiAlSi_2O_6$	8.0	4–7
Lepidolite	$(OH, F)_2KLiAl_2Si_3O_{10}$	3.9	3–3.5
Amblygonite	$LiAl(F,OH)PO_4$	10.1	8–9
Petalite	$LiAl(Si_2O_5)_2$	4.8	3.5–4.5
Dilithium-sodium-phosphate.	Li_2NaPO_4	22.6	19–21

TECHNOLOGY

Mineralogy and Geology

The lithium content of the earth's crust has been estimated to be 65 parts per million while in sea water the lithium content is 0.1 part per million. Approximately 145 minerals in the earth's crust contain lithium but only spodumene, lepidolite, amblygonite, petalite and eucryptite from pegmatites are commercial sources of lithium. In addition to these minerals, dilithium-sodium-phosphate, from California brines, is an important commercial lithium source.

Lithium minerals have been found in heterogeneous pegmatites where the minerals occur in enriched zones, filled fractures, and replacement bodies such as in the Black Hills, S. Dak. and elsewhere, and also unzoned or homogeneous pegmatites where the mineral constituents are somewhat evenly distributed as in the extensive spodumene deposits in the area of Kings Mountain, N.C., which are now being worked for spodumene.

Lithium is also known to occur in sedimentary deposits such as clays and shales.

Mining

Spodumene and other lithium minerals have been mined from pegmatites by open pit and underground methods of mining, sometimes while mining for these minerals alone but more often while also mining for coproducts such as feldspar, mica, quartz, and sometimes beryl, columbite, and tantalite.

Spodumene ore (pegmatite) is mined in North Carolina by Foote Mineral Co. from 20-foot benches in a large open pit employing large-scale mechanized equipment such as wagon drills for primary drilling, 5-ton drop ball for secondary breaking, large mechanical shovels to load, and huge trucks for haulage (*4*). Diamond drill exploration of the deposit is kept well ahead of mining (*5*).

Milling

Lithium minerals are recovered by hand-sorting methods in many parts of the world, but in North Carolina spodumene is currently being recovered from pegmatite type ore by crushing, screening, milling, and flotation (*3*).

In California, dilithium-sodium-phosphate is recovered by treating burkeite salt, the concentrate obtained after evaporation and subsequent separation of the brine, with a fatty acid derivative to which is added a light mineral oil. The dilithium-sodium-phosphate is floated by aeration, and the resulting froth is filtered and dried (*2, 8*).

Extraction

Lithium compounds are processed from spodumene by one of two methods—one is an acid treatment, the other is an alkali treatment (*8*). In the first method alpha spodumene is converted to beta spodumene by calcining at critical temperatures. Sulfuric acid is added, and the mixture is heated to form lithium sulfate. The lithium sulfate is leached from the mass, neu-

[1] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

tralized with limestone, and filtered. Soda ash is added to the aqueous solution of lithium sulfate to precipitate lithium carbonate. This is the basic material from which other compounds are derived. Calcium hydroxide is added to the lithium carbonate to form lithium hydroxide monohydrate. Lithium chloride is produced by reacting lithium carbonate with hydrochloric acid.

The second method involves stage-calcination of the spodumene with powdered limestone and hydrolyzing with steam to produce a soluble lithium hydroxide.

Lithium metal is produced by electrolysis of a fused mixture of lithium chloride and another alkali salt, such as potassium chloride. Lithium hydride is produced by reacting hydrogen and lithium metal. The addition of ammonia to lithium hydride produces lithium amide.

USES

A large variety of applications have been developed for lithium-bearing materials, especially for lithium compounds (*1*).

Five lithium minerals have industrial uses: Spodumene as a source of lithia in chemical and certain ceramic processes; amblygonite as a source of lithia, alumina, and phosphate in glaze and enamel frits and low-temperature glass bond; lepidolite and petalite as material for glass and porcelain enamel ground coats, ceramic body glazes, and fluxes; and eucryptite for various applications. Petalite is also used as a constituent of low-expansion heat-resistant bodies.

Lithium compounds have numerous uses and are shown in table 2.

Lithium metal is used metallurgically as an alloying element, scavenger, and degassifier for stainless and mild steels, and deoxidizer in melting copper and copper alloys. Lithium is also used as a raw material for preparing lithium alkyls and other organo compounds, catalyst in the production of synthetic rubber, selective reducing agent in organic synthesis, and intermediate in vitamin A production. The element also can be used for reactor cooling, heat transfer fluid for high temperature applications, and rocket fuel.

Lightweight lithium-magnesium alloys are attracting attention for structural applications in aerospace vehicles and in industrial uses.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Lithium-bearing pegmatite deposits usually contain other potentially marketable mineral materials, such as feldspar, quartz, mica, columbite, tantalite, beryl, and monazite. In some lithium operations one or more of these are recovered as coproducts, but usually it has not been economically feasible to recover these materials.

Coproducts such as bromine, potash, borax, sodium sulfate, and sodium carbonate are recovered with dilithium-sodium-phosphate from Searles Lake, Calif., brine.

TABLE 2.—*Uses of some lithium compounds*

Use	Lithium compound

ALTERNATE MATERIALS

Lithium is so desirable in most of its uses that few materials are substituted for it.

In ceramics, lead can be substituted for lithium in many instances, but it is less efficient in many ways and may be toxic.

In greases lithium compounds impart water resistance and lubricating properties over extremes of temperatures. These properties apparently cannot be gained if other compounds, such as calcium, barium, or strontium compounds were used as the base component. Certain military grease performance specifications have been met only by lithium base greases.

Although lithium hydride is one of the most efficient hydrogen carriers known, for economic reasons it has been substituted by other efficient but less expensive hydrogen carriers such as calcium hydride.

RESERVES

The indicated and inferred resources of lithia in domestic pegmatites containing at least 1 percent lithia and in brines containing 0.015 percent lithia were estimated in 1955 (*7*). The indicated resources of lithia, totaling 144,000 tons Li_2O content, are located as follows: Tinspodumene belt of pegmatites in North Carolina, containing spodumene mostly but some amblygonite—40,000 tons; Black Hills pegmatites in South Dakota, containing spodumene mostly but some amblygonite and lepidolite—12,000 tons; pegmatite districts in New England, Colorado, Arizona, New Mexico, California, and Wyoming, containing spodumene mostly but some amblygonite and lepidolite—2,000 tons; and Searles Lake, Calif., brine—90,000 tons. The inferred resources of lithia, totaling 1,244,000 tons of Li_2O content, are in the spodumene belt of pegmatites in North Carolina (1,240,000 tons) and in Black Hills pegmatites (4,000 tons).

Significant resources of lithium minerals have been established in several foreign countries. Canadian deposits north of Val d'Or, Quebec, containing 20 million tons of spodumene ore averaging 1.15 percent lithia, have 230,000 tons of Li_2O. Deposits on the north shore of Bernic Lake, Manitoba, contain 9 million tons of spodumene-lepidolite-amblygonite ore averaging more than 2 percent lithia, have more than 180,000 tons of Li_2O. Five deposits in the Bougouni region, Republic of Mali, Africa, are reported to contain 1.3 million tons of spodumene ore averaging 1.3 percent lithia or 17,000 tons of Li_2O. Bakita deposits in Southern Rhodesia contain 6 million tons lepidolite-spodumene-petalite-eucryptite ore averaging 2.9 percent lithia or 174,000 tons of Li_2O. Pegmatite deposits southwest of Kalgoorlie, Western Australia, were reported to be promising for lithium—one deposit alone contains about 428,000 tons of ore averaging 1.9 percent lithia or 8,100 tons of Li_2O.

The Atomic Energy Commission has a stock of lithium hydroxide devoid of lithium-6 isotope.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines canvasses annually for domestic lithium mineral production and recently for consumption, but not for lithium products derived from utilizing lithium minerals. The Department of Commerce canvasses the domestic lithium-producing industry for production data on primary lithium products. Statistical data on imports of lithium minerals and certain lithium compounds are compiled by the Bureau of Census, but no data are available on exports.

Data on world production of lithium minerals are compiled by the Bureau of Mines from information supplied by Foreign Service dispatches, official publications of the mining departments of the respective countries, and from other sources.

PRODUCTION, CONSUMPTION, AND TRADE

Data on lithium mineral and compound output from mines in the United States are shown in table 3.

TABLE 3.—*Shipments of lithium mineral concentrate and compounds from mines in the United States*

Year	Short tons	Value (thousands)	State (listed in order of magnitude)
1950	9,306	$580	S. Dak., Calif., N. Mex., and Maine.
1951	12,897	896	S. Dak., N.C., Calif., and Ariz.
1952	15,611	1,052	S. Dak., N.C., and Calif.
1953	27,240	2,134	N.C., S. Dak., Calif., and Colo.
1954	37,830	3,126	N.C., S. Dak., Calif., and Colo.
1955–57	(1)	(1)	(1).
1958–63	(2)	(2)	N.C., Calif., and S. Dak.

[1] Data not available.
[2] Data withheld to avoid disclosing individual company confidential data.

Record production of these materials occurred in 1959 and was followed by a very sharp decline in production. The trend in recent years is again upward.

Starting in 1964 a canvass is being made on the consumption of lithium source materials in the United States. Quantitative data on annual outputs of lithium metal, alloys, and compounds are not available for publication.

Imports of lithium minerals into the United States for the period 1951–58, not necessarily complete, were reported as follows: 1951–55 (annual average)—19,978 short tons, 1956—114,772 tons, 1957—79,617, and 1958—192,803 tons (*8*). Import figures on lithium minerals, reported by the Bureau of the Census since 1960, are shown in table 4.

As of August 31, 1963, lithium minerals are imported duty free. Lithium metal and lithium compounds are dutiable at 25 percent and 10.5 percent ad valorem, respectively.

TABLE 4.—*U.S. imports of lithium minerals by countries*

[Short tons]

Year	Argentina	Brazil	Canada	British East Africa	Rhodesia and Nyasaland	Mozambique	Republic of South Africa	Total	
								Quantity	Value [1]
1960	110	33	1,409	----------	49,547	----------	----------	51,099	$1,358,573
1961	----------	----------	2,115	----------	22,462	----------	2,252	26,829	776,578
1962	----------	----------	330	----------	23,603	[2] 5,661	1,115	30,709	1,006,037

[1] Value at port of exportation.
[2] Reported as Mozambique but believed by the Bureau of Mines to be from Southern Rhodesia via Mozambique.

STRATEGIC CONSIDERATIONS AND GOVERNMENT PROGRAMS

The domestic reserves of spodumene and lithium-bearing brines are adequate to sustain the lithium producing industry indefinitely. Domestic sources of lepidolite, amblygonite, and petalite are not available. Consequently, the ceramic industry and any lithium production that may develop from the use of these special materials will probably have to come from imports.

No special considerations are given to lithium minerals for Government assistance in exploration and stockpiling.

PRICES

Prices for lithium minerals are on a buyer and seller basis, and they are seldom published. The average price of imported lithium mineral concentrate at the port of exportation in 1963 was $29.55 per short ton. The principal lithium compounds, lithium carbonate and lithium hydroxide, sell for about 60 and 55 cents per pound respectively. Prices on these and other compounds can be found in the issues of Oil, Paint, and Drug Reporter. Lithium metal, 99.5-percent pure, was quoted at $9 to $11 per pound throughout 1963 in the issues of the E&MJ Metal and Mineral Markets.

TAXES

The domestic depletion allowance is 23 percent whereas the foreign depletion allowance is 15 percent.

RESEARCH

Industry-sponsored research under way on lithium includes studies on improving processes and qualities of products, developing new uses and new products, and recovering various minerals including lithium from brines.

Some research on lithium is Government sponsored. Studies are mostly on the properties of various lithium materials and on the occurrence and recovery of various metals including lithium from saline waters.

OUTLOOK

The outlook for the lithium industry is one of optimism—moderate and steady growth in demand is predicted thus narrowing the gap between production capacity and industrial consumption. Market expansion and development will be emphasized. New uses and larger markets in established uses will be vigorously sought.

Research will be continued on the development of new uses, basic properties, and the improvements in mining and processing technology.

Keen competition among lithium producers may result in occasional price reductions in fast-selling lithium compounds. Prices of slower moving lithium metal and compounds also may decrease as consumptions of these materials increase.

Two major producers of lithium chemicals from spodumene are studying the feasibility of recovering various elements including lithium from brines. It is quite possible that one or more new firms may enter the mineral and chemical production fields.

International competition for lithium markets will become more noticeable as the lithium industries in other countries continue to develop.

PROBLEMS

Methods are needed for the efficient recovery and economic disposition of several coproducts and byproducts typically present in lithium-bearing pegmatites to help reduce prices of lithium raw materials.

Reliance on overseas sources for certain lithium minerals (amblygonite, lepidolite, and petalite) could be of concern to the United States if these supplies should become unavailable for any reason. The lack of adequate domestic reserves of these minerals further compounds the problem.

Lithium processing technology is in an early stage of development. Consequently, losses increase the cost of lithium products and adversely affect consumption in certain products, such as lithium hypochlorite as a dry powder bleach and lithium metal in some alloys.

Restrictions on publishing statistical data on the production and consumption of lithium metal, alloys, and compounds and consumption data on lithium raw materials make it difficult for industry and Government to determine requirements, evaluate market potentialities, and plan future action.

Problems of the lithium industry include employment of the production capacities developed to supply the AEC with lithium hydroxide and not needed since 1959, and development of the technology.

MAGNESIUM AND MAGNESIUM COMPOUNDS

By Lloyd R. Williams [1]

WIDESPREAD deposits of dolomite, an inexhaustible supply of magnesium in sea water, and large deposits of evaporites and well brines provide the United States with abundant resources of magnesium and magnesium compounds. In 1963, well brines, bitterns, and sea water combined with calcined dolomite or lime accounted for more than half of the domestic production of magnesium compounds used as chemicals, fillers or bases in many industrial products including basic refractories. Magnesite was used to produce magnesia. Molding sand has become the principal use for the mineral olivine, which also has been used for refractories.

Dead-burned dolomite accounts for the largest volume production of magnesium compounds and has been produced at a rate of about 2 million tons per year for the past decade. Refractory magnesia production increased at an average of about 8 percent per year during 1959–63 to 713,000 tons in 1963.

In 1963, the United States produced about 49 percent of the world production of primary magnesium but consumed only about 33 percent. West Germany consumed about 25 percent and produced less than 1 percent. The United States ranked first in production and the U.S.S.R. and Norway ranked second and third, respectively. About 90 percent of the total U.S. magnesium productive capacity is in electrolytic plants using magnesium chloride produced from sea water; the remaining 10 percent is in silicothermic processes with dolomite as the primary raw material.

Domestic consumption of magnesium is increasing about 8 percent per year. Use in structural products has not shown any definite trends. A decrease in sand castings has been offset by increased consumption in permanent mold and die castings. Use of primary magnesium in aluminum alloys increased at an average of 10 percent per year from 1959 to 1963 and all other uses increased about 5 percent per year.

In producing magnesia from sea water or well brines calcined dolomite or lime is added to the sea water or brines forming $CaCl_2$ and precipitating $Mg(OH)_2$ which is heated above 3,000° F. to produce MgO. Dead-burned dolomite is produced by heating dolomite above 3,000° F. to drive off the CO_2. Brucite ($Mg(OH)_2$) and magnesite ($MgCO_3$) are similarly treated. In producing the metal from sea water the precipitated $Mg(OH)_2$ is neutralized with HCl to form $MgCl_2$ which is reduced electrolytically to magnesium metal. The chlorine is recovered. In the silicothermic process, calcined dolomite is reduced with silicon in a vacuum retort at 700° F. to 1,000° F. producing magnesium vapor which condenses on cooler surfaces of the retort.

A Materials Survey on Magnesium and Magnesium Compounds published in 1963 reviews the magnesium industry's history, geology, sources, production and uses as well as methods for recovering and processing the element and its many valuable compounds (*5*).[2]

BACKGROUND

Previous to the 19th century limestone rock or dolomite had been found useful to facilitate the production of iron. During the 19th century deposits of natural magnesium carbonate or magnesite were discovered in Moravia, Austria, and Greece. By 1890, after a high temperature basic brick had been made from calcined ore, magnesite was in general use in Europe for refractory linings of Bessemer and open hearth furnaces. In 1913 production of

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

magnesia from dolomite began in Pennsylvania.

Previous to World War I, the bulk of world output of magnesite came from Austria-Hungary and Greece. After hostilities started these sources were cut off and in 1917 mining of magnesite deposits was started in California and Washington. At the end of the war a protective tariff placed on crude magnesite discouraged imports from Europe.

By 1928, India began to export caustic-calcined magnesite to the United States. Mining brucite in Nye County, Nev., began in 1929 and in 1937 magnesite mining started in a nearby deposit.

At the outbreak of World War II mining of domestic magnesian ores again expanded for use in the production of refractories and metal. Production of magnesium compounds from ores, brines, and sea water has continued to increase after postwartime adjustments.

Magnesium metal was produced commercially in Germany in 1886 and until World War I most of the world supply of magnesium came from Germany. During the war United States production expanded as foreign sources were cut off. Seven primary magnesium plants were built but at the end of the war, all except two were closed. By 1931, German producers had developed a worldwide market for magnesium and its alloys lasting until World War II.

During 1941–42, to offset the loss of German production and satisfy wartime demands, 16 primary magnesium plants were operating in the United States. Six were silicothermic plants and 10 used electrolytic cells. The peak of U.S. magnesium production was in 1943, 184,000 tons or 62 percent of the world total. By 1946 domestic production had dropped to 6,000 tons, and a plant in Texas was the sole producer. During the Korean war seven government plants were reactivated, but by 1953 all except two of the plants were closed. In 1959 a new silicothermic plant at Selma, Ala., began producing primary magnesium. These three and the Freeport, Tex., plant continue to account for all of the domestic output.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Magnesium Compounds

World production of magnesite in 1963 was estimated at 9 million short tons of which the U.S.S.R. produced an estimated 32 percent and Austria 16 percent. The United States produced 528,000 tons, or 6 percent of the world total.

In 1963, olivine was produced in the United States by several companies in Washington and North Carolina. Northwest Olivine Co. Twin Sisters Quarry in Washington was the major producer. Although brucite was formerly mined in Nevada, no production has been reported since 1959.

In 1963, refractory and caustic calcined magnesia was produced from domestic magnesite in Nevada by Basic, Inc., and refractory magnesia in Washington by Northwest Magnesite Co. Refractory magnesia was made from sea water and calcined dolomite at three plants. The Cape May, N.J., plant obtained dolomite from quarries near Philadelphia, Pa.; that for the Pascagoula, Miss., plant from near Birmingham, Ala.; and that for the Moss Landing, Calif., plant from Natividad, Calif. The latter plant also processed caustic calcined magnesia. At two other plants both refractory and caustic calcined magnesias were produced from sea water; the plant at Port St. Joe, Fla., used oystershell; and the plant at Newark, Calif., sea water bitterns and dolomite with magnesite from Gabbs, Nev. At a plant near Freeport, Tex., refractory magnesia was made from purchased magnesium hydroxide (sea water and oystershell). Near South San Francisco USP grades of magnesium compounds were produced from sea water and dolomite. Magnesium chloride was produced near Freeport, Tex., from sea water and oystershell and magnesium chloride crystals near San Diego, Calif., from sea-water bitterns and dolomite. Magnesium hydroxide is produced at all sea-water plants.

In Michigan near Ludington, Midland, Manistee, and St. Louis various magnesium compounds were prepared from well brines. Precipitated magnesium carbonate was produced at Waukegan, Ill., from dolomite. Magnesium chloride was produced as a byproduct in Delaware, New York, and West Virginia. Small amounts of specified magnesium compounds were produced near Phillipsburg, N.J. Of the 2 million short tons of dead-burned dolomite produced annually in the United States, about half was produced in Ohio. Names, locations, products, and raw materials of plants that produced magnesium compounds in 1963 are shown in table 1.

Magnesium Metal

The United States produced about half and consumed about one-third of the total world production of primary magnesium.

TABLE 1.—*Mines and plants producing magnesite, brucite, and other magnesium compounds in the United States, 1963, by States*

State and company	Location of mine or plant	Products	Raw materials
California:			
Kaiser Aluminum & Chemical Corp. (Refractories Div.).	Moss Landing	Caustic-calcined magnesia; refractory magnesia; magnesium hydroxide; magnesium oxide, extra-light, light and heavy.	Sea water, calcined dolomite.
Do	Natividad	Dead-burned and calcined dolomite	Dolomite.
Marine Magnesium Division, Merck & Co., Inc.	South San Francisco	Magnesium oxides, extra-light, light, and heavy; magnesium hydroxide; precipitated magnesium carbonate; magnesium trisilicate.	Sea water, sea-water bitterns calcined dolomite.
Philadelphia Quartz Co. of California	Alameda County	Epsom salt	Magnesite, brucite, calcined magnesia.
FMC Corp. (formerly Westvaco Chem. Div., Food Machinery and Chemical Corp.).	Newark and San Diego	Caustic-calcined magnesia; refractory magnesia; magnesium chloride crystals; magnesium hydroxide.	Sea-water bitterns, calcined dolomite, magnesite.
Delaware: E. I. du Pont de Nemours & Co., Inc.	New Castle	Magnesium chloride	Byproduct from reducing titanium tetrachloride with magnesium.
Florida: Michigan Chemical Corp	Port St. Joe	Caustic-calcined magnesia; refractory magnesia; magnesium hydroxide.	Sea water, oystershells.
Illinois:			
Johns-Manville Products Corp	Waukegan	Precipitated magnesium carbonate	Dolomite.
Marblehead Lime Co	Thornton	Dead-burned dolomite	Do.
Standard Lime & Cement Co	LaGrange	do	Do.
Michigan:			
The Dow Chemical Co	Ludington	Magnesium chloride crystals; magnesium chloride fluxes; magnesium hydroxide.	Well brines, calcined dolomite.
Do	Midland	Epsom salt; magnesium hydroxide; magnesium oxide, light.	Do.
Harbison-Walker Refractories Co	Ludington	Refractory magnesia	Magnesium hydroxide.
Kaiser Refractories	Midland	Refractory magnesia; periclase	Do.
Michigan Chemical Corp	St. Louis	Precipitated magnesium carbonate; magnesium hydroxide; magnesium oxide, extra-light, light and heavy.	Well brines, calcined dolomite.
Morton Chemical Co	Manistee	Precipitated magnesium carbonate; magnesium oxide, extra-light, light.	Do.
Standard Lime & Cement Co	do	Refractory magnesia	Do.
Mississippi:			
H. K. Porter Co., Inc	Pascagoula	Refractory magnesia	Dolomite, sea water.
Do	do	Dead-burned dolomite	Dolomite.
Missouri: Valley Dolomite Corp	Bonne Terre	Dead-burned dolomite	Dolomite.
Nevada: Basic, Inc	Gabbs	Brucite, magnesite, refractory magnesia, caustic-calcined magnesia.	Magnesite and brucite.
New Jersey:			
J. T. Baker Chemical Co	Phillipsburg	Magnesium chloride crystals, epsom salt; other high-purity magnesium chemicals, magnesium trisilicate.	Magnesium carbonate.
Northwest Magnesite Co	Cape May	Refractory magnesia	Sea water, calcined dolomite
New York: Carborundum Metals Co	Erie	Magnesium chloride	Byproduct from producing zirconium.
North Carolina:			
Balsam Gap Co	Balsam Gap mine (near Sylva).	Olivine	Ore.
Harbison-Walker Refractories Co	Addie mine (near Sylva)	do	Do.
Wiseman Mining Co., Inc	Wray mine (near Burnsville)	do	Do.
Georgia Talc Co	Spruce Pine	do	Do.
Ohio:			
J. E. Baker Co	Millersville	Dead-burned dolomite	Dolomite.
Basic, Inc	Maple Grove	do	Do.
Dolite Co	Gibsonburg	do	Do.
Moores Lime Co	Springfield	do	Do.
Ohio Lime Co	Woodville	do	Do.
Standard Lime & Cement Co	do	do	Do.
Pennsylvania: J. E. Baker Co	York	do	Do.
Texas:			
The Dow Chemical Co	Freeport	Magnesium chloride, caustic-calcined magnesia, magnesium hydroxide.	Sea water, oyster shells.
E. J. Lavino & Co	do	Refractory-grade periclase	Magnesium hydroxide.
Utah: Marblehead Lime Co	Delle	Dead-burned dolomite	Dolomite.
Washington:			
Agro Minerals, Inc	Tonasket	Epsom salt	Lake brine.
Northwest Magnesite Co	Chewelah	Magnesite, caustic-calcined magnesia, refractory magnesia.	Magnesite, ore.
Northwest Olivine Co	Twin Sisters quarry (near Clear Lake).	Olivine	Ore.
Pacific Olivine, Yellow Slide	Clearlake	do	Do.
Scheel Stone Co., Big Slide	Hamilton	do	Do.
Olivine Corp. Whatcom	Bellingham	do	Do.
Omega Mining Inc., Omega	Hamilton	do	Do.
West Virginia:			
Carborundum Metals Co	Parkersburg	Magnesium chloride	Byproduct from producing zirconium.
Standard Lime & Cement Co	Millville	Dead-burned dolomite	Dolomite.

Dow Chemical, the major source of primary magnesium, operates two electrolytic plants in Texas; one at Freeport with a capacity of 55,000 short tons per year, and another at Velasco with a capacity of 37,000 tons. Dow also produces caustic calcined magnesia. Some of the magnesium chloride and magnesium hydroxide processed in an intermediate phase in the production of magnesium from sea water is marketed.

Magnesium also is produced in two silicothermic plants; one with a capacity of 6,200 tons per year is operated by Alabama Metallurgical Corp. at Selma, Ala.; the other with a capacity of 5,000 tons by Chas. Pfizer and Co., Inc., at Caanan, Conn., from dolomite mined near the plant. The last also markets crown magnesium, a magnesium condensate formed in an intermediate stage of the process.

A plant at Henderson, Nev., is capable of producing 12,000 tons of magnesium per year from magnesium chloride, but all of the magnesium recovered at the plant is recycled for titanium production.

Secondary magnesium production was reported from the following plants in 1963: American Smelting & Refining Co., Houston, Tex., and Newark, N.J.; Apex Smelting Co., Chicago, Ill.; and Garfield Alloys, Cleveland, Ohio.

At the close of 1963 about 59 plants in 16 States consumed magnesium for structural products. Eleven plants in California and 11 in Ohio produced castings. In Ohio one also produced forging and another plant produced forgings and extrusions; in Michigan, nine plants produced castings and one produced extrusions; in Illinois, four produced castings, one extrusions, and one sheet and plate; four plants in New York and four in New Jersey produced castings; and in Pennsylvania one plant produced castings, one extrusions, and another forgings. The remaining 11 were scattered throughout the country.

About 140 operations consumed magnesium for distributive or sacrificial purposes, including 82 in making aluminum alloys. Of the 82 plants, 15 are in Ohio; 9 in New York; 7 each in Pennsylvania and Indiana; 6 in Illinois; and 4 each in California, Michigan, New Jersey, and Washington. The remaining 22 consumers of magnesium for aluminum alloys were scattered throughout the country.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Several minerals are used as raw materials for either magnesium metal or compounds production. *Dolomite* (Ca, $Mg(CO_3)$) contains up to about 22 percent magnesia. The term also applies to the rock, dolomite, which is usually a limestone partly transformed to dolomite by hydrothermal alteration. *Magnesite* ($MgCO_3$) has a theoretical magnesia content of 47.6 percent. *Brucite* ($Mg(OH)_2$) contains up to 69 percent magnesia. *Olivine* or *chrysolite* ($(MgFe)_2SiO_4$) is a green to brown mineral used as foundry sand rather than as a source of magnesia. *Magnesia* (MgO) is the product of calcination or thermal decomposition of several magnesium minerals and compounds. *Dead-burned magnesite* is "the granular product obtained by calcining magnesite, or other substances convertible to magnesia upon heating above 2,640° F. long enough to form dense weather-stable granules suitable for use as a refractory or in refractory products" (*1*). Although *periclase* (MgO) occurs as a metamorphic mineral, the term usually applies to a special grade of *dead-burned magnesia* prepared by burning 92 to 98 percent magnesium oxide at about 3,000° F. It has a crystal structure which imparts hardness, chemical stability, and other desirable characteristics. *Calcining* is a heat treatment given to eliminate volatile chemically combined constituents. *Calcined dolomite* is material heated for about 4 hours reaching a final temperature of 2,000° F., thus driving off water and most of the carbon dioxide. *Dead-burned dolomite* is made by burning 0.5-inch size dolomite with an additive of iron oxide in rotary kilns at 3,000° F. to 3,200° F. *Basic refractories* have as major constituents lime, magnesia, or both. Commercial use of this term also includes refractories made of chromite or combinations of chromite and dead-burned magnesite (1). *Brines* are water-base solutions containing dissolved salts. A concentrated brine with sodium chloride (salt) removed is a *bittern*. *Caustic-calcined magnesia* is a reactive magnesium oxide made by calcining magnesium carbonate or magnesium hydroxide at 1,650° F. or lower. It is used in the preparation of oxychloride cement, decoloring agents, rubber, fertilizer, rayon, paper, etc. Specified grades are produced under certain conditions including temperature range and length of time heated. These are designated as extra light, light, and heavy depending on density, chemical purity, reactivity, and grain size.

Specifications for chemical content of primary magnesium set by the American Society for Testing and Materials are as follows:

		Percent
Total of all impurities	Maximum	0.20
Copper	do	.02
Lead	do	.01
Manganese	do	.15
Nickel	do	.001
Tin	do	.01
Other impurities, each	do	.05
Magnesium, by difference	Minimum	99.80

Standards for refractories containing MgO are set by the consumers according to conditions in the furnaces in which they will be used. The American Iron and Steel Institute and the Refractories Institute have published comprehensive data on the properties and uses of basic refractories. Most magnesium compounds are prepared by the producers to meet the specifications set by individual consumers.

ASTM standard designations have been placed on 26 magnesium alloys as shown in table 2. Other magnesium alloys of specific content, required for special applications, are prepared as ordered and priced accordingly.

Temper designations for magnesium alloys cast and wrought, are established by the ASTM, based on sequence of basic treatment. The condition of the designated alloy is noted as follows:

F	As fabricated.
O	Annealed (recrystallized wrought products, only).
H	Strain hardened.
W	Solution.
T	Treated (thermally) to produce strain tempers other than F, O, or H.

Secondary magnesium alloy ingot predominately generated from castings and wrought products is tested to insure the same grades and specifications as the primary alloy with which they are used.

Aluminum is added to magnesium to increase its strength. When manganese is added to magnesium alloys, it increases their resistance to salt-water corrosion. The addition of rare-earth metals to magnesium results in alloys of improved creep strength at elevated temperatures. Zirconium added to magnesium and its alloys results in grain refinement and improved mechanical properties.

TABLE 2.—*Chemical composition of standard magnesium alloy ingot, nominal compositions*

[1] Standard ASTM designation system. Letters represent alloy elements: A, aluminum; E, rare earths; H, thorium; K, zirconium; M, manganese; Z, zinc; and Li, Lithium. A serial letter is arbitrarily assigned (after the numerals) in alphabetical sequence, starting with A and serves to differentiate otherwise identical designations.

[2] Rare-earth elements, usually added as misch metal.

[3] Minimum.

[4] The rare-earth element in this alloy is didymium, essentially 85 percent neodymium and 15 percent praeseodymium. The alloy also contains a nominal 2.5 percent silver.

[5] Maximum.

TECHNOLOGY

Geology

Dolomite, the double carbonate of magnesium and calcium and a sedimentary rock commonly interbedded with limestone, extends over large areas of the United States. Evidence indicated that most dolomites are probably the result of replacement of preexisting limestone beds (*6*).

Magnesite, the natural form of magnesium carbonate, is found in bedded deposits, as deposits in veins, pockets, and shear zones and as replacement bodies in limestone and dolomite. Significant deposits occur in California, Washington, and Nevada. Brucite, the natural form of magnesium hydroxide is found as a decomposition product of magnesium silicates associated with serpentine, dolomite, magnesite, and chromite and in crystalline limestone. A brucite deposit associated with magnesite in Nevada has been mined. Olivine or chrysolite is a magnesium iron silicate usually found in igneous rocks such as basalt and gabbro. It is the principal constituent of a rock known as dunite. Commercial deposits are in Washington, North Carolina, and Georgia.

Evaporites are deposits formed by precipitation of salts from saline solutions. They are found both on the surface and underground. The Carlsbad, New Mexico, and the Great Salt Lake deposits are sources of magnesium compounds. The geological occurrence and chemical composition of inland brines cover a wide range and little information has been published. The only significant commercial source of magnesium compounds from well brines is in Michigan, although brines are known to occur in other areas.

Mining

Open-pit methods are used to mine magnesite and olivine in Washington and North Carolina. Deposits of magnesite and associated brucite at Gabbs, Nev., also have been worked by selective open-pit mining (*21*). The pit design was based on surface mapping and information from diamond drill cores. Mining is controlled by staking mining areas based on assays for lime and silica content obtained from air drill cuttings and entered as isograms on an overlay used in conjunction with a topographic map. Benches 10-foot high are advanced by blasting 12-foot drill holes with ammonium nitrate primed with 60 percent dynamite and detonated with delay electric blasting caps.

Stope and pillar mining using long, ring-drilled blast holes drilled from subdrifts to break the pillar for recovery was used to mine magnesite at Kilmar, Quebec, Canada.

In processing brines to produce magnesium and magnesium compounds consideration is given for discharge of waste water without contamination of water used for other purposes.

Basic Refractories and Magnesium Compounds

Magnesia is the principal product of the magnesium compounds industry. It is obtained from magnesite, sea water, and sea water or well brines combined with dolomite.

Dolomite, magnesite, and brucite ore is delivered from the mines to gyratory or jaw crushers where it is reduced to a minus 5-inch size and carried by belt conveyors to storage piles. The crushed ore is processed according to the manner in which it is to be used. In the case of dolomite, an appreciable quantity of raw, crushed ore is delivered directly to the iron and steel plants. Dead-burned dolomite is obtained by calcining the ore to above 3,000° F. in either blast furnaces or rotary kilns, to drive off CO_2, leaving CaO and MgO. The product is sintered to an extent depending upon the quantity of impurities present.

In the magnesite refractory plants, the minus 5-inch ore is conveyed to cone crushers which reduce it to sizes averaging $\frac{5}{8}$-inch to minus $\frac{3}{8}$-inch, and it is screened and washed. The screens are equipped with washing sprays. The minus $\frac{3}{8}$-inch ore is then passed over rake classifiers to remove slimes, and ground in ball mills to 98 percent minus 100-mesh. The ground discharge from the ball mills is conveyed to flotation cells where a silicate flotation removes talc and serpentine impurities. The cleaned concentrate is dried on a continuous filter and conveyed to the reduction plant.

Magnesite is calcined at temperatures below 1,650° F. to produce caustic calcined magnesia, in which 2 to 10 percent CO_2 is retained. Refractory magnesia is produced from crude magnesite by calcining the ore in rotary kilns at temperatures ranging from 2,640° F. to 3,200° F. Two classes of refractory magnesia are made: Brick, grade and maintenance grade. Periclase is produced when a pure grade of MgO is calcined at temperatures above 3,100° F.

Brucite is beneficiated in a heavy media process for use as refractory material (*10*).

In producing magnesia from sea water or well brines and dolomite, ore containing approximately 22 percent MgO and 30 percent CaO is used. The dolomite is taken from the quarry and crushed in gyratory or jaw crushers, washed, and further reduced in size by ball mills. It is then screened and calcined at temperatures ranging from 1,800° F. to 2,000° F. to drive off carbon dioxide and produce mag-

nesian lime. The magnesian lime is added to sea water to form magnesium hydroxide, the calcium oxide going into solution as calcium chloride. The magnesium hydroxide slurry is filtered to remove water, after which it is conveyed to rotary kilns fired to temperatures that may be as high as 3,360° F. The calcined product containing approximately 97 percent MgO.

When the source of magnesia is sea water or well brine, the waters are treated with calcined dolomite or lime obtained from oystershell by calcining to precipitate the magnesium as magnesium hydroxide. All refractory magnesia obtained from sea water, sea-water bitterns, or well brines is of brick grade.

Commercial grades of magnesium chloride are prepared by combining magnesium hydroxide with hydrochloric acid. The recycling of magnesium chloride resulting from the use of primary magnesium as a reducing agent to produce titanium sponge from $TiCl_4$, is described in the Titanium chapter.

Magnesium sulfate (epsom salts) is produced by dissolving magnesia in sulfuric acid, with subsequent crystallization. When natural epsomite ($MgSO_4 \cdot 7H_2O$) is utilized, it must be cleaned and recrystallized. When the ore is washed, the sulfate dissolves and passes through sieves; the gangue and other impurities remain behind on the sieves. The crystallized powdered magnesium sulfate is washed with water and is packed in conical wooden molds for drying and recrystallization. Various grades of magnesium carbonate are obtained by mixing solutions of magnesium sulfate and sodium carbonate, followed by evaporation.

Magnesium Metal

Two methods are employed to produce magnesium in the United States on a commercial scale: the electrolysis of magnesium chloride obtained from sea water, sometimes referred to as the Dow process, and the thermic reduction of dolomite with ferrosilicon.

In the Dow electrolytic process, sea water is mixed with a slurry of calcium hydroxide. The magnesium in solution in the sea water is precipitated as magnesium hydroxide in large settling tanks or thickeners and is pumped from the bottom of these tanks as a thin slurry containing about 17 percent magnesium hydroxide by weight. Precipitation permits elimination of about 98 percent of the sea water. The magnesium hydroxide slurry is filtered and neutralized with hydrochloric acid to form a 15 percent solution of magnesium chloride. The magnesium chloride solution is evaporated and dehydrated to a solution containing about 48 percent $MgCl_2$, which is mixed with enough dried granular $MgCl_2$ to a consistency of heavy paste and dried in a series of shelf driers to granules containing 74 percent $MgCl_2$. This granular material is fed to the electrolytic cells.

Artificial graphite electrodes are suspended in the bath to serve as anodes. The outer steel shells of the cells, or pots, and their internal baffles, serve as cathodes. Passage of direct current between the pot and electrodes, breaks down the magnesium chloride into chlorine and magnesium. Each cell operates at about 6 volts and 30,000+ amperes. Current efficiency is 75 to 80 percent. Power requirements are approximately 8 to 9 kilowatt-hours per pound of magnesium produced. The magnesium chloride cell feed continuously enters the cell to maintain the correct bath composition and level within the cell.

When the magnesium metal is liberated at the cathode, it rises to the surface of the bath where it is guided by inverted troughs to the metal wells in the front of the cell. This molten metal having a purity of 99.8 percent or more, is dipped from the storage wells into pig forms. The hot chlorine given off at the anode is collected under the tightly closed refractory cell cover and piped to the hydrochloric acid plant (*8*).

In the silicothermic process metallic magnesium is produced in two operations: (1) calcined dolomite and 75-percent-grade ferrosilicon, in ratio of 5 to 1, are mixed, ground heated and briquetted, and (2) the briquettes are charged into tubular retorts, which are heated and evacuated. The magnesium oxide in the calcined dolomite is reduced by the silicon, producing magnesium vapor which is condensed as crystals on a removable condenser that projects from the furnace, and is easily removed. The crystals of 99.98 percent magnesium in the shape of crowns or muffs, are melted and ladled into casting forms.

Other methods of production of magnesium were tried before the close of World War II and abandoned soon thereafter.

Alloying

Usually magnesium is melted and alloyed in open steel pots. Steel does not alloy appreciably with molten magnesium, especially if the bath contains a small quantity of manganese. Because of the chemical reaction of magnesium with the oxygen and nitrogen in the air, it is necessary to cover the molten metal with fluxes which float on top to form a fluid layer or solid crust. Although magnesium will not unite with beryllium to form a binary alloy it will absorb about 0.0005 percent. This small

amount retards oxidation of the molten magnesium.

Fluid flux is heavier than the molten magnesium, and therefore most of it accumulates at the bottom of the container and carries such impurities as MgO with it. A thin film of the fluid covers the top by virtue of its surface tension. The flux which forms a solid crust on top of the molten magnesium is also heavier than the bath but floats on top because it is porous or spongy. Fluid fluxes give better protection to the molten metal, but the solid crust fluxes are easier to separate from the metal during ladling and pouring operations.

Metalworking Techniques

Casting in sand was the first method of forming magnesium alloys. Development of permanent mold and die casting processes followed soon afterward. Casting magnesium alloys in permanent molds instead of sand lowers the cost of production when the number of castings reaches 1,000 pieces. Permanent mold magnesium castings have smoother surfaces and closer dimensions than sand castings. The permanent molds are made of high-carbon gray cast iron. Die casting, which is the process of forcing the molten magnesium alloy into steel dies under pressure, has found favor because of the speed and accuracy of production.

Although magnesium has a hexagonal crystal structure which limits forming at room temperature, it can be readily rolled, extruded, drawn, and forged when it is heated to temperatures ranging from 450° to 700° F.

Magnesium alloys are extruded into many shapes by forcing the solid metal through steel dies. Cast into round billets to fit the cylinder of the extrusion press, the alloy is preheated to 700° to 800° F. and then placed in the cylinder. The press is maintained at a temperature 650° to 850° F., depending upon the alloy to be extruded. Pressures up to 100,000 pounds per square inch are applied to force the alloy through the die.

Pellet extrusion of magnesium alloys is used at the Dow Chemical Co. plant at Madison, Ill. The molten magnesium alloy is poured onto a metal disk spinning at high speed within a large steel tank and hurled in globules or pellets to the inner walls of the tank. Each cooling spherical pellet retains the exact ratio of alloying constituents as the molten mass. As the spherical pellets, about 0.16 inch in diameter, settled to the bottom of the tank, they are transferred to the extrusion press. The extruded sections have extremely fine grain size and high compressive yield strength (*12*).

Magnesium alloys to be rolled into sheet and plate are cast into slabs, the original thickness of which is 3 to 5 inches. They are kept at temperatures of 600° to 850° F., by reheating when necessary, while they are rolled to about ¼-inch thickness, or less. If annealed sheet is required, the hot rolling ceases at about 20 percent above the gage desired, and the metal is annealed for a short time and is cleaned in a solution of acetic or sulfuric acid. The sheet is then cold rolled down to the required gage, after which it is again annealed under heavy cast iron plates to insure flatness.

Magnesium alloy sheet and extrusions are worked in much the same manner as other sheet metals. When it is drawn at 450° to 700° F., according to the alloy, it is possible to accomplish, in a single draw, all that could be done in three operations in steel, brass, or aluminum.

Forging magnesium alloys is accomplished similarly to other metals. Cast forging billets can be used, but an extruded blank is preferred. As in rolling or extrusion, both the metal and the tools are preheated. The forging stock is preheated to 550° to 800° F., according to the composition of the alloy and the design of the forging. Approximately 1 hour is allowed for heating each inch of metal thickness of the blank. Forging dies are usually heated to 400° to 600° F. As in forging other metals, accurate knowledge of metal flow is required in developing die design and blank specifications.

Magnesium and its alloys are the easiest of structural metals to machine, and can be sawed and drilled at room temperature, at greater speeds than most other metals. Magnesium and its alloys can be joined by brazing, riveting, soldering, and adhesive bonding. Primary magnesium and most of its alloys are weldable.

Safety

Before adequate safety measures were adopted, disastrous fires and explosions have resulted in plants that accumulated magnesium dust and drosses, and permitted them to become wetted or exposed to fire. During World War II, the Bureau of Mines provided advice to magnesium producers and consumers for the safe disposal of these waste materials. The care with which magnesium alloy scrap was handled in modern foundries and fabrication plants has been described in detail (*14*). Dust collectors were described, and dust disposal methods were given.

In 1954, when magnesium-thorium alloys were developed, it became necessary for studies to be made of radiation safety in the plants producing and fabricating these alloys, even though radioactivity was comparatively low. Nominal thorium content was 3 percent or less. The Dow Chemical Co. published a bulletin relating its experience with the alloys thus far

and stating that external radiation is not a serious problem when melting and fabricating these alloys. The following precautions should be observed: (1) local exhaust ventilation of areas where the alloys are melted and milled; (2) check regularly air sampling of these areas to determine extent of radiation; and (3) provide adequate local exhaust at the point of welding, to control exposure to radiation.

USES

Magnesium Minerals and Compounds

Dolomite is used in large quantities by the steel industry as a flux and for patching open hearth furnaces. It is an important raw material used in silicothermic magnesium plants and for the production of refractory magnesia and other magnesias from sea water. Large quantities of material which may be classed as dolomite or dolomitic limestone are used widely outside the metallurgical field as a soil conditioner, as an aggregate in concrete, and in road beds. Refractory magnesia and other magnesias are produced from magnesite and brucite. Olivine is used primarily as a molding sand in foundries; its use for the production of refractories has diminished.

The principal uses for magnesium compounds are in the following industries:

Compound and grade	*Use*
Magnesium oxide:	
Refractory grades.	Basic refractories.
Caustic-calcined	Cement, rayon, fertilizer, insulation, magnesium, metal, rubber, fluxes, refractories, chemical processing and manufacturing, uranium processing, paper processing.
U.S.P. and technical grades.	Rayon, rubber (filler and catalyst), refractories, medicines, uranium processing, fertilizer, electrical insulation, neoprene compounds and other chemicals, cement.
Precipitated magnesium carbonate.	Insulation, rubber, pigments and paint, glass, ink, ceramics, chemicals, fertilizers.
Magnesium hydroxide	Sugar refining, magnesium oxide, pharmaceuticals.
Magnesium chloride	Magnesium metal, cement, ceramics, textiles, paper, chemicals.

Basic refractories used in metallurgical furnaces are produced from magnesium oxide. Technological advances in steel production required higher temperatures which were met by refractories manufactured from high purity magnesia capable of withstanding temperatures above 3,500° F.

Magnesia is used as a stabilizing or vulcanizing agent in rubber. The high electrical resistance of fused magnesia or periclase makes it useful as an insulator in electric furnaces and domestic appliances. Magnesia serves as an absorbent and catalyst in the carbonate leach circuits for the recovery of uranium oxide from uranium ores.

Basic magnesium carbonate is used as a thermal insulator for boilers, pipes, etc.; in table salt to prevent caking; and in preparation of pharmaceuticals and cosmetics. Magnesium chloride derived from sea water is primarily used for the production of magnesium metal. Small quantities derived from sea water and well brines are used in industrial chemicals and oxychloride cement for flooring. Magnesium sulfate is used for pharmaceuticals, dyes, sizing, paper manufacture, fertilizers, explosives, and matches.

Magnesium and Magnesium Alloys

During 1959–63 magnesium used as a constituent of aluminum alloys amounted to about 40 percent of the total magnesium used and magnesium alloys consumed another 40 percent. Magnesium alloys are used in aircraft engines and in airframe structures, wings, undercarriages, floor beams and plates, skins, and wheels. In helicopters, applications of magnesium alloys include extrusions, sheet, castings, forgings, bars, and tubes. Magnesium alloys are used in jet engines and guided missiles (*13*). The lightweight magnesium metal has replaced heavier metals used for many parts of automotive and transportation equipment.

Other uses for magnesium were as a reducing agent for titanium, zirconium, hafnium, uranium, and beryllium; and as a scavenger and deoxidizer. Magnesium anodes are standard equipment for the cathodic protection of iron and steel, particularly in underground pipe, ships, and water tanks.

Trends of uses of primary magnesium for structural materials during 1961–63 are shown in table 3.

ALTERNATE MATERIALS

Refractories are made from many materials including bauxite, alumina, zirconia, mullite, silicon carbide, and boron carbide. Depending upon requirements, many of these may be used in place of magnesia refractories.

Aluminum can be used in most structural applications where magnesium is now used.

Sodium also is used to reduce titanium tetrachloride to produce titanium metal.

SECONDARY SOURCES AND RECOVERY OF MAGNESIUM

Secondary magnesium is obtained from two general sources: New scrap and old scrap. New scrap is generated in sheet mills and fabricating plants. It consists of clippings, turnings, borings, skimmings, slags, drosses, and defective articles rejected by the manufacturer or returned to him unused. Old scrap is metal contained in articles that have been discarded because of wear, damage, or obsolescence, usually after they have served a useful purpose. Typical sources of old magnesium scrap are wrecked aircraft, old and obsolete mobile equipment, and lithographers' plates.

RESERVES

Magnesium and magnesium compounds are produced from the following four raw material sources: (1) sea water, (2) dolomite, (3) ores other than dolomite, and (4) evaporite deposits and lake and well brines. Sea water with a magnesium content of 0.13 weight-percent is an inexhaustible resource.

Large deposits of dolomitic limestone and dolomite are widely distributed throughout the world. Four major dolomite areas are in the following areas of the United States: (1) Appalachian Valley region extending from Vermont through Massachusetts, Connecticut, New York, New Jersey, Pennsylvania, Maryland, Virginia, Tennessee, Georgia, and Alabama; (2) western Ohio and eastern Indiana; (3) a U-shaped belt starting in southeastern Minnesota and extending through northeastern Iowa, northern Illinois, southern and eastern Wisconsin and across upper Michigan along the north shores of Lakes Michigan and Huron; and (4) southern Missouri and northern Arkansas. In the West widespread deposits of high-magnesium limestones are reported in central and southern New Mexico. Discontinuous masses of dolomite occur throughout central and southern California and southwestern Arizona. Large quantities of dolomite are available in Texas, Oklahoma, Colorado, Utah, Wyoming, Montana, and northeastern Washington.

The principal magnesium ores other than dolomite are magnesite, brucite, and olivine (chrysolite). Magnesite is the most plentiful of these. Estimated data on world magnesite reserve of 8.3 billion tons, shown in table 4, do not include all deposits. Large deposits also occur in Spain, Austria, Yugoslavia, Pakistan, and Sudan. Deposits estimated at less than 1 million tons were reported in Mexico, Iran, Philippines, Australia, United Arab Republic (Egypt), and Republic of South Africa. Small deposits have been noted in Cuba, Sweden, Norway, Poland, Scotland, France, Italy, Kenya, and Tanzania (*5*).

TABLE 4.—*World magnesite reserves*

Country	Million tons	Country	Million tons
China	5,000	United States	65
Korea, North	2,000	Brazil[1]	7
New Zealand	600	Venezuela	3
U.S.S.R.	400	Greece	1
Czechoslovakia	100	Turkey	1
India	100	Canada	1

[1] Per meter of depth (average depth not known).

The reported estimate of 65 million tons of magnesite reserves and resources in the United States is divided as follows: 88 percent in Nevada including 27 million tons of magnesite containing less than 5 percent MgO; 11 percent in Washington; and the remaining 1 percent in California (*6*). Magnesite also occurs in Texas, New Mexico, Idaho, Utah, Pennsylvania, Massachusetts, Maryland, New Jersey, and New York, but reserves have not been estimated in these States.

Brucite reserves are estimated to total 3 million tons in Nevada, and 2 million tons in North Korea. The mineral also is found in Arizona and in the United Kingdom, Ireland, and Canada.

The reserve of olivine is estimated at 230 million tons averaging 48 percent magnesia in North Carolina and Georgia (*10*).

In Washington the olivine reserve in the form of dunite is estimated at 50 million tons on Cypress Island and many million tons in the Twin Sisters Region (*9*).

Reserves of magnesium salts obtained as brines from underground evaporite deposits are difficult to estimate. Available information on magnesium salts in surface evaporites is insufficient to estimate reserves. A preliminary survey in 1950 indicated 13 million tons of MgO equivalent in brines in Saskatchewan, Canada.

SOURCES OF STATISTICAL INFORMATION

In addition to its annual canvasses of production, sales, and use of magnesium and magnesium compounds in the United States, the Bureau of Mines gathers monthly statistical information covering domestic production, stocks, and shipments of primary magnesium.

Export-import figures covering magnesium, crude magnesite, and magnesia, are taken from the information gathered by the Bureau of Census, Department of Commerce. Information concerning production of magnesium and magnesite ore in foreign countries, is accumulated by the Bureau of Mines from published sources and reports by mineral attaché at foreign offices.

PRODUCTION, CONSUMPTION, AND TRADE

Magnesium Ores and Compounds

Statistical data from foreign countries on production of magnesium ores and compounds are limited to crude magnesite. Table 5 shows a comparison of crude magnesite production in the United States with total world production. Although the world growth rate is about 11 percent per year, magnesite production in the United States showed little overall change during the past decade. Table 6 presents data on magnesia sold or used by producers. Data in table 7, give exports and imports of magnesium compounds. Imports are principally crude and calcined magnesite.

In 1963, about 74 percent of the caustic calcined and refractory magnesia sold or used came from well brines, bitterns, and sea water using calcined dolomite or lime in the process. The remaining 26 percent was from magnesite. About 2 million tons of dead-burned dolomite used for refractories and flux was produced from dolomite.

TABLE 5.—*Magnesite production*

[Thousand short tons]

Year	World	United States
1954–58 (average)	5,150	526
1959	6,100	594

Year	Imports		Exports	
	Quantity	Value	Quantity[1]	Value
1954–58 (average)	100	$5,799	47	$2,529
1959	171	10,434	97	5,828
1960	134	8,334	101	6,674
1961	72	4,357	130	8,522
1962	122	6,527	78	5,790
1963	110	5,588	87	6,298

[1] Chiefly magnesite and dead-burned magnesia. Includes estimate of small quantities of other magnesium compounds.

Magnesium

During World War II, the United States became the leading magnesium producing country. Since 1952 exports have exceeded imports. Statistics for consumption of magnesium in foreign countries are not available.

Data in table 8 show a steady increase in United States production of primary magnesium, and data in table 9 show domestic consumption and producers and consumers stocks of the primary metal. Industry reports indicated that exports of primary magnesium exceeded 10,000 tons in 1963. Of the world total production of 155,000 tons, West Germany imported about 25 percent.

In 1960, Furukawa Magnesium Co., Ltd. expanded its silicothermic plant at Oyama, Japan, to increase annual magnesium capacity from 2,000 to 4,500 tons. Dominion Magnesium, Ltd., of Canada expanded its silicothermic plant capacity from 8,000 to 10,000 tons per year in 1961. The Norsk-Hydro-Elektrisk A/S expanded its plant at Herya, Norway, to an annual capacity of 19,000 tons in 1962. In 1963, a 5,000-ton capacity thermal reduction plant was erected at Hopton, England, by Magnesium Elektron, Ltd.

The U.S. tariff rates for magnesium and magnesium compounds are shown in table 10.

TABLE 8.—*Primary magnesium production*

[Thousand short tons]

Year	World	United States
1954–58 (average)	116	62
1959	82	31
1960	103	40
1961	116	41
1962	146	69
1963	155	76

TABLE 9.—*Domestic consumption and imports for consumption of primary magnesium (ingot equivalent and magnesium content of magnesium base alloys)*

[Short tons]

Year	Consumption				Imports for consumption
	Structural products	Used in aluminum alloys	Nonstructural purposes except aluminum alloys	Total	
1954–58 (average)	18,745	10,894	14,178	43,817	969
1959	18,638	14,780	8,133	41,551	645
1960	12,419	12,511	12,170	37,100	433
1961	13,391	19,754	12,388	45,533	1,041
1962	21,032	18,405	7,883	47,320	2,447
1963	19,500	21,780	9,960	51,240	2,374

TABLE 10.—*Tariff schedules of the United States*

Item	TSUS No.	Rate of duty, Aug. 31, 1963	Statutory rate of duty
Magnesite:			
Crude	522.61	$5.25 per ton	$10.50 per ton.
Caustic calcined	522.64	$10.50 per ton	$21.00 per ton.
Refractory magnesia (including dead-burned magnesite, fused magnesite, and dead-burned dolomite):			
Less than 4 percent lime	531.01	0.38¢ per pound	0.75¢ per pound.
More than 4 percent lime	531.04	12 percent ad valorem	30 percent ad valorem.
Magnesium compounds:			
Carbonate, unprecipitated	419.20	8.5 percent ad valorem	25 percent ad valorem.
Carbonate, precipitated	419.22	0.35¢ per pound	$1.50 per pound.
Chloride, anhydrous	419.24	1¢ per pound	1¢ per pound.
Chloride, other	419.28	0.42¢ per pound	0.625¢ per pound.
Oxide, calcined	419.32	2¢ per pound	7¢ per pound.
Epsom salts	419.34	0.375¢ per pound	0.75¢ per pound.
Magnesium: unwrought other than alloys, waste and scrap.[1]	628.55	40 percent ad valorem	100 percent ad valorem.
Magnesium alloys:			
Unwrought	628.57	16¢ per pound contained magnesium +8 percent ad valorem.	40¢ per pound contained magnesium +20 percent ad valorem.
Wrought	628.59	13.5¢ per pound contained magnesium +7 percent ad valorem.	40¢ per pound contained magnesium +20 percent ad valorem.

[1] Duty on waste and scrap temporarily suspended as provided by Public Law 88-324, effective July 1, 1964.

STRATEGIC CONSIDERATIONS AND GOVERNMENT PROGRAMS

In addition to deposits of magnesite, olivine, and evaporites the wide distribution and large deposits of dolomite and development of plants using the virtually limitless supply of magnesium in sea water assure self-sufficiency for the United States of magnesium and magnesium compounds including refractory magnesia.

On June 30, 1964, government inventories totaled 173,500 short tons of specification grade and 54 tons of subspecification grade magnesium in the national (strategic) stockpile.

There are no current government programs concerning magnesium.

PRICES

The price per pound of primary magnesium has declined from $1.83 in 1918 to become steady at 20.5 cents from 1943 to 1950. Three increases in 1950 brought the price to 24.5 cents in September. In January 1951, the Government's General Ceiling Price Regulation fixed the price at 24.5 cents. In 1953, the price was raised to 27 cents, and remained at that point throughout 1954. Gradual increases during 1955 and 1956, resulting from the rise in cost of fuel, raw materials, transportation, and labor, brought the price of primary magnesium to 35.25 cents a pound in 1956. It has remained at this price in the United States.

The average prices paid for dead-burned dolomite and magnesium oxide during 1959–63 are shown in table 11.

TABLE 11.—*Average values per short ton of principal magnesium compounds in the United States*

Year	Dead-burned dolomite	Crude magnesite	Caustic-calcined magnesia	Refractory magnesia
1954–58 (average)	$15.46	$4.66	$60.14	$52.77
1959	16.63	4.05	65.43	60.73
1960	16.66	4.11	65.03	60.99
1961	16.40	5.14	62.55	59.11
1962	16.73	4.65	62.27	61.09
1963	16.96	3.37	58.26	62.24

TAXES

Depletion allowance for deposits of magnesite, dolomite, and brucite in the United States was 15 percent, and for olivine, 23 percent.

RESEARCH

Research by industry, government, and educational institutions in production and use of magnesium and magnesium compounds has progressed steadily since World War II.

Investigations in the laboratories of Metal Hydrides, Inc., Beverly, Mass., has provided information on the use of magnesium powder as solid fuel in missiles. Harbison-Walker Refractories Co. has a research center near Pittsburgh, Pa., and Kaiser Refractories Division operates research facilities at Milpitas, Calif. The latter two companies developed methods to produce high-purity magnesia for the manufacture of high-temperature refractories, to meet the requirements of the basic oxygen furnace.

Research for the development of refractories to withstand temperatures up to 4,000° F. is continuing. Magnesium oxide ceramic material with a purity of 99.95 percent MgO is available for crucibles that will withstand temperatures as high as 5,000° F.

Much work was done on the relationship of the melting temperature of the bonding material in the refractory to the strength of the refractory. High-purity magnesite either alone or in combination with other high-purity minerals produced better grade refractories than less pure magnesite.

FMC Corp. does research at chemical laboratories in Newark, Calif., to develop specific types and grades of magnesia products (*5*).

Dow Chemical Co. developed processes for recovery of magnesium compounds from deep-well brines in Michigan. The company developed the "bath-tub" cell for electrolysis of magnesium chloride to produce magnesium. Research on the feed, amperage, and design of the electrolytic cell is continuing to improve its efficiency.

Technologic research for the production of high-strength premium quality magnesium castings led to the development of alloy systems and improved casting design and techniques (*9*). Alloys in the magnesium-aluminum-zinc system were useful up to 550° F.; and those in the magnesium-thorium-zirconium system were useful up to 650° F. A comparatively new alloy containing lithium was developed (LA 141A), with a specific gravity of 1.35 (*17*).

The Bureau of Mines does research to provide safer and more efficient methods of mining and mineral processing. This work includes fundamental studies of magnesium alloys and recovery of the metal and its alloying ingredients from scrap (*3*). The Bureau measured the vibration-damping capacity of magnesium alloys in missiles and space vehicles subject to vibration stresses and provided fundamental information on the lightweight magnesium-lithium series of alloys (*17*, *20*).

OUTLOOK

Ores such as dolomite, magnesite, brucite, and olivine should continue as the principal world source of refractory magnesium oxide. However, the refractory industry is expected to require increasing quantities of high-purity magnesium oxide such as that which can be made from sea water and dolomite and various brine solutions.

Dead-burned dolomite accounted for the largest volume production of magnesium compounds. Use of dolomite covers a comparatively wide field and the outlook is based primarily on consumption records that show little change during the past decade. There is no outstanding new use for dead-burned dolomite. Future production will probably continue to average about 2 million tons per year.

Increased knowledge of the advantages of high-purity magnesium oxide used for basic refractories will lead to increased production of magnesia. Using this assumption and relying upon the record of the past decade the consumption of magnesium oxide for refractories will increase 7 to 8 percent per year and will reach 1.2 million tons in 1970 and 2.5 million tons in 1980.

Although electrolytic processes using sea water will continue to be the predominate method for making magnesium metal, thermal reduction plants also will be built in areas with high cost electric energy.

Magnesium consumption from 1961 to 1963 inclusive, together with increased interest in better casting techniques, indicates a 4- to 6-percent increase in consumption per year; consumption in 1970 is projected to about 27,000 tons of magnesium for structural products and will reach 43,000 tons in 1980.

Based on records of past consumption and anticipated demand, magnesium consumption for use in aluminum alloys is estimated to increase 9 to 10 percent per year amounting to a projected consumption of 43,000 tons of magnesium in 1970 and 100,000 tons in 1980.

Estimates of future titanium production show that consumption of magnesium as a reducing agent for titanium will increase about 10 percent per year amounting to a projected consumption of 5,000 tons in 1970 and 12,000 tons in 1980.

Past consumption records of magnesium for other uses indicate an increase of about 4 percent per year, amounting to a projected consumption of 10,000 tons in 1970 and 15,000 tons in 1980.

The total consumption of magnesium in the United States is expected to increase 7 to 8 percent per year and reach 85,000 short tons in 1970 and 170,000 tons in 1980.

This growth rate may be increased substantially if marketing practices are intensified, research and development are increased, and new plants planned in 1963 are constructed.

Harvey Aluminum, Inc., and Standard Magnesium and Chemical Co. (a division of Kaiser Aluminum and Chemical Corp.) announced plans to build primary magnesium plants in the Pacific Northwest—a 20,000-ton-per-year plant and a 10,000-ton-per-year plant, respectively.

PROBLEMS

The magnesium metal industry in the United States is confronted with the basic problem of expanding markets to fully utilize available productive capacity and vast resources.

An important problem is the lack of understanding by prospective consumers of the advantages of magnesium over other lightweight materials. A special problem is the unfounded apprehension that all forms of magnesium are fire hazards, a belief acquired when it was used extensively for flares and other pyrotechnics in wartime.

There is a need for improving the technology of primary metal production and secondary recovery. The present continuous process of electrolysis of magnesium chloride requires large expenditures for electric energy, and uses magnesium chloride, a material that is difficult to handle, for cell feed. The silicothermic method is a batch process with the high labor requirements inherent in such operations, and special care is required in operating the retorts to prevent burning of the magnesium.

The use of magnesium alloys as structural materials has been restricted because of their low strength at elevated temperatures, limited resistance to galvanic and stress corrosion, and the high cost of magnesium, relative to competing materials. In 1963, only about 30 magnesium alloys had been developed, and the range of their properties fell short of that needed for wide use of the metal commensurate with its potential lightweight applications. Accurate physical, metallurgical and corrosion data on many potentially useful magnesium alloys are lacking.

More intricate machinery is used to manufacture magnesium die cast parts than aluminum parts. Consequently, magnesium has not been fully utilized in many consumer-oriented products such as sporting goods, hand and motor operated household and garden tools, and business machines where lightness and superior dampening properties of the metal would be advantageous. Manufacturers of castings need more information on casting techniques to produce good magnesium castings.

Incomplete knowledge of worldwide resources and industry activities continues to be a problem in evaluating sources of supply, determining requirements, and planning future programs.

Future expansion of installations for producing refractory magnesia from sea water is faced with the problem of selecting plant sites adjacent to sea water and close to an adequate supply of suitable dolomite. Although refractory bricks, made from magnesia produced from sea water and dolomite and containing 98 percent MgO, stand tests under 25-pound load at 3,500° F., there remain problems of meeting specifications for diversification of requirements which include reducing the silica and calcium carbonate to lower percentages enabling production of a brick that will withstand temperatures up to 5,000° F.

High-temperature refractories made from high-purity magnesia raise the problem of finding methods to lower the firing temperature in making the product and still maintain a periclase to periclase bonding.

Expansion of the export markets for magnesia refractories is retarded by high foreign tariffs.

MANGANESE

By Gilbert L. DeHuff [1]

THE PRINCIPAL use of manganese is in producing steel, chiefly to counteract the effects of sulfur. It is also used to impart strength, toughness, hardness, and hardenability to some steels. Moreover, manganese has beneficial deoxidizing effects, although it is not primarily used for this purpose. For these applications, manganese usually is introduced in the form of ferromanganese. Manganese dioxide ores have important uses in manufacturing manganese chemicals, as an oxidizing agent, and as a depolarizing agent in dry-cell batteries. Electrolytic manganese is a satisfactory form to introduce manganese to metallurgical or chemical operations where impurities are particularly objectionable.

Manganese ore is classified according to category of use into the following three general grades: Metallurgical, battery, and chemical, including miscellaneous.

The world reserve of manganese ores of varying grades is estimated to exceed 2 billion tons, the largest deposits being in U.S.S.R., Gabon, Republic of South Africa, Brazil, India, and China. The Gabon reserves include battery-grade ore. The manganese ore reserve in the United States from which a concentrate containing 35-plus percent manganese can be obtained by ordinary means of concentration is roughly 1 million tons, largely dependent on premium prices. In addition, large domestic manganese resources occur as low-grade and refractory deposits in Aroostook County, Maine, the Cuyuna range Minnesota, Chamberlain, S. Dak., Batesville, Ark., and the Artillery Mountains, Ariz.

In the period following the Korean war, with premium Government prices, U.S. production of manganese ore was about 15 percent or less of its requirements, most of the production going to Government stockpiles. By 1963, U.S. production had dropped to a negligible quantity in terms of consumption. Because of the strategic importance of manganese, the Federal Government has been greatly interested in assuring an adequate supply. It has established substantial stocks of ore, ferromanganese, and metal; has investigated virtually every known manganese occurrence in the United States; has financed important new production at home and abroad; and has devoted much energy and financial support to research. This research developed silicomanganese and electrolytic manganese to the point of commercial production and application; led to the commercial production of high-purity synthetic manganese dioxide from low-grade domestic manganiferous materials; and demonstrated the technical feasibility of several processes for utilizing the large domestic manganese resources.

There remains no satisfactory substitute for manganese in its major metallurgical uses, and the problems of stockpiling—the optimum quantity and best type of material—continue to demand consideration.

BACKGROUND

Manganese oxide was used by the ancient Egyptians and Romans for controlling the color of glass. This application for glass and pottery constituted the principal commercial use for manganese until the latter part of the 18th century. From then until about 1855, manganese ores were used extensively in the manufacture of chlorine (*19*).[2] The use of umber as a drier for oils appears to date from the middle of the 17th century (*10*). The first recorded mining of manganese ore in the United States was in 1837 in Hickham County, Tenn., apparently for the purpose of coloring earthenware. The use of

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

manganese in manufacturing iron and steel dates from 1839, when Heath demonstrated that it improved malleability of the product (*19*).

In 1856 the Bessemer process for making steel was initiated but the product was not satisfactory because it could not be forged or hot rolled without cracking or tearing. Shortly afterwards, Robert Mushet discovered this failing could be overcome by the introduction of manganese in the form of spiegeleisen. Since then, manganese has been necessary to the commercial production of steel in the various production methods which have developed since Bessemer's discovery.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Minable manganese ore deposits have worldwide distribution, and many countries are substantial producers. The principal producing countries are the U.S.S.R., Republic of South Africa, Brazil, India, China, Gabon. Total manganese ore production in 1963 was estimated at 16 million tons, compared to an estimated world iron ore production of 510 million tons for the same year.

Since the close in 1961 of the emergency-generated operations of Manganese, Inc., at Henderson, Nev., the only manganese ore (35 percent or more manganese) producing industry in the United States has consisted of the production in Montana of manganese oxide nodules by The Anaconda Company from stockpiled Montana carbonate ore and the production of battery ore by Taylor-Knapp Co. at Philipsburg, Mont., together with some production of metallurgical ore in Socorro County, N. Mex., and in 1962 in southern California. In 1963, New Mexico's production exceeded that of Montana. Total U.S. production for 1963 was only 11,000 short tons, whereas domestic consumption was 1.8 million tons.

The United States and the U.S.S.R. are the principal manganese-ore-consuming countries, the former using ore chiefly for the production of manganese ferroalloys and the latter for the production of pig iron as well as of alloys. The large steel-producing countries of continental Europe, the United Kingdom, and Japan, are consumers of lesser importance by their production of manganese ferroalloys. The Republic of South Africa and Japan, as well as the United States, produce electrolytic manganese metal for export. The Republic of South Africa and India, together with other ore-producing countries, have become ferromanganese producers of some consequence.

Most of the manganese ferroalloys and metal used in the United States are consumed by the iron and steel industry. The nonferrous, dry-cell battery, chemical and miscellaneous industries consume only a small quantity. Except for The Anaconda Company, which has been a domestic producer of ferromanganese as well as of high-grade metallurgical ore in the form of nodules, the U.S. manganese-ore-producing industry has not been integrated with the ore-consuming industries. The principal producers of manganese ferroalloys, Bethlehem Steel Co., United States Steel Corp., and Union Carbide Corp., however, have substantial investment in important foreign manganese-mining operations, and the two steel companies are large alloy consumers. E. J. Lavino & Co. holds a significant position as a producer of ferromanganese and an importer of manganese ore. In all, approximately a dozen companies produce ferromanganese, silicomanganese, or spiegeleisen in the United States, and the greater part of this production comes from plants east of the Mississippi River. Three companies, American Potash & Chemical Corp., Foote Mineral Co., and Union Carbide Corp., produce electrolytic manganese metal.

Manufacturers of dry-cell batteries and certain manufacturers of chemicals, and users of dioxide ore for other chemical purposes, constitute separate segments of the traditional domestic manganese-ore consuming industry. Most are in the eastern United States.

Manganese ores and products are imported into the United States by some of the large consumers, either directly or through agents, and by importer-dealers, traders, or brokers. In the United States, these importing and trading firms have offices principally in New York and Philadelphia. A number of these particular firms are subsidiaries or affiliates of houses headquartered in London or Europe. Actual import of ores is largely through Baltimore, Md., Philadelphia, Pa., Virginia, and gulf coast ports.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

In its statistical presentations, the Bureau of Mines has for many years used the term *manganese ore* for those ores containing 35 percent or more manganese; *ferruginous manganese ore* for those containing 10 to 35 percent manganese; and *manganiferous iron ore* for those containing 5 to 10 percent manganese. In each instance, the material reported as ore may actually have been concentrate, nodules, or a synthetic ore. In the two lower grades, particularly that of the ferruginous

manganese ore, ores may be included which do not have sufficient iron content to allow them to qualify technically as ferruginous or iron ore. These are matters of expediency that avoid unwieldy and unnecessary detail in the tabulation of statistics, and avoid difficulties as to publication, confidentiality, and practical use of data which arise from too narrow classification. The general term *manganiferous ore* may be used statistically by the Bureau to include any ore of importance for its manganese content containing less than 35 percent manganese but not less than 5 percent. The industry, however, may go as low as 2 percent manganese in its use of the modifier "manganiferous."

In this chapter, unless otherwise qualified, *manganese ore* will be used to mean ore containing 35 percent or more manganese, and may include concentrate, nodules, or synthetic ore. The term *synthetic ore*, as used in this chapter and to date in the Bureau's statistics, refers to material that is the equivalent of, or better than, natural ore, which can be put to the same uses, and is produced by means other than ordinary concentration, calcining, sintering, or nodulizing. The most important use of the term "synthetic ore" has been to label manganese dioxide produced chemically or electrolytically for use in the manufacture of dry-cell batteries.

Manganese ore, and to a lesser extent the lower grade manganiferous ores, falls into three general classifications determined largely by adaptability to the three principal categories of use—metallurgical, battery, and chemical (including miscellaneous or associated industries). In the Bureau's statistics, this is recognized by classifying the various ores as metallurgical, battery, or miscellaneous. The determining factor is suitability of ore for use by the iron-steel-ferroalloy industry, or by the battery industry.

For the national stockpile specifications essentially three major grades of ore have been established—metallurgical, battery, and chemical. The chemical-grade is not otherwise recognized by the industry, although it is based primarily on industry requirements for the manufacture of potassium permanganate and for use as an oxidizing agent in chemical processes such as the manufacture of hydroquinone.

National Stockpile Specification P–30–R, Manganese—Metallurgical, January 8, 1953, covered ore, nodules, and sinter "suitable for the manufacture of commercial grades of ferromanganese and special manganese alloys, and for the production of chemicals which do not require ore of high manganese dioxide content." The chemical requirements, for it and for the March 14, 1958 revision, P–30–R1, were essentially as follows:

		Percent by weight (dry basis)			
		P–30–R [1]	P–30–R1 [2]	P–30–R [3]	P–30–R1 [4]
Manganese	Minimum	46.00	46.00	40.00	44.00
Iron	Maximum	8.00	8.00	16.00	12.00
Silica-plus-alumina	do	12.00	12.00	([5])	15.00
Phosphorus	do	.18	.18	.30	.24
Copper	do			.25	
Copper-plus-lead-plus-zinc	do	.10	.20	1.00	.30

[1] Any proposal could be rejected if its guaranteed chemical analysis on the weighted average basis were inferior.
[2] Material purchased "shall conform" on a weighted average basis for each contract.
[3] No proposals considered unless guaranteed chemical analysis on the weighted average basis is equal or better.
[4] Each lot delivered "shall conform", a lot being "any quantity determined by the Government to require a separate chemical analysis report."
[5] "No limit specified for material, which may be offered; however, material over 15 percent will be purchased in exceptional cases only."

National Stockpile Specification P–29–R3, Manganese Dioxide—Battery Grade, June 16, 1961, "covers manganese dioxides in the form of synthetics, ores, or concentrates, suitable for use in the manufacture of dry-cell batteries." Although two grades, military (Grade A) and commercial (Grade B), are recognized for both synthetic and natural manganese dioxide, only the two natural grades and the military grade of synthetic are provided for in P–29–R3. Suitability for the manufacture of satisfactory batteries is in reality the minimum controlling specification for the three grades of P–29–R3. Available oxygen as percent minimum MnO_2 is set by this stockpile specification as 85.0 for Synthetic Grade A, 75.0 for Natural Grade A, and 68.0 for Natural Grade B.

National Stockpile Specification P–81–R, Manganese Ore—Chemical Grade, October 28, 1957, recognizes two types:

"Type A shall be satisfactory for use as an oxidizing agent in chemical processes, such as in the manufacture of hydroquinone.

"Type B shall be satisfactory for use in the production of potassium permanganate and other permanganate chemicals."

The chemical requirements for Type A follow:

Type A	*Percent by weight (dry basis)*
Manganese dioxide (minimum)	80.0
Iron (maximum)	3.0

In addition, "Final acceptance of Type A material shall be based upon the results of evaluation tests by the purchaser, or his designee, to determine its suitability as an oxidizing agent in chemical processes such as in the manufacture of hydroquinone." Specification P–81–R dropped the requirement of immediately pre-

ceding Specification P–81 (18 April 1950) that upon X-ray examination there shall be evidence of the predominance of pyrolusite.

The chemical requirements for Type B for P–81–R and the immediately preceding P–81 are:

Type B		Percent by weight (dry basis)	
		P–81	P–81–R
Manganese dioxide	Minimum	85.0	82.0
Managanese	do		53.0
Iron	Maximum	3.0	3.0
Silica	do	3.0	5.0
Alumina	do	3.0	3.0
Phosphorus	do	.10	.20
Arsenic	do	.05	.10

Commercially, all manganese ores are purchased by negotiation. Although the national stockpile specifications represent the grade of ores desired by industry, the practice of blending ores, adapting particular ores to special conditions of operation, supply, use or price, permits considerable room for negotiation and explains the lack of standard industry specifications. The specifications of one company will differ from those of another, and the specifications of a particular company will change with the passage of time. When the supply of ore is plentiful, specifications are more severe than when ore is scarce.

National Stockpile Specification P–30a–R2, Ferromanganese (Standard High-Carbon), July 26, 1961, "covers standard high-carbon ferromanganese suitable for use in the production of iron and steel." Its chemical requirements are as follows:

	Percent by weight
Manganese	74.00 to 77.50
Carbon (maximum)	7.50
Silicon (maximum)	1.00
Phosphorus (maximum)	.35
Arsenic (maximum)	.20
Phosphorus plus arsenic (maximum)	.45
Sulfur (maximum)	.05
Iron (by analysis) (minimum)	14.00

This generally reflects the domestic industry's specification for standard high-carbon ferromanganese, usually considered as 74 to 76 percent manganese. Other important manganese ferroalloys, with their approximate manganese or other significant content ranges, are as follows: Low-carbon ferromanganese (80 to 95 percent Mn), medium carbon ferromanganese (80 to 85 percent Mn), silicomanganese (65 to 68 percent Mn, 12 to 20 percent Si), and spiegeleisen (up to 30 percent Mn, but usually between 16 and 23). Other intermediate and special manganese ferroalloys are marketed under various trade names. Briquets are ferromanganese or silicomanganese fines which have been bonded together so as to provide a standard known weight (for example, 2 pounds) of elemental manganese. They are used chiefly by iron foundries.

Several grades of electrolytic manganese metal are produced in the United States, including the regular, nitrided, hydrogen-removed, and hydrogen-reduced grades. National Stockpile Specification P–98–R2, Manganese Metal-Electrolytic, May 17, 1961, requires a minimum manganese content of 99.9 percent. Electric-furnace metal which had a minimum manganese content of 95.5 percent is no longer offered. Manganese metal, with a manganese content falling somewhere between these two, is produced abroad by the thermite process.

TECHNOLOGY

Geology

More than 100 minerals contain manganese as an essential element (*8*). Oxides, carbonates, and silicates, in that order, are the most important ore minerals or possible ore minerals of manganese. The principal manganiferous carbonate mineral is rhodochrosite, $MnCO_3$, which is one of an isomorphous series, including the carbonates of iron, calcium, magnesium, zinc, and cobalt, such that a great variety of intermediate compositions are to be found. The manganese oxide minerals frequently grade from one to another in composition with the result that identification is difficult and the terminology is confused. The common terms of 25 years ago, psilomelane, pyrolusite, and manganite, have been redefined by the mineralogist and are no longer acceptable to him in the manner in which they were formerly used. In recognizing the difficulties of applying to field use terms which have become narrow and dependent on X-ray or other laboratory examination, members of the Geological Survey have suggested "psilomelane type" in place of "psilomelane" to describe the hard massive oxides which are not specifically identified and which actually may be mixtures of more than one discrete oxide mineral. Similarly, the term "soft oxides" has been proposed for the soft black oxides which have not been specifically identified in the laboratory and which may be a mixture of several different manganese oxide minerals. In the same context, wad is an impure soft earthy mixture of oxides in which those of manganese predominate. Dana's System of Mineralogy,[3] however, applies the name,

[3] Dana, James Dwight, and Edward Salisbury Dana. The System of Mineralogy. John Wiley & Sons, Inc., New York, 7th ed., v. I, 1944, rev. by Charles Palache, Harry Berman, and Clifford Frondel, p. 566.

wad, "as a field or generic term to substances whose chief constitutent is a hydrous manganese oxide and whose true identity is unknown." It adds that these substances are largely mixtures. The difficulties with regard to the manganese oxides are compounded because fine-grained material may defy conclusive identification even with sophisticated laboratory equipment. Hausmannite, Mn_3O_4, and braunite, $(MnSi)_2O_3$, are distinct species which have been important as ores of manganese. Excluding braunite, the most important manganese silicate mineral is rhodonite, $MnSiO_3$, although it has not yet become an ore of manganese because of its refractory nature.

Geologically, manganese deposits are of a wide variety of types. The large and long-exploited Chiatura and Nikopol deposits of the U.S.S.R. are flat lying, or gently dipping, sedimentary deposits of relatively recent geologic age. On the other hand, metamorphic deposits of Madhya Pradesh, India, occur as tabular lenses conformable with the enclosing, intensely deformed and metamorphosed, ancient sediments. Examples of residual deposits are those of Madhya Pradesh associated with the metamorphosed deposits, the lateritic deposits of the Indian States of Orissa and Bihar (*7*), and the nodular ores in the residual clays of Arkansas and the southern Appalachians. The rhodochrosite ores of Butte and Philipsburg, Mont., are examples of manganese deposits occuring as steep-dipping hydrothermal veins and irregular replacement bodies.

One type of deposition may be superimposed on another, and the geologic history at a particular location may be quite complex. The highest grade ores are usually the result of oxidation and enrichment by circulating meteoric waters and the upper parts of many manganese deposits have experienced this activity to some degree.

In the United States the deposits of greatest interest as potential manganese resources are those of Aroostook County, Maine, the Cuyuana range, Minnesota, Chamberlain, S. Dak., Batesville, Ark., and Artillery Mountains, Ariz. All contain less than 10 percent manganese, except for the nodules at Chamberlain when they are considered by themselves.

The Aroostook deposits are more than 40 in number, scattered over an area some 70 miles long by 30 miles wide (*12*), grouped into northern, central, and southern districts. They are bedded in steep-dipping, folded and faulted, Paleozoic slates. The mineralogic character varies, but an extremely fine texture and intimate mixture of minerals are common to all. Iron content is roughly twice that of manganese. The largest known single deposit, Maple-Hovey Mountains in the central district, is complexly folded and faulted (*31*), and extends 1,500 feet below surface. The ore of this deposit is more siliceous than that of the other Aroostook deposits.

The low-grade Cuyuna range manganese deposits also extend to depth. They are of the following two classes: Unoxidized iron formation, commonly a manganiferous carbonate slate; and oxidized iron formation, either carbonate slate or chert, not sufficiently oxidized to be marketable as manganiferous iron ore or ferruginous manganese ore. They are of Precambrian age, are complexly folded, and have substantially higher iron than manganese content. Depth of oxidation extends to 500 feet or more. The presently merchantable manganiferous ores shipped from the range are the most highly oxidized material, and most of these ores now are concentrated before shipping (*25*).

Manganese occurs in a variety of associations in the Artillery Mountains region of western Arizona, but the occurrences of principal interest, because of large tonnages, are the extensive stratified deposits of manganese oxides in the Pliocene(?) sediments of the Chapin Wash formation. The manganiferous material has been classified as sandstone ore, clay ore, and hard ore. The latter is sandstone ore altered by weathering and circulating ground water. Perhaps two-thirds of the hard ore has been enriched in a few places to the extent that it averages more than 20 percent manganese. The upper manganiferous zone of the Chapin Wash formation outcrops along the Artillery Mountains as the northeast limb of a shallow syncline. Overlain by barren sediments and basalt, it extends continuously for 3 miles along the strike and is traced discontinuously for another 3 miles. Its thickness is variable, but is frequently on the order of 165 feet. Another manganiferous zone, from 750 to 1,000 feet stratigraphically lower, outcrops along the Rawhide Mountains on the southwest limb of the syncline. This lower zone consists of widely separated, relatively thin manganiferous lenses, and is up to 4 miles long by 350 feet thick (*23*). It does not have the promise of the upper zone and has not received as much investigation.

In south-central South Dakota, a horizontal deposit of manganiferous bentonitic shale, averaging roughly 40 to 50 feet thick in its central and northern portions, outcrops for many miles along both banks of the Missouri River and its tributaries. The deposit is particularly well exposed in the general vicinity of Chamberlain. Manganese-iron carbonate concretions, averaging 15.5 percent manganese and 9 percent iron, forming discontinuous layers 1 to 9 inches thick, constitute 3.8 percent of the principal manganiferous horizon. The manganese content of

this horizon otherwise has been indicated to be 1 percent (*32*). Associated with these deposits are smaller, but nevertheless extensive, deposits of gravels which carry a heterogeneous and irregularly distributed collection of manganiferous concretions having an oxide shell of varying thickness. A few of the concretions are completely, or almost completely, oxidized.

In the vicinity of Batesville, Ark., a large potential source of manganese remains as disseminated hausmannite, braunite, and rhodochrosite in the upper 15 to 50 feet of nearly horizontal, unweathered Paleozoic limestone, which outcrops along the hillsides (*36*). Most production of manganese ore from the district has been from deposits of manganese oxides occurring as lenses, pods, and disseminations in residual clays derived from weathering of the limestone. Although of relatively minor importance, some material from the residual deposits has been transported and redeposited as placers.

Mining

Manganese-mining operations range from primitive to those which are most modern and mechanized. The greater part of the world's manganese-ore production is from open pits or from underground mines using room-and-pillar or longwall systems of mining at relatively shallow depths. The recent trend has been toward open cuts, and greater mechanization.

Because of marked differences in the manner in which manganese deposits occur, a wide variety of mining methods are used—from square-set stoping in Montana to hydraulic underground mining in the U.S.S.R. Certain large low-grade U.S. deposits, because of their size and manner of occurrence, offer possibilities for development and use of exceptionally low-cost mining methods.

Just as there are no mining methods peculiar to manganese-ore mining—and for the same reasons of variable geological conditions and geographical habitat—neither are exploration, drilling and blasting, or loading and hauling operations distinctively identified with manganese ore mining. An exception is the now-completed mining operation of Manganese, Inc., at Henderson, Nev., where the necessity for uniform mill feed was met by using three blending and storage piles between mine and mill: One pile in process of accumulation, one in reserve as storage, and one in process of feeding the mill. The piles were built in 1-foot layers to heights of less than 20 feet, a record being kept of analysis of the ore as it was added to the pile. Stripping and mining operations, which included drilling, blasting, loading, and hauling, were under contract to a firm which specialized in western open-pit mining operations.

Mining of battery- and chemical-grade manganese ores must usually be selective, requiring experience on the part of the operator.

Manganiferous iron ores and ferruginous manganese ores for the most part are mined in the same manner as iron ores of the same district.

Beneficiation

Before 1950, few of the world's manganese ore producers had milling plants other than simple crushing, screening, and washing installations. Except for flotation and nodulizing of Montana carbonate ores, and magnetic concentration of Montana battery-grade ores, this was also largely true for the United States. With the high rate of industrial activity during and since the Korean war resulting in a heavy drain on the world's supply of high-grade manganese ores, more and more producers, both in foreign countries and in the United States, have installed heavy medium, jig, table, and other concentrating equipment, either alone or in various combinations. Sintering and nodulizing equipment also have come into greater use to agglomerate fines and to remove deleterious impurities, such as zinc and lead.

Beneficiation of manganese ores must not only increase the manganese content, but must also decrease the phosphorus below a prescribed maximum and obtain a proper manganese-to-iron ratio. Because of wide variation in the nature of manganese ores, there can be no standard treatment process.

However, the growth of custom mills in the United States was noted as the Government's domestic manganese purchase program progressed in the 1950's. Increasing centralization of milling in the U.S.S.R. was a feature of that same period and has been a feature of the following years, and it is believed that virtually all of the ores shipped now from both Chiatura and Nikopol undergo some concentration. Milling of the Chiatura ores of the U.S.S.R. involves crushing, washing on moving screens, jigging, and magnetic separation. Manganese recovery was reported to be 80 percent in the Chiatura plants in 1955, and it was expected that construction of a central plant for flotation of slimes, begun in 1956, would result in considerable reduction of the losses.

The two principal manganese-ore producers in the United States in the past decade, Manganese Inc., and The Anaconda Company, employed either oil-emulsion or conventional soap flotation as the major feature in beneficiating lowgrade ores—a wad ore of 10 to 20 percent

manganese content for the former, a carbonate ore of roughly 14 percent or less manganese content for the latter. By calcining the flotation concentrate in a rotary kiln Anaconda produced an oxide nodule containing approximately 57 to 58 percent manganese. Similarly, Manganese Inc. produced an oxide nodule containing 44 to 47 percent manganese, but at a high cost in reagents. In the Manganese Inc., operations reagent requirements per ton of ore varied from 120 to 180 pounds of lightweight petroleum oil, 25 to 40 pounds (dry weight) of soap, 5 to 10 pounds (dry weight) of a petroleum sulfonate, and about 8.5 pounds of sulfur dioxide (*18*). Economical treatment of this wad ore required that good manganese recoveries be made from slimes. Such recoveries were accomplished by intensive conditioning of the pulp by mechanical agitation after addition of all the reagents. This resulted in high power consumption.

Numerous hydrometallurgical processes reported in the Research section of this chapter have been developed for utilizing the manganese in the large low-grade domestic resources. Only one of these, the Dean-Læute ammonium carbamate process, has experienced successful commercial-scale operation. This was accomplished by producing synthetic manganese dioxide, a relatively high-priced item having a limited market. Using this process, roasted low-grade Cuyuna range materials were leached with ammoniacal ammonium carbamate solution to yield a high quality carbonate from which a wide variety of manganese end products were obtained. Careful control of the initial reduction step was necessary in order that the iron content be maintained in an insoluble form while the contained manganese was reduced to soluble manganous oxide. Control of temperature of the reacting slurry in the exothermic leaching step was also important to prevent loss of manganese carbonate in the slurry. Further, to achieve good recovery, care was required so that reoxidation of the manganous oxide did not occur (*39*).

Smelting and Electrometallurgy

The principal form in which manganese is used as such by the steel industry is as high-carbon ferromanganese, the greater part of which is made in blast furnaces and the remainder in electric furnaces. Virtually all spiegeleisen was made in blast furnaces until 1963 when one of the principal producers completed conversion to electric furnaces. Silicomanganese, medium carbon, low carbon, and special grades of ferromanganese are made in electric furnaces. Low-carbon ferromanganese is made commercially, also, by fused salt electrolysis.

The blast furnaces making ferromanganese or spiegeleisen are the same or similar to those making pig iron. It has been the case in a few plants, and may still be, that production of spiegeleisen or ferromanganese is obtained periodically from a pig-iron furnace by running it on alloy production long enough to build up a supply of alloy, after which the furnace is returned to its normal operation of producing pig iron.

Electric-arc furnaces used for making manganese ferroalloys are the same types as those used to make other ferroalloys, and there often is a certain amount of interchangeability in the scheduling of production of the various ferroalloys for any one furnace in a plant. Other materials such as calcium carbide, also, are made in the same types of furnace, but it is not good practice to use the identical furnace.

Both high-grade manganese ore and slag from electric furnace production of ferromanganese (*5*) are used as raw material for the production of electrolytic manganese metal. The Bureau pioneered in the production of electrolytic manganese from low-grade manganese ores, but commercial producers have found that costs favor the aforementioned materials. Regardless of the feed material used, a low iron content is desirable. Since 1957, a plant has been in operation in the Republic of South Africa producing electrolytic manganese from the manganese-bearing effluent of a mill leaching uranium ores.

High-, low-, and intermediate-grade manganese ores have each been used in the electrolytic production of synthetic manganese dioxide. As with the production of electrolytic manganese, costs are high. The best possibilities for producing a synthetic managanese dioxide more nearly competitive with natural dioxide ores appear to lie with chemical processes.

USES

The three major categories of use for manganese and manganese ore are metallurgical, dry-cell battery manufacture, and chemical including miscellaneous. Metallurgically, in the United States, manganese is used chiefly in the form of ferromanganese and to a lesser extent other manganese ferroalloys and manganese metal. For battery manufacture, either natural or synthetic battery-grade dioxide ore is used, although the large cost differential severely limits the quantity of synthetic dioxide consumed. In the chemical category a variety of manganese or manganiferous ores are employed, but the most important uses call for chemical-grade ore or its approximate equivalent.

The principal use of manganese is to counteract the harmful effects of sulfur in the production of steel. It is used for this purpose in the production of virtually all steels and consequently is essential to the quantity production of steel. The manganese addition acts as a deoxidizer as well, although it is not normally added for this purpose, a stronger deoxidizer such as ferrosilicon or aluminum being preferred (*1*). Silicomanganese is sometimes used as one alloy the manganese content of which counteracts sulfur, and the silicon content, with some help from the manganese, accomplishes the deoxidation. Manganese is used, also, as an alloying agent to impart one or more of the properties of strength, toughness, hardness, and hardenability to certain steels. The Hadfield or manganese steels, containing approximately 10 to 14 percent manganese and dating commercially from 1887 (*28*), are noted for the peculiar property of work-hardening, whereby hardness is increased by continued cold working under impact while the toughness and high ductility, which had been achieved by heat treatment, are retained. Manganese steel is limited in application to uses within relatively low-temperature ranges (*26*).

Other important metallurgical applications, although involving only small quantities, include the production of aluminum and magnesium. Manganese imparts strength, hardness, and stiffness to aluminum; hardness, stiffness, and corrosion-resistance to magnesium. A small manganese content in the magnesium bath inhibits alloying of magnesium with steel and so facilitates melting and alloying of the light metal in steel pots. Manganese additions to aluminum are made in the form of a master alloy containing 4 or 5 percent manganese, the balance being aluminum. Either electrolytic manganese or a special low-iron grade of ferromanganese is used in making up the master alloy. Manganese commonly is added to magnesium in the form of a flux, the major constituent of which is a manganese compound, usually manganese chloride. Manganese is alloyed with copper for the manufacture of manganese bronzes for ship propellers and other applications. High-damping manganese copper alloys have shown some promise, within limitations, for uses where vibration and noise are to be kept to a minimum. The principal use of manganese in the production of cast irons is to nullify the effects of sulfur.

Manganese ore, chiefly as the dioxide, has important uses in the chemical industry as an oxidizing agent in the manufacture of hydroquinone, and for the production of various manganese chemicals including potassium permanganate, manganese sulfate, manganous chloride, and manganous oxide. Hydroquinone is important as a photographic developer and has other uses; potassium permanganate is a powerful oxidant. A big use of manganese sulfate is as a fertilizer or fertilizer additive. It is important as a constituent of animal and poultry feeds and of fungicides, as a paint dryer, a coloring agent for the textile and ceramic industries, and as a base for the production of other manganese chemicals. Manganous chloride is used in dyeing textiles, in welding rod fluxes, and as a vehicle for alloying manganese with magnesium. Manganous oxide has a variety of uses, including fertilizer, animal and poultry feeds, and welding applications.

An important use of manganese dioxide, apparently poorly crystalline material, is as a depolarizing agent in the ordinary dry-cell battery. Hydrogen released from the electrolyte of the cell tends to form around the carbon electrode slowing down the action of the cell. This tendency is corrected by reaction of the hydrogen with available oxygen provided by manganese dioxide contained in the cell mix.

Other uses of manganese ore are in the production of synthetic manganese dioxide, in the leaching of uranium ores where it is used as an oxidant, in the manufacture of welding rods, welding rod coatings, ferrites, dyes, paint and varnish dryers, fertilizers, pharmaceuticals, frits, glass, and ceramics, and to give a variety of coloring effects to face brick. For certain of these uses, the ore is used directly; for others it may be processed first into compounds or salts of manganese. Manganese ore and manganiferous ores are used in base metal smelting and refining.

Where it is advantageous to introduce manganese in exceptionally pure form, such as in the production of stainless steels, certain chemicals, and the nonferrous metal industries, electrolytic manganese has become of increasing importance. Its use in the United States has grown from 2,000 short tons in 1954 to 19,000 tons in 1963.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

The demand for manganese depends upon the fortunes of the steel industry, varying in direct proportion to steel production.

The iron associated with many manganese ores is the most important coproduct of manganese. Although it is desired that the ratio of manganese to iron be kept at 6:1 or 8:1 in the production of ferromanganese, there is no restriction on the iron content of ores used in the production of pig iron. Because of the abundance of manganese and manganiferous ores in the U.S.S.R., they have been used much

more freely there in the production of pig iron than has been the case in the United States. Manganiferous iron ores and ferruginous manganese ores used in making pig iron are in effect essentially premium quality iron ores; their market and prices are tied to the iron ore market and price structure.

The lead, zinc, silver, or other nonferrous metal content of certain manganese ores contributes to the economics of their mining, and in certain instances means the difference between a successful operation and closed mine.

ALTERNATE MATERIALS

Although titanium, zirconium, and the rare-earth metals can assume some of the functions of manganese in steel, there are technical limitations to the extent to which they may be interchanged, as well as other problems of technology, cost, and supply. On the other hand, manganese has established itself as a replacement for part of the nickel of certain stainless steels, costs favoring the manganese.

A number of dry cells have been developed which do not use manganese, and their use is extending to more than the special applications, such as hearing aids, which had been their particular field.

The chemical and miscellaneous industries offer possibilities for use of other materials in place of manganese, and such substitutions are made when costs are favorable. Some of the best examples of this are the uses of manganese-dioxide ore as an oxidant, as in the processing of uranium ores.

SYNTHETICS

A synthetic manganese dioxide of high quality for use in dry cells is produced both electrolytically and chemically. High-grade, intermediate-grade, and low-grade ores are used as the raw material, but high costs of the processes limit use of the product. Where the ammonium carbamate process has been used as a preliminary step in producing synthetic managanese dioxide, high-purity manganese carbonate was obtained as an intermediate product. Some of this was sold as the carbonate, and some used to make other manganese chemicals in addition to its main use—that of producing the dioxide. In 1955, metallurgical nodules containing 60 percent manganese were the principal product made from it. In that it competed with natural ores, the chemically made manganese carbonate was considered a synthetic ore.

Certain processes developed for the utilization of manganese from low-grade or refractory ores have as their objective the production of high-manganese slag, or comparable material, which will be used in place of manganese ore as feed for the ferromanganese furnace. These materials might be considered synthetic metallurgical ores, and have been so termed (*3*), but none are being produced.

SECONDARY SOURCES AND RECOVERY

More manganese enters the steel-making process as a component of iron ores and of recycled open-hearth slags fed to the pig-iron blast furnaces, plus that in metal scrap fed to the open hearths, than is introduced via the medium of ferroalloys.

The quantity of manganese contained in the annual production of open-hearth slags has been approximately as much as that contained in the total manganese ore imported in some years. In 1952, it was estimated that 4.5 million tons of flush slags, averaging 9 percent manganese, and 7.25 million tons of tap slags, averaging 5 percent manganese, were being produced each year by integrated steel plants (*3*). Some of this slag, 25 percent or more, is recycled to the iron blast furnaces for its iron content and for fluxing effects—its manganese content serving only as a beneficial accessory. The possibility of using the wasted slags as a source of manganese for the production of ferromanganese has received much study (*4*). Because of mixing with other waste materials, accumulations of these slags on the dumps were believed to be too diluted and contaminated for serious consideration, but the daily outputs which would be contemporaneous with processing seemed to offer a good prospect. Slags from the basic oxygen furnace are sufficiently lower in manganese content than the open-hearth slags so that they do not appear interesting as an emergency source of manganese for the production of ferromanganese. In fact, their manganese and iron contents probably are not high enough to make them worth recycling to the blast furnace. With the expected rapid growth of the basic oxygen process of steel production supplanting the open hearth, the quantity of manganese available as a manganese source in open-hearth slags can be expected to decrease annually until these slags will no longer be worthy of further consideration for such recovery. Pig-iron blast furnace slags contain less manganese than do the basic oxygen process slags, and they have not been considered a possible source of manganese for the production of ferromanganese.

Electric-furnace ferromanganese slags are used in the production of other manganese

ferroalloys and electrolytic manganese. There may be some recycling of blast-furnace ferromanganese slags back to the blast furnace, but tonnages are not large and manganese contents are not high. The waste formed in pouring the metal from the furnace, which might run 20 percent manganese, is fed back to the furnace.

Some blast-furnace ferromanganese flue dusts are recovered, briquetted, clinkered, or sintered and fed back to the furnace. A high alkali content makes them otherwise undesirable.

In the chemical and uranium milling industries, where manganese dioxide is used as an oxidant, the spent liquors are a secondary source of manganese from which manganese sulfate and electrolytic manganese are obtained.

RESERVES AND RESOURCES

The United States has virtually no reserve of direct shipping manganese ore. Its reserves of ore from which a 35-plus percent manganese concentrate can be produced by normal concentration methods are scattered and may be given an order of magnitude of roughly 1 million tons, dependent to large extent on premium prices. There is a large low-grade domestic resource contained for the most part in the following five deposits: Aroostook County, Maine (*12*); Cuyuna range, Minnesota (*35*, *25*); Batesville, Ark. (*36*); Artillery Mountains, Ariz. (*23*); and Chamberlain, S. Dak. (*32*). The average grade of the manganese nodules occurring at Chamberlain is 15 percent manganese, but average for the deposit as it occurs in the ground is estimated at 1 to 2 percent. Manganese content of each of the other four deposits is less than 10 percent. Iron content of the deposits varies, being 33 percent for Cuyuna, 21 percent for Aroostook, 9 percent for the Chamberlain nodules, and less than 4 percent for both the Artillery Mountains and Batesville. Mining and metallurgical problems are inherent in recovering manganese from these low-grade natural resources, but for most of them research has indicated the problems to be surmountable at a cost—appearing better for some than for others.

The manganese reserve of the U.S.S.R. probably exceeds 1.5 billion tons containing from 16 to 49 percent manganese. More than 50 percent of this reserve is in the form of low-grade carbonate ores of which there has been little production as yet. Nearly one-third of the total reserve consists of metallurgical oxide ores of Chiatura and Nikopol, ranging from 25 to 49 percent in manganese content but apparently requiring concentration for the most part. Oxide and/or carbonate deposits are found in the Urals, both western and eastern Siberia, Kazakhstan, and the Far East. These ores are of low or intermediate grade but are being considered for exploitation in connection with regional development plans.

Manganese ore resources of mainland China have been estimated to total from 50 to 100 million tons of various grades, the better ores occurring south of the Yangtse River.

Gabon, Brazil, India, and the Republic of South Africa have a combined reserve of approximately 500 million tons of manganese oxide ore. In terms of ore in the ground, the basis apparently used in calculating the U.S.S.R. reserve, this is more than 800 million tons of oxide ore.

The Moanda deposits of Gabon have been estimated to contain approximately 200 million tons of merchantable ore with a manganese content of 48 percent, to be derived from 450 million tons of crude ore. This is as explored on three plateaus covering 35 to 40 square miles (*38*). Although most of the ore is metallurgical-grade material of excellent quality, a battery-grade ore containing 76 percent manganese dioxide is concentrated to obtain an 83 percent manganese dioxide product for use directly as a depolarizer in dry-cell batteries.

Recent estimates of Brazilian manganese ore reserves have been made which differ in providing totals on the order of 100 million (*33*) and 150 million tons (*16*). The latter figure contains a greater proportion in the inferred category not qualified as to grade. The largest reserve is in deposits in the Urucum district near the Bolivian border, estimated by Barbosa in 1956 to contain 70 million tons of ore (*8*). The later estimate of Abreu increased this to more than 100 million tons in including extension to the Serras Jacadiga and Mutum (*16*). Exploration to date of the Serra do Navio deposit of Amapa territory, northwest of the Amazon mouth, has established 30 million tons of ore of excellent quality, apparently with good possibilities for finding additional ore (*27*). The deposits of Minas Gerais, from which much of the past production has come, are estimated to have approximately 16 million tons (*16*), of which some 7 million tons contains more than 40 percent manganese and 8 million tons grades from 35 to 40 percent manganese (*8*). Bahia and Amazonas also possess reserves worthy of mention, and deposits are known in other States.

Manganese ores are widespread throughout peninsular India. Reserves of all grades in 1956 were estimated to exceed 100 million tons of mine-run ore, or the equivalent of 60 million tons of marketable ore. That of Madhya Pradesh alone was estimated in 1956 at 80 million tons of mine-run ore having a manganese content of approximately 35 percent. Other deposits of

importance are in northern Bombay State, Orissa, and Andhra (*8*). Allowing for production, 50 million tons of marketable ore is probably a likely current reserve figure for India.

No recent comprehensive estimate appears to have been made of the reserve of manganese ore in the Republic of South Africa other than recognition that it is extensive. The more enriched portions of the thick 50-foot (plus) lower ore body of the Kuruman field yielding ore in the 40 to 55 percent manganese range, suitably enriched to a width of 500 or 1,000 feet, is expected to provide many tens of millions of tons of ore when only 1 or 2 of some 20 miles of proven strike are considered.

If ore down to 30 percent manganese is included, a very large increase of reserve results for the thick lower body. In this grade range, it tends to a very attractive manganese to iron ratio of 7 to 1 or even 10 to 1. The upper 20-foot ore body, although thinner, appears to have a persistently higher metal content of 45 to 55 percent manganese, but its iron content is also high, being in the 5 to 15 percent range. Present knowledge concerning this upper ore body is scant, but it is indicated that a very large potential tonnage may be available (*2*). Kupferburger, in 1956, estimated conservatively for the Kuruman a probable ore reserve of well over 100 million tons of all grades down to 25 percent manganese content. At the same time, he estimated the potential reserve of the older Postmasburg field to be at least 20 million tons of ore ranging from 25 to more than 50 percent manganese (*8*). Production in the meantime has probably cut this down, with the result that a 12 to 15 million ton figure is ventured as probably being more indicative of the present status of Postmasburg reserves, assuming that the extracted reserves have not been replaced. On the other hand, the total manganese resource for the Kuruman conceivably can be double the 1956 reserve estimate of Kupferburger.

Manganese ore deposits occur in many other nations of the free world, but are small in comparison with those of the countries mentioned. In many instances they are not well defined as to quantity and/or grade.

Many locations on the deep ocean floors have a cover of manganese oxide nodules, which also contain nickel, cobalt, copper, and iron. Manganese dioxide analyses are quite variable and vary up to 63 percent (*9*). Estimates of total quantities of nodules involved in this potential resource have been in the billions, or even trillions, of tons.

CONSERVATION

In the steel-making process, manganese may be conserved to some extent by controlling slag volume through the use of molten pig iron low in silicon content, by making manganese additions to the ladle rather than to the furnace insofar as the quality requirements of the product will allow, by making silicon additions to the furnace before maganese additions, and by maintaining a high lime-slica ratio in the finishing slags. In 1949, a special committee of the American Iron and Steel Institute concluded that not more than 5 percent of manganese consumption could be saved by attention to such considerations in steel-making practices; and not more than 5 percent could be saved by changes in steel specifications, adding that perhaps another 5 percent or more might be saved by concerted action of the industry if processing difficulties of producers and consumers received secondary consideration. In the latter connection, the effects on surface quality, production rates, safety factors, and minimum job requirements must be taken into account (*1*).

The use of other alloys—silicomanganese, spiegeleisen, off-grade ferromanganese, silicospiegel—in place of ferromanganese offers some possibilities in savings of high-grade manganese ore in that low-grade or off-grade ores may be used for their production. The applications are limited, the possibilities of higher operating costs are to be considered, and conservation of manganese itself does not necessarily result. Silicomanganese is recognized to have certain advantages over ferromanganese in the production of deoxidized and partly deoxidized steels, particularly those of low-carbon content. Consumption of silicomanganese has increased to 16 percent that of ferromanganese from 8 percent in 1941.

SOURCES OF STATISTICAL INFORMATION

Statistics for domestic production and consumption of manganese ore, manganiferous ores, and manganese products, are obtained on a voluntary reporting basis by regular canvasses of the Bureau of Mines.

United States import and export statistics are collected by the Bureau of the Census from data obtained by the Bureau of Customs from the importer or exporter. Lack of incentive for the importer to report accurately information which is of no particular concern to the

Bureau of Customs apparently results in an appreciable number of errors of classification and also of country of origin. Where these are apparent and of some consequence, efforts are made to have the questionable data checked.

Statistics on foreign ore production, alloy production, ore and alloy consumption, and trade in both ore and alloy are compiled by the Bureau of Mines from annual questionnaires sent to consular offices, official statistical publications of foreign governments, State Department dispatches, and other sources. Difficulties in this area include confusion as to grade, units of nomenclature, and inadequate data. The different bases for reporting these data by the different countries may require considerable adjustment for their correct interpretation.

PRODUCTION, CONSUMPTION, AND TRADE

World production of manganese ore is shown in table 1. This table is based essentially on an arbitrary cut-off grade of approximately 30 percent manganese content, although production of some countries continues to be included even though grade has dropped below that point. Their ores are essentially the same as the ores of higher grade which were previously mined, and they are put to the same uses. The grades given in the percent manganese column of the table are not meant to be firm figures, but are only estimates to provide a comparative idea of grade. Because of the number of years covered by the table, and the frequent lack of definite information with regard to grade for a country's production in any one year, they can not be more than this. The figures followed by a plus mark are rough minimums with no limit set for the maximum.

The tonnages for the largest producer, the U.S.S.R., are not qualified as to grade, nor are they identified as shipping product, crude ore mined, or one of these converted to a pre-set grade base. There is good evidence, however, that the figures represent shipping product of which approximately 90 percent can be considered to be a good metallurgical ore, or its equivalent, and the remainder to be an intermediate grade ore.

U.S. record production of 366,000 short tons in 1957 was generated by the Government's domestic manganese purchase program, and production for other years has approached this only in 1918, 1956, and 1958. U.S. production dropped off rapidly upon termination of this program.

The United States and the U.S.S.R. are the largest consumers of manganese and of manganese ore, no other country being comparable to either in tonnage consumed. The large U.S. consumption coupled with its small production of ore makes this Nation the world's largest importer of manganese ore. Other ore-deficient consuming countries which are to be reckoned as importers of substantial quantities of ore are the United Kingdom, West Germany, France, the Benelux group, Japan, Norway, Italy, and Canada (*8*). All of these nations export ferromanganese to the United States, as do also Brazil, Chile, Mexico, Yugoslavia, India, Republic of South Africa, Spain, and Sweden. Some of these are ore-producing countries which have increased their capacity to produce ferromanganese with the intention of becoming, as much as possible, an exporter of alloy rather than ore.

Except for electrolytic manganese, exports are not an important part of U.S. foreign trade in manganese. Consumption of manganese ore in the United States is given in table 2; U.S. imports of manganese ore are given in table 3. Prior to 1949, the U.S.S.R. was an important supplier of manganese ore to the United States. These shipments were cut off by a Soviet embargo and have not been resumed, although Soviet manganese ore is again an important item in the world manganese trade. Barter deals of various kinds are also a factor in world trade of managanese ores and alloys.

U.S. tariffs on manganese ore, metal, and ferromanganese are set forth in table 4.

STRATEGIC CONSIDERATIONS

In 1958, U.S. production of manganese ore equaled 22 percent of the quantity consumed in the country, a higher ratio than the 15 percent or less which had normally prevailed since the Korean war. However, most of this 1958 production went to government stocks with the result that only 3 percent of the total manganese ore consumed actually was of domestic origin. Imports from Western Hemisphere sources equaled 63 percent of consumption in 1958, and a Western Hemisphere sufficiency of approximately 85 percent was attained.

In 1963, U.S. production of manganese ore was only a token quantity compared with consumption, and both imports from Western Hemisphere sources and Western Hemisphere sufficiency equaled 62 percent of consumption.

Government stockpile accumulations exceed the maximum objectives for metallurgical, battery, and chemical grades of manganese ore. Inventories on June 30, 1964, are shown in table 5. In addition stocks of ferromanganese, manganese metal, and non-stockpile-grade metallurgical ore have been acquired.

[1] Czechoslovakia and Sweden report production of manganese ore (approximately 13 to 17 percent manganese content), but since the manganese content averages substantially less than 30 percent, the output is not included in this table. Czechoslovakia averages annually 165,000 short tons and Sweden approximately 11,000 tons the last 5 years.

[2] This table incorporates some revisions. Data do not add exactly to totals shown because of rounding where estimated figures are included in the detail.

[3] Estimate.

[1] Excludes manganese contained in iron ores, manganiferous ores (containing less than 35 percent Mn), or in secondary materials such as scrap or recycled slag. Assumes manganese content of ore consumed is approximately the same as that of ore imported for consumption.
[2] Includes manganese in form of ore (containing 35 percent or more Mn) used in making pig iron.

GOVERNMENT PROGRAMS

The defense program at the time of the Korean war and the following period, vigorously pursued with regard to manganese, took several forms: Stockpiling of ore and alloy, expansion of plant capacity, development of new plants using new processes, extensive research, and conservation through allocations. These ends were achieved by means of purchase contracts, advancement of funds or loans for exploration and development, accelerated tax amortization, research and development contracts, technical assistance for foreign lands, and incentive prices for home production. The results were reflected in record imports and record production.

The most noteworthy achievement of the program was the buildup of Government stocks of manganese ore by means of purchase contracts for widely scattered foreign ores. The large deposit of high-grade ore in Amapa, Brazil was brought into production in January 1957 as a result of an Export-Import Bank loan and a Defense Materials Procurement Agency purchase contract.

The domestic manganese purchase program, started in 1951, was essentially of two parts: The so-called "carlot" program calling for metallurgical ore to be purchased by the Government at railhead; and the depot program for low-grade ores to be purchased in quantities as small as 5 tons at depots established at Deming, N. Mex., Butte and Philipsburg, Mont., and Wenden, Ariz. The "carlot" program terminated August 5, 1959, and the last depot program was completed in May 1958.

The domestic exploration program of Defense Minerals Exploration Administration provided assistance for exploration for manganese on a participating basis to the extent of 75 percent of the approved exploration costs, the money to be repaid from proceeds of future production. A revised program has continued to offer assistance under the Office of Minerals Exploration with the Government's share of the costs cut to 50 percent, but there has been little activity as regards manganese.

Manganese ore, ferromanganese, and manganese metal enter prominently into contracts for barter of surplus U.S. agricultural products under the program conducted by the Office of Barter and Stockpiling, Foreign Agricultural Service, U.S. Department of Agriculture. In some contracts, the alloy and metal are produced in the United States from foreign ores imported especially for the purpose; in other contracts the ferromanganese may be produced abroad.

The supply requirements and stockpile position of manganese is reviewed at periodic intervals by the interested Government agencies, with consideration given to indicated actions such as acquisition, upgrading, and disposal.

PRICES

All manganese ore prices are by negotiation, being dependent on chemical analysis, physical structure, quantity offered, included freight and insurance costs, delivery terms, whether duty is included or excluded, needs of the buyer, and availability of ores of the desired quality. As a result, published quotations can only reflect the general condition of the market. Continuing quotations of the same basis, for metallurgical-grade ore, are of value in showing the price trend over a period.

The cost of ocean freight makes up approximately one-third the price of imported ore delivered at eastern seaboard ports. Consequently, an appreciable change in ore price can be entirely apart from any demand or supply factors. Prices for domestic ore in commercial markets are governed by the price of foreign ore and relative transportation costs. From 1951 to August 5, 1959, the Government price for domestic ore under the domestic purchase program re-

TABLE 4.—*U.S. tariffs for selected manganese items, as of Dec. 15, 1964*

Item	Rates of duty [1]	
	1	2
Manganese ore, including ferruginous manganese ore, and manganiferous iron ore, containing over 10 percent Mn.	Free [2]	1 cent per pound contained Mn.
Ferromanganese:		
Containing not over 1 percent carbon	0.6 cent per pound contained Mn plus 4.5 percent ad valorem.	1.875 cents per pound contained Mn plus 15 percent ad valorem.
Containing over 1 percent but not over 4 percent carbon.	0.9375 cent per pound contained Mn	1.875 cents per pound contained Mn.
Containing over 4 percent carbon	0.625 cent per pound contained Mn	1.875 cents per pound contained Mn.
Manganese metal	1.875 cents per pound plus 15 percent ad valorem.	1.875 cents per pound plus 15 percent ad valorem.

[1] Duty rate 1 is applicable for most nations; duty rate 2 is applicable for U.S.S.R., Mainland China, and certain other specified Communist countries.
[2] On June 30, 1964, the duty of 0.25 cent per pound of contained manganese was suspended for a period of 3 years.

mained constantly based at $2.30 per long-ton unit of manganese for manganese ore containing 48 percent manganese. This was usually about twice the market price, but had been as much as three times. A long-ton unit of manganese is 22.4 pounds of contained manganese.

Prices of the principal manganese items, reduced to comparable bases, are shown approximately for comparative purpose in table 6.

TABLE 5.—*Manganese materials in Government inventories*

[Thousand dry short tons]

Manganese	National strategic stockpile	DPA inventory	CCC stocks	Supplemental stockpile	Total
Battery-grade, natural	144			138	282
Battery-grade, synthetic dioxide	21	4			25
Chemical-grade, Type A	29			118	147
Chemical-grade, Type B	2			99	101
Metallurgical-grade	5,230	1,351	111	3,676	10,368

TABLE 6.—*Approximate comparative prices, November 1964*

Item	Per pound (gross weight)	Per short ton (gross weight)	Per pound of contained Mn
Manganese ore, metallurgical grade (48% Mn)	1.5¢	$30.00	3.1¢
High carbon ferromanganese (domestic, 74–76% Mn)	7.5	150.00	10.0
Medium carbon ferromanganese (80–85% Mn)	14.9	297.00	18.0
Low carbon ferromanganese (85–90% Mn, 0.10% max. C)	23.6	472.50	27.0
Silicomanganese (18–20% Si, 1.5% max. C)	8.3	166.00	12.5
Spiegeleisen (19–21% Mn)	3.9	77.68	19.4
Electrolytic manganese metal (regular grade)	30.0	600.00	30.0

TAXES

The U.S. depletion allowance is 23 percent for domestic manganese mining properties, 15 percent for foreign.

TRANSPORTATION

The large tonnages involved and the remote location of most manganese deposits makes transportation—both ocean and overland—a significant factor in development and exploitation.

The problems inherent in the long sea routes traversed, up to halfway round the world, are at times complicated by a shortage of vessels, port congestion, and by high ocean freight rates which constitute part of the price. These complications were very evident when the Suez Canal was closed.

The rail systems of a number of the large producing countries are not able to keep pace with the ability of the mines to produce, or with the demand for their ores. In addition, certain ores must be moved long distances before railhead or shipping port is reached. In Mexico this is a matter of 100 miles by truck over difficult terrain; at the Urucum deposits of Brazil, a river barge trip of some 1,200 miles is made before the ocean vessels are reached; and in Gabon an aerial tram line 45 miles long delivers the ore to the railroad.

In the United States, the cost of the long rail haul to the principal markets, which are in the East, decidedly limits the commercial potential of western ore sources, and limits the market for western ferromanganese.

RESEARCH

Intensive research on manganese by government and industry began around World War I. During each of the two World Wars as well as the Korean war and the immediately following years the Bureau of Mines and the Geological Survey investigated U.S. manganese supply potentialities. In the course of this work, virtually every known manganese occurrence was examined. The Bureau alone has made hundreds of examinations and investigations of domestic manganese deposits and of methods for utilizing them.

In 1935–36 the Bureau conducted pioneering research on the feasibility of producing electrolytic manganese from low-grade ores. Subsequent research by both industry and the Bureau led to commercial production of this metal beginning in 1939. An outgrowth of this work of the Bureau has been its development of high-damping manganese-copper alloys having high strength and unusually low thermal conductivity. Bureau research is credited with making possible the commercial production and acceptance of silicomanganese. Commercial application of soap flotation to western manganese ores and of the ammonium carbamate leach (Dean-Leute) process to Cuyuna range materials were also developments stemming from Bureau research.

The Bureau's ore dressing studies have contributed to successful operation of many of the Nation's small marginal deposits and could play an important part in helping the economics of the more complicated hydrometallurgical and pyrometallurgical processes which have been under consideration for utilizing the large low-grade and offgrade resources. The Bureau is currently engaged in evaluating these processes which have been under investigation by both the Bureau and industry.

One of the major Bureau investigations on manganese involved field work to explore and develop the "hard ore" in the Artillery Mountains deposit of Arizona, with detailed laboratory and pilot plant investigations of oil-emulsion flotation, dithionate leaching, sintering, and electric furnace smelting of concentrate to ferromanganese. Other fields of intensive endeavor have been the development of a selective reduction-oxidation process for obtaining a synthetic ore in the form of a high manganese slag from open-hearth slags, chloride volatilization of Maine manganiferous materials, differential sulfatization of manganiferous carbonate slate and other prospective ores from the Cuyuna range of Minnesota, a combination of the lime-clinkering (Sylvester) and ammonium carbonate leach processes as applied to open-hearth slags, the acid leaching of Aroostook and other manganiferous materials, the melt-quench-leach process for rhodonite and other siliceous feed materials, the acidulated ferrous sulfate or "pickle-liquor" leaching of offgrade manganiferous ores, and basic research on manganese and its compounds.

Industry, universities, and research institutes, independently and in cooperation with various agencies of the Government, have made important contributions to manganese research. For the most part these efforts have had a shorter range aspect than those of the Bureau—often tied to a particular process and/or a particular deposit. Basic research has been left largely to the Bureau of Mines.

Research by industry, either with or without Government assistance, has resulted in substantial interest in a number of processes for utilizing the Nation's large low-grade manganese resources. One of the more highly publicized processes has been that of Nossen Laboratories, Inc., constituting a cyclic nitric-acid leach in which manganese dioxide is produced after the manganese content of the feed has been reduced to manganous oxide. The Bruce Williams process (Ores Beneficiation Inc.) produces manganese carbonate after roasting a mixture of feed and ammonium salts. It is cyclic except for that part of the ammonia which is chemically destroyed. The Sylvester (Sylvester & Co.), or lime-clinkering, process is designed particularly for highly siliceous feed materials. Open-hearth slags or other low-grade siliceous manganiferous feeds are mixed with the proper proportions of limestone before roasting to a clinker, the magnetic fraction of which contains most of the manganese and iron. The Sheer-Korman high-intensity arc process, sponsored by Vitro Corporation of America, has as its particular objective the utilization of rhodonite deposits. A mixture of rhodonite and carbon is shaped into an electrode which is vaporized in a high-intensity arc. Manganese is then extracted from the resulting powder by leaching with sulfuric acid (*6*). The Udy electric furnace process of Strategic Materials Corp. employs specially designed electric furnaces in a two- or three-stage selective reduction smelting operation to produce high-, medium-, or low-carbon ferromanganese from siliceous ferruginous low-grade materials.

Among processes that received earlier attention, the sulfur dioxide leach of Manganese Ore Co. was tried on an operating scale during World War II. The many difficulties experienced in the operation of this plant, using Three Kids (Nevada) ore containing approximately 18 percent manganese, have been attributed in large part to the jump from a 1-ton-per-day pilot plant to an operating plant having a capacity of 1,000 tons per day, and to the wartime shortages of materials and trained personnel. The operation was not successful and was halted within a year of its start. The Bradley-Fitch ammonium sulfate process, previously tested on Cuyuna range material in a 4-ton-per-day pilot plant at the Minnesota School of Mines, was considered to be less desirable than leaching with sulfur dioxide gas. One of the reasons given was the greater wartime availability of sulfur as compared to ammonia.

Other processes, parts of processes, variations of above-mentioned processes, and combinations of parts of processes, have been proposed and studied in laboratory or pilot plant. A failing of many of these propositions is that too many steps are involved to allow much hope for favorable economics. Some of the products of these processes are in reality synthetic ores which must still compete with relatively low priced, good quality, imported ore.

Much research on different methods for producing high-quality synthetic manganese dioxide was conducted by industry under sponsorship of the U.S. Army Signal Corps for about 10 years. Previously, investigators at the National Bureau of Standards and elsewhere studied the constitution of manganese dioxide with particular regard to its suitability for battery manufacture. It was determined that there are several types of manganese dioxide. Although it is generally considered that the best material for batteries is a poorly crystallized form, and analysis and certain tests give indications of suitability, as yet no means have been found which will take the place of an actual use test to determine whether a particular natural or synthetic dioxide ore will be desirable for battery use.

OUTLOOK

The impact on manganese consumption of the anticipated steady growth of the basic oxygen process of steelmaking is difficult to assess for lack of conclusive information. Although the higher bath temperature of the basic oxygen furnace causes some manganese to revert from the slag to the metal, other factors may very well balance out the resulting drop in manganese requirements. For one, the iron and manganese contents of the slags resulting from the basic oxygen process probably will be too low to warrant their recycling to the blast furnace, as is done now with open hearth slags. This will result in a deficiency in manganese content of the hot metal charged to the steel furnace.

In view of the uncertainties involved in these and similar considerations, it is believed reasonable to project that manganese ore consumption will continue in approximate direct relation to the production of steel. An examination of table 2 shows the average of the last 5 years to be approximately 36 pounds of manganese ore consumed for all uses per short ton of steel produced. The fluctuations in the yearly rate suggest the futility of drawing conclusions too finely, and it is most probable that the net effect of the various factors involved will be less than these yearly variations. However, the possibility of a lower demand for manganese at some future date cannot be completely dismissed.

The world supply of good quality manganese ore is substantial, well distributed in a general way, and probably not a matter of concern for the next 25 years as long as the producing sources remain politically available to the consuming countries. The trend toward more beneficiation and other processing before export from the ore-producing countries may be expected to continue.

In the event that foreign supplies should no longer be available to the United States, this country will develop the more favorably situated—both technologically and geographically—of its low-grade natural domestic resources. As the basic oxygen process of steelmaking grows, steel furnace slags will become less and less attractive as a possible domestic manganese resource.

The outlook for battery-grade ore supply has improved with Gabon expected to take over the production of quality ore as the Ghana deposits become exhausted. No particular growth in consumption of these ores is foreseen because of the trend toward smaller batteries and the growing use of rechargeable batteries which do not contain manganese.

PROBLEMS

Efforts to make the United States self-sufficient with respect to manganese have been interrupted by withdrawal of the immediate need through the availability of abundant ores of high quality in other free world countries at favorable prices. The basic problem remains, however, with the following two differences: (1) One of the more favored sources, steel plant slags, has become less promising as a major domestic resource, and the load is correspondingly shifted to the natural deposits; and (2) the problem now appears essentially to be one of scaling up the most likely process for a particular resource to pilot plant or commercial operation. The problems of low manganese content, variations in chemical and physical nature in the same or different materials, intimately fine mixtures of manganese with other minerals, refractory nature of certain of the manganese minerals, manganese-to-iron and manganese-to-phosphorus ratio considerations, unfavorable locations, costs of mining, and recovery of by-products or coproducts, now are believed to be largely problems of economics for most of these materials. An exception to this statement is probably the Chamberlain deposit, the status of its technology appearing to be less satisfactory than that for the other four natural deposits.

Removal of the tariff on manganese ore for 3 years accentuates the problem of the domestic battery ore miner to mine, mill, and market an acceptable product at a price which can compete with imported ore.

The overriding problem of the potential western metallurgical manganese ore or alloy producer, apart from the availability of good foreign ore, remains one of transportation to markets. The problems for the eastern alloy producer are those of foreign alloy imports, overcapacity with an appreciable part in the form of outmoded plant or equipment, and low-profit margins. The potential eastern ore producer has the problem of ore imports, coupled with virtual exhaustion of good ores in the eastern part of the country.

There is no satisfactory substitute for manganese in its major metallurgical uses, and manganese as a metal has no uses of its own. Knowledge concerning the properties of the pure metal is limited and confused by incon-

sistencies and contradictions in the published data.

Continued adequate supply of foreign manganese ores is subject to the hazards and delays inherent in transportation over long sea and rail routes and to unfavorable actions on the part of the producing countries, such as imposition of embargoes, export taxes, royalties, port and other charges, and any actions arising from the compelling wish to do as much processing within the country as is economically possible. The demands of other manganese consuming countries are to be reckoned with as well.

When considering these factors, the problems of stockpiling become more pointed: How much? In what form? Where? Under how much surveillance? What are to be the conditions for disposal?

The production and export of manganese is an important factor in the economies of most of the major ore-producing countries, and the United States is an important market. These countries are faced with a problem of oversupply in the world market.

Discussions of supply and requirements still have the problem of the degree of interchangeability among the different grades of ore, and the problem of inadequacy of foreign supply statistics on a grade basis and of foreign consumption or stocks data on any basis.

While the deposits of the ocean floors are believed to represent very large manganese resources, the problems connected with their eventual exploitation are many. These include the depths at which they occur, actual physical recovery of the ore from the bottom, storage and transportation to land, metallurgical separation and recovery of the valuable constituents, and the problems of ownership and international law.

MERCURY

By John E. Shelton [1]

THE PRINCIPAL commercial mineral of mercury is the red sulfide, cinnabar, which usually occurs in small irregular deposits at comparatively shallow depths. Although cinnabar occurrences are known throughout the world, those of economic importance are limited to a few areas.

Mercury production is relatively small and in quantity ranks 10th in world output of nonferrous metals. Italy and Spain dominated world mercury production and furnished almost half of the 236,000 flasks produced in 1963. Other countries producing smaller but significant quantities included China, Japan, Mexico, the Philippines, the United States, the U.S.S.R., and Yugoslavia. Of the 19,000 flasks of mercury produced in the United States in 1963, California supplied 71 percent; Nevada 26 percent; and Alaska, Arizona, Idaho, and Oregon the remainder. Arkansas, Texas, Utah, and Washington have produced mercury in the past.

Consumption of 78,000 flasks in the United States in 1963 was the highest in history. It resulted from the large requirements for expansion and installation of plants to produce chlorine and caustic soda. Large quantities were also used for replacement of losses in the electrolytic preparation of chlorine and caustic soda, in electrical apparatus, in industrial and control instruments, and in chemicals for agriculture and industrial purposes. Appreciable but smaller quantities were used in precision castings, dental preparations, general laboratory applications, and mildew-proofing paints.

For many of mercury's uses, satisfactory substitutes are known or could be developed; however, there are few satisfactory substitutes for uses that depend upon mercury's liquidity at ordinary temperatures, high specific gravity, and electrical conductivity. Consequently, large-scale substitution is deterred except when shortages of mercury are severe and continued.

The United States is not self-sufficient in mercury and depends on imports, mostly from Italy, Mexico, Spain, and Yugoslavia, for part of the supply.

To bolster domestic production, to provide stability to the industry, and to assure an adequate supply of mercury, the Government has a program providing exploration assistance.

Production and consumption of mercury should continue to rise both in the United States and in foreign countries. However, until production rises or other sources of supply become available, the price of mercury is expected to rise.

The domestic mercury industry is confronted with several problems, principally the necessity of finding additional ore reserves, impediments to efficient and low-cost procedures for recovering mercury, and the lack of a stable market.

BACKGROUND

SIZE AND ORGANIZATION OF THE INDUSTRY

World production of mercury is relatively small and ranks 10th in quantity of output among the nonferrous metals. In the United States production of mercury at individual mines ranges from a few to about 8,000 flasks, and usage at individual consumers ranges from a few pounds to about 10,000 flasks per year.

Only one of the domestic mercury producers—the Buckman Laboratories, Inc.—is considered a vertically integrated company. The other producers sell virgin mercury through brokers and dealers or directly to consumers. Some consumers act also as brokers and dealers.

Foreign mercury operations differ from those in the United States principally in the number, size, and ownership of mines. In most instances only one or two mines furnish virtually the entire output of a foreign country; in addition, the mines in Italy, Spain, and Yugoslavia are wholly or partly State owned and controlled.

[1] Commodity specialist.

Mercurio Europeo, a cartel of Spanish and Italian producers, was formed in 1928 when world stocks of mercury were excessive. The aims of the organization were distribution of sales, control of production, and stabilization of prices. Spanish and Italian producers controlled over 80 percent of world production at the time; sales were allocated 55 percent to Spain and 45 percent to Italy. The cartel was formally disbanded January 1, 1950, after the U.S. Government purchased a large quantity of Italian mercury with counterpart funds.

In January 1958 it was announced that mercury production of the Monte Amiata and Siele operations in Italy would be marketed by a joint sales office, Mercurio Italiano. Mercurio Italiano was dissolved on January 1, 1963, because of antimonopoly rules of the European Common Market. The two companies were to operate separately thereafter.

GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Mercury occurrences are known in many countries; however, only a few produce mercury, and Italy and Spain dominate world production. Virtually all the Spanish production comes from one large mine, the Almadén, Province of Ciudad Real; Italian production comes from two large mines in the Monte Amiata area. Other major producers are China, Mexico, Japan, the United States, the U.S.S.R., Yugoslavia, and the Philippines.

The principal mercury-producing States are California and Nevada, with smaller quantities produced in Alaska, Arizona, Arkansas, Idaho, Oregon, Texas, Utah, and Washington.

In 1963, 8 mines furnished 97 percent of domestic primary production, about 40 other operations supplying the remainder.

State and county:	*Mine*

Nye	Ione.

Of the 300 companies which consume virgin mercury, 80 account for about 96 percent of the total domestic consumption and are mainly in the Eastern United States. About 400 companies throughout the United States use approximately 20 percent of the total annual consumption in redistilled form.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Mercury produced by the mines is known as prime virgin mercury and usually contains more than 99.9 percent mercury. Virgin metal with a clean and bright appearance contains less than 1 part per million of any base metal and is satisfactory for nearly all uses. There are no overall market specifications, but market quotations cover only virgin mercury in flasks of 76 pounds.

Flasks for prime virgin metal are made of wrought iron and spun steel. There are many variations in diameter, height, and weight, ranging as follows: Diameter, 4 to 7 inches (usually in the upper part of this range); average height, about 12 inches; weight, 7 to 15 pounds, averaging about 8 pounds.

Reclaimed mercury, generally as clean as the virgin metal, may contain more gold and silver when not subjected to distillation in the reclaiming process.

Grades of mercury other than virgin are produced by concerns that reduce the impurities in virgin metal by multiple distillation or other means.

General Services Administration Material Purchase Specifications P–31–R1, dated May 27, 1958, for purchases for the national stockpile require prime virgin mercury that averages not less than 99.9 percent mercury and that "shall be bright and clean."

TECHNOLOGY

Geology

The principal ore mineral of mercury is the red sulfide, cinnabar (HgS—86.2 percent mercury and 13.8 percent sulfur). The native metal occurs in some ores; mercury has also been obtained from livingstonite, metacinnabarite, and approximately 25 other minerals. Pyrite and marcasite and small quantities of other sulfides, such as arsenic and antimony, often are associated with the cinnabar.

Mercury deposits usually occur at relatively shallow depths, and almost entirely in regions of volcanic activity. The ore bodies are not true veins and were deposited in irregular chambered veins and brecciated zones, as stockworks of minute seams, and as disseminations and replacements in porous rock. The common gangue rocks are limestone, calcareous shales, sandstone, serpentine, chert, andesite, basalt, and rhyolite.

Cinnabar ore may be classified into two general types—disseminated ore, in which the cinnabar has impregnated a fine-grained or highly

brecciated gangue, and ores deposited in fissures and cracks of the country rock. The second type of ore merges into the first as the fissures and cracks become very minute. At the other extreme are veins and bodies of almost pure cinnabar sharply separated from the gangue. The porosity of the rock determines the grade of the ore formed; open-textured sandstone or coarse breccia yield generous space for deposition of high-grade ore bodies, whereas receptacle rocks such as shales or schists give little room for deposition. Proper trap structures, such as clay gangue or relatively impervious rock, are necessary for localizing the ore-bearing solutions in the receptacle rock.

Mining

Mercury ore is mined by both underground and surface methods. Of the two types, underground mining furnishes approximately 90 percent of the mercury production in the United States.

At the larger underground mercury mines, square-set stoping or some modification is most frequently used, although sometimes shrinkage and sublevel stopes are employed. After the ore has been broken by conventional drilling and blasting, it is removed by scrapers, by direct drop to drawpoints, or by mechanical loaders. Hand tramming is used, for short distances, but locomotives are used for longer hauls. The ore is either trammed or hoisted to the surface.

Open pit or surface mining is done by the usual drilling, blasting, and loading. Power shovels or mechanical loaders, usually of less than 1-cubic-yard capacity, are used to load gasoline- or diesel-powered dump trucks that haul the ore to the extraction plant.

Operations in the United States mine as much as 300 tons of ore per day at underground mines and 175 tons per day at open pits. Underground mines average less than 5 tons per man-shift, but open pit production per man-shift ranges up to 40 tons. Consequently, at the lower cost open pit mines, ore that averages as low as 3 pounds of mercury per ton is mined, compared with about 8 pounds per ton at underground mines.

Metallurgy

Milling of mercury ore consists of crushing, sometimes followed by screening. The principal purpose of these operations is to reduce the material to a size required for furnacing; mercury minerals crushing easier and finer than the gangue rock can be upgraded by screening and rejecting the larger pieces of low-grade or barren material. The material also can be upgraded by hand sorting. Gravity concentration by jigs and tables has been attempted but with little success due to excessive losses in slimes. Concentration of mercury minerals by flotation is efficient and produces a high-grade concentrate. Despite the necessity of fine grinding and an ample water supply, the treatment of low-grade ores by flotation before roasting or leaching is advantageous.

Mercury is extracted from ore and concentrate by heating in retorts or furnaces to liberate the metal as a vapor, followed by cooling of the vapor and collection of the condensed mercury. Retorts are inexpensive installations for small operations and require only simple firing and condensing equipment. They are best adapted to operations treating 500 pounds to 5 tons per day of high-grade sorted ore. One of the most objectionable and costly features of retorts is the manual charging and removal of material.

For larger operations, either rotary or multiple-hearth furnaces with mechanical feeding and discharging devices are preferred. It is unnecessary to size the feed, which may range up to 3 inches for rotary and 1.25 inches for multiple-hearth furnaces. Standard furnace capacities range from 10 to 100 tons per day with larger sizes to suit requirements. Mercury-laden gases pass from the furnaces through dust collectors into the condensers, where the vapor is cooled and the mercury is collected. Final traces of mercury in the gases from the condensers are removed in washers, and the stripped gases are discharged through a stack into the atmosphere. The mercury from the condenser always contains some dirt and soot, which are separated by hoeing the mixture with lime. Mercury from this operation is clean and sufficiently pure for marketing.

Mercury also can be leached from its ores and concentrates with a solution of sodium sulfide and sodium hydroxide and recovered as the metal by precipitation with aluminum or by electrolysis (*22*).[2] Leaching of mercury ores has not been practiced extensively because of reagent-consuming constituents in some ores, irregularity in compositions of ores, and the cost of fine grinding. However, recent studies have indicated that some of these objections can be overcome by concentrating the ore by flotation and leaching the resulting concentrate.

Mercury Poisoning

Poisoning may occur in mining and extracting metallic mercury and in any industry in which mercury is used, as a result of handling or exposure to its vapor. The Bureau of Mines and many other organizations have studied the subject and issued reports.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Precautions that should be taken to insure the safe mining and handling of mercury include proper ventilation of working areas, use of respirators or gas masks, personal cleanliness, spraying contaminated surfaces with various compounds to render the mercury inert, use of mercury vapor detectors, and periodic physical and dental examinations.

USES

One of the large and growing uses of mercury is as a cathode in the electrolytic preparation of chlorine and caustic soda. Actual consumption of mercury in this manufacturing process is small for each unit, although large quantities are required for the original installation. Because of the large number of plants now in operation, the requirement for mercury to replace losses has become a major use.

Large quantities of mercury are also used in electrical apparatus and in industrial and control instruments. Applications include the use of mercury in various lamps, arc rectifiers, batteries, switches, thermometers, barometers, and related equipment. Significant quantities of mercury are used in dental preparations, as catalysts, and in general laboratory applications; small quantities are consumed in amalgamation and manufacturing fulminate for detonators.

A relatively new application of mercury is in frozen mercury patterns for precision casting. Owing to its smooth surface and low uniform expansion upon heating, mercury is superior to wax or plastic pattern materials.

Compounds of mercury are used extensively in insecticides, fungicides, and bactericides for agricultural and industrial purposes. Pharmaceuticals, the control of slime in pulp and paper mills, and protective paints use smaller but appreciable quantities of mercury compounds.

Uses that may become important are catalysts in manufacturing organic compounds, pigments, and new applications of amalgam metallurgy. The latter use will depend upon results of current and future research studies.

ALTERNATE MATERIALS

Other processes are available to replace those using mercury as a cathode in the electrolytic preparation of chlorine and caustic soda and in boilers for generating power. For agricultural and industrial purposes, copper and numerous organic chemicals may be substituted for mercury compounds. In the pharmaceutical field, sulfa drugs, iodine, and various antiseptics and disinfectants may be used instead of mercury chemicals. In some dental uses, metal powders, porcelain, and plastic materials are preferred to mercury amalgams. Lead azide, diazodinitrophenol, and other organic initiators may replace mercury fulminate.

There are few satisfactory substitutes for those applications in electrical apparatus and industrial and control instruments that depend on mercury's high specific gravity, fluidity at normal temperature, or electrical conductivity.

SECONDARY MERCURY

Secondary mercury furnishes a significant part of domestic supply. Production in 1963 was 10,520 flasks. Of the total, approximately 4,000 flasks of excess Government mercury was transferred to other Government agencies. The balance, about 6,500 flasks recovered from dental amalgam, oxide and acetate sludges, and battery scrap, represented 25 percent of the total domestic production of primary and secondary mercury. Virtually all metal can be reclaimed from mercury cells, mercury boilers, electrical apparatus, and control instruments, when the plant or equipment is dismantled or scrapped.

RESERVES

The Bureau of Mines studied the potential resources of mercury at 1,000 domestic mines, prospects, and occurrences thought capable of contributing to future production. Table 1 shows the reserve potential at these 1,000 properties at selected price levels, based on 1961 costs and technology.

TABLE 1.—*Mercury resources of the United States at selected price levels*

[Thousand flasks [1]]

State	Mercury price per flask					
	$100	$200	$300	$500	$1,000	$1,500
Alaska		14.5	33.5	69.5	124.5	142.5
Arizona			2.5	8.0	12.0	13.5
Arkansas				4.5	6.5	7.5
California	39.0	112.5	258.0	566.5	853.0	941.0
Idaho			20.5	37.5	65.0	72.0
Nevada	7.5	13.0	34.5	71.5	115.5	157.5
Oregon			12.5	34.5	55.0	71.0
Texas			17.5	35.0	54.0	59.0
Utah					.5	.5
Washington				.5	1.0	1.0
Total	46.5	140.0	379.0	827.5	1,287.0	1,465.5

[1] Flask as used in this chapter refers to a 76-pound flask.

Resources of 140,000 flasks at $200 per flask represent ore grades of about 10 pounds of mercury per ton at most domestic mines and about 20 pounds of mercury per ton of ore in

the very narrow veins in Alaska. A country-wide average of 5 pounds of mercury per ton of ore is equivalent to a total resource of about 575,000 flasks at $400 per flask, based on costs in 1962.

World reserves of mercury minable under economic conditions existing in 1957 and 1962 were estimated by the Federal Geological Survey. In 1957–62 the reserves of mercury in the United States decreased about 80,000 flasks owing to depletion of ore by mining the known reserves and lack of exploration because of declining prices. Almost all of the measured and indicated reserves were in mines active at the end of 1961. World reserves in thousand flasks are shown in table 2.

TABLE 2.—*World reserves of mercury*

[Thousand flasks]

Country	1957		1962	
	Measured and indicated	Inferred	Measured and indicated	Inferred
Canada	150	150		
China		500		400
Czechoslovakia	10		5	
Italy	500	1,000	200	500
Japan	30	50	30	30
Mexico	30	100	25	100
Philippines	45	45	35	
South America	4	10	10	10
Spain	100	1,000	500	500
Turkey		50		40
United States	125	190	45	30
U.S.S.R.	850	500	150	150
Yugoslavia	150	300	100	300
Total	2,000	3,900	1,100	2,100

The data for Spain are inadequate and the reserves may be much larger. The reserves of the U.S.S.R. may be larger considering the amount of exploration to the time of the estimate.

SOURCES OF STATISTICAL INFORMATION

Monthly and annual data on production, shipments, and stocks of mercury are obtained from domestic producers by the Bureau of Mines. Quarterly data on consumption, by end uses, are obtained from consumers and account for about 95 percent of the total consumed; users of small quantities of virgin mercury report annually; thus, 100-percent coverage is obtained. Some consumers who are also processors report quarterly the quantity of virgin mercury redistilled, and an annual survey is conducted to obtain the end use in which the redistilled mercury was consumed. Consumers also report stocks of mercury at plants and in transit. Brokers, dealers, and importers furnish quarterly reports showing receipts of mercury from abroad, purchases of domestic mercury, and stocks in bonded or free warehouses. A preliminary survey of dealers each year obtains data from small-quantity producers. The domestic data collected are sufficiently adequate and accurate for current programing and planning.

World production and trade data of foreign mercury-producing countries are also compiled by the Bureau. U.S. imports and exports of mercury are obtained by the Bureau of the Census, U.S. Department of Commerce. Mercury statistics on production for some foreign areas are not adequate.

PRODUCTION, CONSUMPTION, AND TRADE

Production

Italy is the leading mercury-producing country, followed closely by Spain. World production for 1963 declined 4 percent from a near-record high in 1962, primarily owing to the 7,177 flask decrease in U.S. output (table 3).

In 1963, California was again the leading producing State and Nevada remained in second place. Small quantities were produced in Alaska, Arizona, Idaho, and Oregon (table 4).

TABLE 3.—*Mercury produced in the world, by principal countries*

[1] Estimate.
[2] Includes Austria, Chile, Colombia, Czechoslovakia, Rumania, and Tunisia.
[3] Exports.

Consumption

Annual consumption rose steadily from 51,200 flasks in 1960 to a record 78,000 flasks in 1963. Increases in the use of mercury were recorded in most major categories. The high rate of increased usage was due mainly to the large quantities used in the expansion and installation of new chlorine and caustic soda plants. The quantity involved in this use is shown under "Other" to conceal company confidential information (table 5). The consump-

tion of mercury also increased significantly in making electrical apparatus, in replacing losses in the manufacturing of chlorine and caustic soda, for mildew-proofing paints, and in pharmaceuticals.

The major sources of mercury imported into the United States are Italy, Mexico, Spain, and Yugoslavia. Small quantities are also imported from other countries (table 6). Some of these countries are normally importers of mercury, some of which probably is reexported to the United States.

A duty of 25 cents per pound ($19 per flask) on imports of mercury has been in effect since 1922.

STRATEGIC CONSIDERATIONS

From the beginning of mercury production in the United States in 1850 until 1918, output was ample to fill demands. Since 1918, however, except for 1931 and 1940 through 1942, it has been necessary to import mercury to satisfy industrial requirements. In 1950, domestic production was the lowest ever recorded and supplied only 9 percent of the requirements. Total production in the United States increased gradually and in 1958 supplied 83 percent of the domestic consumption; it then decreased to 38 percent of requirements in 1963.

During a war, the United States could probably attain self-sufficiency in mercury (table 7). Yet, at the 1963 rate of consumption, which probably would be exceeded during a war, mercury reserves would be adequate for only 2 years.

TABLE 7.—*U.S. self-sufficiency in mercury*

Year	Consumption (flasks)	Production		
		Mine (flasks)	Secondary (flasks)	Percent of consumption
1954	42,796	18,543	6,100	58
1955	57,185	18,955	10,030	51
1956	54,143	24,177	5,850	55
1957	52,889	34,625	5,800	76
1958	52,617	38,067	5,400	83
1959	54,895	31,256	4,950	66
1960	51,167	33,223	5,350	75
1961	55,763	31,662	8,360	72
1962	65,301	26,277	5,800	49
1963	77,963	19,100	10,520	38

As the availability of European mercury, which furnishes the major part of the U.S. imports has been restricted, if not eliminated, in wartime, mercury has been designated a strategic and critical material for stockpiling. The stockpile objective for conventional war was set at 200,000 flasks as of July 1963. On June 30, 1964, Government inventories totaled 200,501 flasks, of which 184,501 was in the national (strategic) stockpile, and 16,000 in the supplemental stockpile.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration (OME) is authorized to grant loans up to 50 percent of the approved costs on exploration projects for mercury. From January 1, 1959 to December 31, 1963, OME executed eight contracts for exploration totaling $580,590.

In 1958, the U.S. Department of Agriculture announced that mercury was included in the list of material eligible for the supplemental stockpile through barter or exchange transactions, as provided by section 303 of the amended Agricultural Trade Development and Assistance Act of 1954. A total of 16,000 flasks was received from Spain under the program. Mercury was removed from the barter list in 1959, reinstated in 1961, and then removed in 1962.

The U.S. Tariff Commission held a public hearing on February 20, 1962, following its investigation of the mercury industry in 1961. Members of the mercury mining, selling, and consuming industries were present. The Commission report of November 1958 was updated and results were published in "Report to the Congress on Investigations No. 332–32 (Supplemental)," TC 57, May 1962.

In 1963, the Atomic Energy Commission reported that it held 50,000 flasks of excess mercury. Approximately 46,000 flasks was transferred to the national stockpile. The balance was transferred to various Federal agencies to meet their requirements.

PRICES AND COSTS

Average quoted prices of mercury at New York and London, 1954–63, are given in table 8.

Very little information is available on costs of production either in the United States or abroad; however, for comparative purposes it is noteworthy that Spanish ore averages about 50 pounds of mercury per ton; Italian, about 15 pounds, and United States, about 8 pounds.

TAXES

No special taxes are imposed on the mercury industry. Producers are granted a depletion allowance, 23 percent on domestic production and 15 percent on foreign production.

TABLE 8.—*Average yearly prices per flask of mercury at New York and London*

Year	New York [1]	London [2]	Year	New York [1]	London [2]
1954	$264.39	$255.33	1959	$227.48	$208.61

RESEARCH

Investigations of the geology and resources of mercury are being made by the Government; mercury products research is undertaken almost exclusively by private industry.

The Bureau of Mines is evaluating the mercury resources of the Kuskokwim River Basin in Alaska. A study of the resource potential

in the United States is nearing completion. The Federal Geological Survey is studying the geology of selected mercury deposits.

Concentration of mercury minerals by flotation and optimum conditions for leaching and precipitation of mercury were investigated by the Bureau.

The Bureau's metallurgy research program investigated the recovery of waste metals by amalgam electrolysis. The studies were successful in recovering zinc from sal skimmings, ashes, and dross and in recovering tin from hardhead. Mercury was used to leach zinc and tin from the waste material to form amalgams of each metal, which were subsequently refined electrolytically to produce high-purity metal. Investigations are being made on refining commercially available metals to a superpure state by amalgam electrolysis. Some impurities in cadmium, indium, lead, tin, and high-grade zinc may be reduced from parts per million to a few parts per billion.

Most of industry's research is directed to developing new and improved mercury chemicals for agricultural, industrial, and pharmaceutical purposes and to improvements in utilization of mercury cells for producing chlorine and caustic soda. One new development is a mercury flywheel for stabilizing space vehicles in flight.

OUTLOOK

The demand for mercury is expected to rise throughout the world for the next 5 to 10 years. Plans in Asia, Europe, and North America to increase the production of chlorine and caustic soda, the principal use of mercury in recent years, indicate that requirements for mercury for this use will become greater. Technologic advancements resulting in a greater usage of mercury in mildew-proofing paints and the plastics industry, as well as increased use of mercury in dental and health applications and batteries, also will contribute to the rising demand.

Potential new uses of mercury may be in amalgam metallurgy and in ion exchange engines for deep space exploration. Availability and technical advancement will be important factors in how much mercury is used for these purposes.

World production will increase for the next few years. However, the increase in output probably will be about equal to the increased demand. Many mines in the United States have closed owing to depletion of reserves, decreasing grade of ore, and the downward trend in prices from 1957 to late 1963. Under the impetus of rising prices since 1963, exploration and development activities have increased, but it will be some time before domestic ouptut will rise significantly. The high-grade reserves of some of the large foreign producers are being depleted, but increased efficiency of operations and opening of new areas should result in increasing production. Although Italy and Spain should continue to be the major producers of mercury, other countries probably will produce a greater share of the total.

Demand for mercury in the United States will far exceed production; however, domestic production, releases of excess mercury by the Government, and imports should be sufficient to meet requirements.

Research by Government and industry is expected to continue. Improvements in ground support techniques, control of ground movement, and slope stabilization could lower mining costs and improve efficiency of recovery.

The quantity of mercury reclaimed from secondary sources has shown little change, except when a mercury boiler was removed from service or excess mercury held by the Atomic Energy Commission was made available. However, increased use of mercury in manufacturing processes and in batteries may result in expansion of the secondary industry.

PROBLEMS

The major problems of the U.S. mercury industry are the domination of the world market by a few relatively large low-cost foreign operations and the instability of the price of mercury. Domestic mines can produce mercury profitably and in large quantities only during periods of rising demand accompanied by firm high prices.

The narrow, irregular, and small size of ore deposits make impractical the use of large-scale development, mining, and metallurgical techniques to enable low-cost efficient mining and processing. Costly recycling or specific treatment of soot, dust, and residues is necessary to minimize the loss of mercury. High fuel and labor costs in many of the isolated areas makes the treatment of low-grade ores uneconomical.

Another problem is the gradual depletion of ore grade and reserves in currently producing mines. The depletion of ore reserves is due to curtailment of exploration while prices were decreasing from 1957 to late 1963 and is compounded because the narrow, irregular mercury occurrences make reliable estimates difficult. Deposits often may be bypassed during prospecting or exploration because overlying caps of rocks prevent detection.

The principal problem of the reclamation of mercury from secondary sources is that most scrap mercury-bearing items contain small quantities of mercury. The large ratio of extraneous materials raises recovery costs.

The toxic nature of mercury is an ever-present problem in the handling and treatment of mercury ores, especially when fumes and dust are present.

MICA

By Benjamin Petkof [1]

THIN mica sheet, used in ancient Rome for windows, provides man with a natural material suitable for electrical and thermal insulation. Finely ground mica is used in many products ranging from paints to well drilling mud. The most important commercial varieties of mica are muscovite and phlogopite. This chapter is concerned principally with muscovite and to a minor extent with phlogopite, which is not produced commercially in the United States.

Because the domestic sheet mica industry produces only a small fraction of U.S. requirements for high-quality sheet mica, the electrical and electronic industries must import most of their sheet mica.

Muscovite sheet mica is recovered only from pegmatite deposits; phlogopite sheet mica is recovered from pyroxenites. Skilled hand labor is required to prepare sheet mica in forms suitable for stamping and punching into shapes and sizes required by the end user. Fabricating plants are situated principally in electrical-products manufacturing centers in the Eastern United States.

Scrap mica is mined from pegmatite deposits as a sole product; it also is a byproduct of mining, trimming, and fabricating sheet mica, or it may be recovered from disseminated deposits. Most scrap mica is ground, but increasing quantities are specially delaminated and reconstituted into sheets.

Sheet mica is an important dielectric and insulating material in the electronic and electrical industries. Ground mica is used as a filler and surface coating in numerous products, including roofing materials, wallboard cements, paints, rubber, plastics, and drilling muds.

Miniaturization of electronic components and development of some substitutes have reduced the total quantity of block and film mica required. Reconstituted mica is satisfactory for most applications now using built-up mica made from muscovite splittings and for some applications using built-up mica made from phlogopite splittings.

Synthetic mica is produced commercially by the internal electric-resistance heating process. Nearly all the product is a flake material which is ground for use in glass-bonded mica. Because large crystals are difficult to produce and recover, synthetic mica is not yet a substitute for strategic natural mica.

The measured reserve of sheet mica in the United States is insignificant, but resources of scrap mica are adequate.

The United States is not self-sufficient in any category of sheet mica or in high-quality scrap mica. Research has been focused on substitutes for strategic mica. Much of this has been government-sponsored research on synthetic mica, but some has been conducted by industry on synthetic mica, reconstituted mica, and other substitutes.

The long-range problem concerning sheet mica is the assurance of an adequate economic supply of the strategic categories of block and film or of a satisfactory substitute material. Research is needed to improve the competitive position of ground mica through better processing methods and to develop new uses for scrap and ground mica, particularly the lower qualities.

A comprehensive report on mica was published by the Bureau of Mines as one of its Materials Survey series on strategic mineral commodities (*26*).[2]

BACKGROUND

In ancient times mica was used for decorative and medicinal purposes and as a translucent or transparent sheet material. Later it became widely used in store windows, lamp chimneys, and lampshades. Because of heat resistance and transparency, only clear sheets were suitable for these applications. With the intro-

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

duction of electrical appliances in the late 19th century, the consumption of sheet mica in the electrical industry soon greatly exceeded that for all other uses. In the electronic industry, mica became the preferred material as the dielectric material in capacitors and for electronic tube spacers.

Commercial production of mica in the United States began in 1803 at the Ruggles mine, Grafton County, N.H., and until 1868 New Hampshire furnished all the domestic mica. When mica mining began on a large scale in North Carolina soon after 1868, mica output from New Hampshire declined (*20*).

Production of sheet mica in the United States fluctuated greatly before World War II. Total output from 1880 to 1919, was 23,600,000 pounds. From 1920 to 1940, uncut sheet mica output ranged from 340,000 to 2,200,000 pounds per year. From 1940 to 1945, wartime demand and Government assistance through the Colonial Mica Corp. stimulated increased output. During this period, peak annual output was 3.5 million pounds in 1943, and the average annual output was about 2.3 million pounds. When the Government support program ceased in 1945, production declined sharply to 270,000 pounds in 1948. Under the Defense Production Act of 1950, as amended, the Government in 1952 instituted a domestic mica purchasing program which terminated in June 1962. From 1952 though 1963 the maximum annual domestic output of sheet mica was 890,000 pounds in 1956; of this total, 236,000 pounds was the calculated quantities of full-trimmed mica, equivalent to Government purchases under this program. In 1958 the corresponding figure for domestic mica sold to the Government was 274,000 pounds, the highest to date, while total sales of domestic sheet mica dropped to 660,000 pounds. This mica, valued at $2.8 million, was produced at about 600 operations, mostly small scale, with the 10 largest producers accounting for about 40 percent of the output.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Mica can be divided into two main classifications, sheet mica and scrap mica (including flake mica). Separate divisions of the mica industry produce these two classes of mica, which differ widely in their uses and in the forms in which they are marketed.

In addition to production by organized enterprises, substantial quantities of mica have been mined in off-seasons by persons with other primary occupations, particularly farming. Small, part-time mining operations supply a significant quantity of the total output of sheet mica.

Removal of adhering rock, dirt, and defective mica from the mine-run mica takes place either at the working face or at the surface of the mine. The resultant product, called handcobbed mica, is processed into sheet mica in small shops at the mine or shops accessible to a group of mines. The trimmed mica from these shops is shipped to a fabricator.

The fabricator stamps or punches trimmed sheet mica into specified shapes and sizes, in accordance with specifications of the ultimate consumer. The fabricating industry is highly specialized, and includes firms that fabricate the mica to supply the electronic and electrical industries and firms that manufacture electronic and electrical equipment and fabricate mica for their own consumption. In the United States in 1963, block and film mica was fabricated by 20 companies, and mica splittings were manufactured into built-up mica by 12 companies.

Increasing quantities of fully manufactured mica parts stamped to the exact dimensions and designs required for tube spacers, capacitor films, and various other uses also are imported into the United States from a number of countries. In some instances these fabricating operations in foreign countries are under the direction and control of manufacturers in the United States.

Scrap mica usually has been the dominant product of the U.S. mica industry, and in recent years more than 99 percent of the total tonnage of domestically produced mica has been scrap mica. In 1963 sales of scrap mica totaled 109,000 short tons, a record figure, and had a value of slightly less than $2.8 million. There were 29 producers of scrap mica during 1963, with 31 operations. North Carolina was the largest producing State.

Although mica is produced in a number of countries, the foreign sources of principal importance to the United States are India, Brazil, the Malagasy Republic, and Canada. Malagasy and Canada produce principally phlogopite mica. The others produce muscovite mica, the preponderant commercial variety.

Mica mining in the United States is confined largely to pegmatites in a few well-defined areas. The largest region extends from central Virginia southward through western North and South Carolina, northern Georgia, and east-central Alabama. A second region lies discontinuously in the New England States—New Hampshire, Connecticut, and Maine each possess mica-bearing pegmatites. A third region comprises districts in the Black Hills of South Dakota and in Colorado, Idaho, and New Mexico.

Although production of mica has been reported in 25 States, the outputs from only a few have been large. Throughout the years, North Carolina and New Hampshire have been the principal producers of sheet mica. The most important area has been the Spruce Pine, N.C., district in Avery, Mitchell, and Yancey Counties.

In 1963, North Carolina produced the bulk of the total output of domestic sheet mica and over half the tonnage of domestic scrap mica. Georgia, Alabama, and South Carolina furnished substantial quantities of scrap mica.

The fabricators of block, film, and splittings are situated principally in electrical products manufacturing centers, which lie outside the productive mica regions. However, several fabricators are in the North Carolina mica district. In 1963, fabrication of muscovite block and film mica was reported in 10 States, mostly near the east coast. About 51 percent (2.3 million pounds) of the total was reported by 12 companies in 3 States—New Jersey (5), New York (3), and North Carolina (4). Fabrication of splittings was reported in 9 States by 11 companies with 12 plants.

Reconstituted mica, often called mica paper, was produced in 1963 at Schenectady, N.Y., and Rutland, Vt.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Mica is a group name for a number of complex hydrous potassium aluminum silicate minerals differing in chemical composition and physical properties but characterized by excellent basal cleavage that facilitates splitting into thin, tough, flexible, elastic sheets. These minerals can be classified into four principal types, named after the most common mineral in each group, muscovite, phlogopite, biotite, and lepidolite. Muscovite (potassium mica) and phlogopite (magnesium mica) are the most important commercially and are the ones discussed in this chapter.

Muscovite mica is classified according to color. The Geological Survey has arranged mica into seven main color categories and three commercial groups (*14*). However, the National Bureau of Standards has established two color categories, ruby and nonruby, the color classifications used by the Government in purchasing mica for the stockpile.

The crystals of crude mica obtained from the mine in various shapes and sizes are called *books* because of the appearance given by the laminar structure.

Hand-cobbed or *cobbed mica* is the usable rough sheet mica that remains after all adhering rock, dirt, and defective mica has been removed from the books.

Rifting is the process of splitting the hand-cobbed mica into usable thicknesses.

Trimming removes broken and ragged edges, loose scales, and major imperfections. *Thumb-trimmed mica* is rifted mica from which the ragged edges have been removed with the thumb and fingers. *Half-trimmed mica*, which must have no cracks extending into the area by which the piece is graded, is rifted mica trimmed by cutting the ragged edges from two sides—the two adjacent sides of at least two-thirds of the pieces and the two parallel long sides of the balance of the pieces. *Full-trimmed mica* is rifted mica with the ragged edges cut from all sides in such a way that all cracks and corrugations are removed.

Sheet mica is relatively flat and sufficiently free from structural defects to enable it to be punched or stamped into specified shapes for use by the electronic and electrical industries. Sheet mica is classified further as *block*, *film*, or *splittings*, based on thickness. *Block mica* is not less than 0.007 inch thick with a minimum usable area of 1 square inch. *Film mica* is split from the better qualities of block mica to specified thickness groups ranging from 0.0012 to 0.004 inch. *Splittings* are sheets with a maximum thickness of 0.0012 inch, and a minimum usable area of 0.75 square inch. Small-sized, low-quality block mica is subdivided as *punch*, *circle*, and *washer mica*. *Punch mica* now includes all three and designates a thumb-trimmed material up to about 2 inches in diameter (*26*).

Block mica, based on the relative quantity of visible inclusions and structural imperfections in accordance with American Society for Testing and Materials (ASTM) specifications, is classed into 12 quality groups (described in table 1). Film mica is classified by ASTM as first, second, or third quality. First quality is equivalent to fair stained block mica, second quality to good stained block, and third quality to stained block. Using ASTM specifications based on the maximum usable rectangle, block and film mica can be classed into 12 size groups, or grades, ranging from the smallest, No. 6, to the largest, OOEE special. The sizes designated by these grades are indicated in table 2. Mica splittings are supplied in three commercial forms and in eight grades.

Strategic muscovite block and film mica is ruby and nonruby block, good stained or better qualities (the top four qualities), grade No. 6 or larger; ruby stained A/B quality (minimum 30 percent of fifth quality, maximum 70 percent of sixth quality), grade No. 6 or larger; and ruby and nonruby film, first and second qualities, grade No. 4 and smaller. Both muscovite and phlogopite splittings in certain cate-

TABLE 1.—*Visual classification of muscovite block mica*

ASTM visual quality	Commercial designation	Description [1]
V-1	Clear	Hard, of uniform color, nearly flat, free from all stains, foreign inclusions, cracks, and other similar defects.
V-2	Clear and Slightly Stained	Hard, of uniform color, nearly flat and may contain slight crystallographic discoloration, and very slight air inclusions in not more than one-fourth of the usable area.
V-3	Fair Stained	Hard, of uniform color, may contain slight waves, slight crystallographic discoloration, and slight air inclusions in not more than one-half of the usable area.
V-4	Good Stained	Hard, of uniform color, may contain medium waves, slight crystallographic discoloration, and medium air inclusions in not more than two-thirds of the usable area.
V-5	Stained A	Hard, may contain medium air inclusions uniformly distributed in the usable area, slight green vegetable stains, and medium waves.
V-6	Stained B	Hard, may contain heavy air inclusions and heavy waves, medium green vegetable stains, slight light black and red dots (mineral), and slight clay stains.
V-7	Heavy Stained	Same as V-6 plus medium cloudy stains and medium clay stains. Soft, buckles, ridges, and sand blast acceptable if specified.
V-7A	Densely Stained	Hard and soft. May contain heavy waves and air inclusions, heavy cloudy stains, heavy light black and red dots (mineral), medium black and red stains (mineral), medium buckles and ridges. Also green stains (vegetable type), clay stains, herringbone, and sand blast.
V-8	Black Dotted	Hard, may contain medium waves, heavy air inclusions, cloudy stains, light black and red dots (mineral), and green stains (vegetable).
V-9	Black Spotted	Same as V-8 plus slight black stains (mineral), and sand blast.
V-10	Black Stained	Same as V-8 plus sand blast, medium black stains (mineral), slight red stains (mineral), and clay stains.
V-10A	Densely Black and Red Stained.	Same as V-8 plus red stains (mineral), black and red stains (mineral), sand blast, slight clay stains, heavy black stains (mineral), and heavy waves. Soft acceptable if specified.

[1] From ASTM Specifications D351-60T.

TABLE 2.—*ASTM grades (sizes) of muscovite block and film mica*

ASTM grade	Area of minimum rectangle (square inches)	Minimum dimension of a side (inches)
OOEE Special	100	4
OEE Special	80	4
EE Special	60	4
E Special	48	4
A-1 (Special)	36	3½

2	15	2
3	10	2
4	6	1½
5	3	1
5½	2¼	⅞
6	1	¾

gories are classed as strategic materials, but none of the categories of phlogopite block and film is strategic (*2–3*).

National Stockpile Specifications P–32a–R1, Mica-Muscovite Block, Stained A/B and Better; P–32b–R, Mica-Muscovite Film; P–33–R, Mica-Muscovite Splittings; and P–34–R, Mica-Phlogopite Splittings, cover the physical requirements for the categories of mica designated as strategic or critical.

Built-up mica is a composite material built to any desired thickness by alternating layers of partly overlapped splittings and a suitable binder, usually organic. The mica is then formed into sheets, plates, or special configurations by heating, pressing, and trimming.

Reconstituted mica (mica paper) is a paper-like material consisting of fine flakes of scrap mica deposited as a continuous mat. The sheet usually is impregnated with an organic material.

Scrap mica, in the broad sense, is mica that because of size, color, or quality is below specifications for sheet mica. Scrap mica may be obtained from pegmatite deposits as a sole product or as a byproduct (mine scrap); derived from rifting and trimming sheet mica (shop scrap) and from fabrication waste (factory scrap); or recovered from schists and from the beneficiation of feldspar and kaolin (flake mica).

Synthetic mica, as referred to in this chapter, is produced by crystallization during the slow cooling of a melt of accurately proportioned raw materials. Although hundreds of micas can be synthesized by this process, normal fluorphlogopite mica is the composition that has been most promising for producing crystals having desirable mechanical and dielectric properties. In this composition, the hydroxyl ions of natural phlogopite are replaced by fluoride ions. In general, synthetic micas are true micas that have been manufactured by reacting suitable raw materials under proper conditions and need not be limited to fluorine micas.

TECHNOLOGY

Geology

Muscovite sheet mica is recovered only from pegmatite deposits. Zoned pegmatites are the principal source. Concentrations or shoots of mica are distributed sporadically throughout the deposit as books or crystals of various sizes and thicknesses. These crystals, usually roughly hexagonal and tabular, range from less than an inch to several feet in maximum dimension. It is not possible to identify reliably a potentially productive pegmatite dike or to establish the exact location of mica within a productive dike except by close sampling.

Large crystals of phlogopite usually are found in pyroxenite dikes in association with calcite and apatite.

Throughout the world the occurrence of higher quality and larger grades of sheet mica is irregular and spotty. Even in the famous Bihar mica field of India, only two or three veins in a hundred are said to be rich enough to permit development on an extensive scale. In all areas, low- and high-quality mica are found together.

Mica occurs widely as flakes in many igneous, metamorphic, and sedimentary rocks. The muscovite content of some schists and kaolins is high enough to be recovered for use as scrap mica.

Prospecting, Exploration, and Mining

The only practical method of prospecting for sheet mica is to sink test pits in the pegmatite to determine the percentage, size, and quality of trimmed sheet that might be obtained from a deposit. Preliminary stripping and trenching, usually by bulldozer or other mechanical equipment, may be used to outline the size, shape, and attitude of the pegmatite vein, either to aid in selecting the sites for test pits or to supplement the information obtained from the test pits. The most common method of exploration for sheet mica is to sink a shaft either down dip in the pegmatite body or vertically to cut the pegmatite at the desired depth. Drifts are then driven along the strike in both directions. Some pegmatites are explored by adits. Diamond drilling seldom is used to explore pegmatites for mica.

Most sheet mica mines are operated on a small scale. Open pit mining is economically feasible in relatively flat or gently rolling country where pegmatites occur at or near the surface and dip gently. Many mica-bearing pegmatite dikes are mined by underground methods. Care must be taken to avoid drilling through good crystals of mica. A low velocity, 40-percent dynamite usually is used in blasting around a pocket of mica, and only a few holes are blasted at a time to avoid shattering the mica books. Headings usually are advanced by slabbing to prevent excessive damage to the mica books.

Larger scale open pit methods are used to exploit mica deposits worked solely for the recovery of scrap mica, and also to mine disseminated deposits of mica schist.

PREPARATION FOR MARKET

Preparation of sheet mica for market depends entirely on hand labor. Cobbing and rifting are done with hammers, knives, and fingers; trimming may be done with knives, sickles, shears, or fingers. First, the rough books are cobbed to remove adhering dirt, rock, and defective mica. Next, the cobbed mica is rifted or split into suitable thicknesses, and the major flaws are removed. The products of the rifting operation are classified broadly as untrimmed sheet mica and scrap mica. Trimming, the next step in processing, removes broken and ragged edges, loose scales, and other major imperfections. In the United States, trimming is done with a knife to produce a beveled-edge cut, the preferred type of trim. Care must be taken during rifting and trimming to determine what part of the mica should be removed to result in minimum waste and a sheet with the maximum usable area. The trimmed mica is classified first according to grade (size) and then according to quality. The quality of natural muscovite sheet mica is determined visually. Interpretation of visual standards may vary from one observer to another. After being classified, the trimmed mica is ready to market.

Scrap mica from mining, trimming, or fabricating sheet mica is bagged and sold without further preparation to mica grinders. To recover scrap mica from schist, the rock is crushed and transported, usually with water, to a series of roll crushers and screens. Here the gangue materials pass through the screens, while the mica is washed from the screens and carried to a draining bin from which it is fed by screw feeder to an oil-fired rotary drier. The discharge from the drier is sent to a 14-mesh screen from which the fines go to waste. The oversize is passed through a roll crusher and sent to a dry-grinding operation.

Raw material for dry-ground mica is obtained from mine scrap, from crushing and milling schists, or as a coproduct of kaolin washing or feldspar flotation. Buhr mills, rod mills, high-speed hammer mills all have been used for dry grinding mica. At present, high-speed hammer mills are the most widely used for dry grinding. The mill feed consists of mica that has been washed, screened, and dried. The mill is in circuit with an air separator which returns oversize for additional grinding and discharges the fine material to a screening operation. Various sized fractions are bagged for marketing. The yield of ground mica from beneficiated scrap is usually 95 to 96 percent. A special type of dry-grinding machine, called a Micronizer, produces "micronized" mica. This is an ultrafine material produced in a disintegrator that has no moving parts but depends on jets of high pressure superheated steam to reduce the mica to micron sizes. Micronized mica is produced

780-887 O—65——38

in particle size ranges of 10 to 20 microns and 5 to 10 microns. Another device for dry grinding mica by means of fluid energy is the Majac Mill. Mica is fed continuously from a screw conveyor into a chamber containing two horizontal directly opposed jets. The particle size of the product can be controlled over a broad range down to the micron sizes.

Raw material for wet-ground mica is mainly shop scrap and factory scrap but high-quality mine scrap can be used. Wet-ground mica is produced in mills of the chaser type. Grinding surfaces, which must be such as to preserve the luster or sheen of the mica, usually are made of wood. The type of mill usually employed consists of a cylinder steel tank which is lined with wooden blocks laid with the end grain up. The rollers used are usually wooden, which revolve at 15 to 30 r.p.m. Scrap mica is fed from hoppers to the mill where water is added gradually to form a thick paste. After the bulk of the mica has been ground to the desired size (5 to 8 hours, depending on the feed material), the charge is sluiced from the mill into settling bins where the gritty impurities sink. The mica overflows to a settling tank and is further dewatered by centrifuging and steam drying. The dried product is sized by screening on enclosed multiple-deck vibrating screens, transferred to storage bins, and then bagged for shipment.

MANUFACTURE OF SYNTHETIC MICA

Synthetic mica is manufactured in a furnace which consists of a shell to hold the batch and a pair of graphite electrodes positioned to generate heat in the interior of the batch. A variable transformer controls the supply of alternating-current electricity to the electrodes.

The batch for normal fluorphlogopite consists of a properly proportioned, dry, pulverized, uniform mixture of potash feldspar, potassium silicofluoride, magnesia, alumina, and silica. The batch usually is compounded to have fluorine present in excess of stoichiometric proportions. Although the fluorphlogopite melt is an excellent electrical conductor, the cold batch is a good insulator. Hence, a small-diameter graphite resistor connecting the vertical electrodes is used to start the melting and is consumed by oxidation after several hours of operation but not before a small pool of melt connects the electrodes. Heating is continued until the melt has advanced to within a few inches of the steel shell. Thus, the raw and partially reacted batch remaining around the melt is the container for the melt which has a temperature of about 1,360° C. After the power is cut off, the melt is permitted to cool slowly. After several days, the crystallized melt is broken with pavement breakers, large crystals hand sorted and finer mica crushed, and ground.

USES

Such characteristics as flexibility, resilience, transparency, excellent cleavage, moderate softness, extreme smoothness, vitreous luster, chemical inertness, low electrical and thermal conductivity, tolerance to fairly high temperatures, high dielectric strength, low power-factor losses, and low unit cost make mica usable in many industries and in many diversified applications. Sheet mica, either as single pieces split from crystals or as composite pieces in a built-up form, is an important material in the electronic and electrical industries. The higher qualities of block mica are used principally in the manufacture of electronic tubes, high-temperature steam gage glasses, and regulator diaphragms. Lower qualities of block mica, including punch mica, are used as electrical insulation in household appliances, incandescent lamps, fuse plugs, and other electrical equipment. Film mica is used principally as a dielectric in capacitors, particularly for the electronic industry.

Phlogopite is inferior to muscovite in many electrical properties but replaces muscovite as an electrical insulator where its ability to withstand temperatures up to 1,000° C, compared with 500° C for muscovite, is important.

Data on the end-product uses of muscovite block and film fabricated in 1963 are given in table 3.

Mica splittings are used in the manufacture of sheets of built-up mica. Products cut or stamped from this material are used principally as an insulating material in electric motors, generators, and transformers.

Table 4 gives data on the various products of built-up mica made from splittings in 1963.

Scrap mica is used principally as a raw material for producing ground mica. Dry-ground mica is used in large tonnages as a filler and surface coating for roofing materials, as a filler in wallboard joint cements, and as an ingredient in paints. Smaller quantities are used in numerous products, including rubber, plastics, drilling mud, pipeline enamel, and welding rods. Wet-ground mica is used principally by paint, wallpaper, and tire manufacturers.

Table 5 shows the use pattern for ground mica sold in 1963.

A growing use for scrap mica is in the production of reconstituted mica. Reconstituted mica is used in some applications formerly requiring built-up mica and in electronic capacitors.

[1] Includes punch mica.
[2] Includes First- and Second-quality film.
[3] Includes other-quality film.

TABLE 4.—*Built-up mica [1] sold or used in the United States, by products*

[Thousand pounds and thousand dollars]

Product	1963	
	Quantity	Value
Molding plate	1,143	$2,965
Segment plate	1,214	2,917
Heater plate	524	(2)
Flexible (cold)	602	1,755
Tape	1,441	5,911
Other	83	2,065
Total	5,007	15,613

[1] Consists of alternate layers of binder and irregularly arranged and partly overlapped splittings.
[2] Included with "Other" to avoid disclosing individual company confidential data.

TABLE 5.—*Ground mica sold by producers in the United States, by uses*

Use	1963	
	Short tons	Value (thousands)
Roofing	38,980	$1,370
Wallpaper	1,269	188
Rubber	6,979	728
Paint	23,597	1,890
Plastics	(1)	(1)
Welding rods	1,169	58
Joint cement	24,625	1,603
Well drilling	(1)	(1)
Other uses [2]	20,632	968
Total	117,251	6,805

[1] Included with "Other uses" to avoid disclosing individual company confidential data.
[2] Includes mica used for molded electric insulation, house insulation, Christmas tree snow, annealing, and other purposes.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Feldspar is produced as a byproduct at some sheet mica mines, particularly in New England. Beryl, lithium minerals, and columbite-tantalite sometimes are recovered along with sheet mica. Often the concurrent recovery of two or more pegmatite minerals is necessary for economic exploitation of a deposit. Mica encountered in feldspar mining is recovered as a byproduct. In the recovery of feldspar by flotation and in the processing of kaolin, scrap mica and silica sand are byproducts.

ALTERNATE MATERIALS

Other materials have displaced mica in certain fields; for example, heat-resistant glass in stove windows; sintered aluminum oxide in spark plugs; and glass, paper, and ceramic materials for certain capacitor uses. While mica has not been displaced from many electronic applications, widespread miniaturization of equipment and the use of substitutes where practicable have combined to reduce the quantity of mica needed.

Ceramic electronic tubes are constructed according to entirely different concepts than the common glass envelope tubes and require no mica spacers. The all-ceramic tube will withstand high temperatures, and is expected to last much longer than the electronic tubes commonly used today. Evacuating these tubes and

forming a vacuum-tight seal are troublesome. The technology, at present, is not sufficiently advanced to overcome these and other problems so that ceramic tubes can be mass produced. Although small quantities have been made for special applications, these tubes are primarily in the development stage. Ceramic capacitors use plates or bodies made principally of titanium dioxide with other titanates. Wherever high power factors and large changes in capacitance with temperature can be tolerated, ceramic capacitors are used for low capacitance applications.

Transistors have replaced electronic tubes for many applications. A transistor consists of a small piece of semiconducting material, such as germanium or silicon, contacted by three or more electrodes and sealed in plastic. Transistors require no heater current, operate on low voltages, and are smaller, lighter, and more resistant to shock and vibration than vacuum tubes. Transistors, as presently developed, are limited to operating at temperatures, frequencies, and power levels much lower than those attainable with electronic tubes.

For most uses reconstituted muscovite mica can replace built-up mica made from muscovite splittings, and substitution for a substantial part of phlogopite splittings also could be achieved.

A heat-resistant electrical insulation in the form of sheet made by bonding ground mica with aluminum phosphate, is being used in place of lower qualities of sheet mica in some electrical appliances.

SYNTHETICS

Synthetic micas are true micas that have been prepared by reacting suitable raw materials in the proper proportions. The term synthetic mica often is used loosely at the present time to mean synthetic normal fluorphlogopite. Of all the fluormicas synthesized, only a few thus far have been considered as commercial possibilities, and only normal fluorphlogopite is being produced and used industrially (*1*).

Synthetic mica flake is ground and used in the manufacture of glass-bonded mica. The substitution of synthetic fluorphlogopite mica for natural mica in the glass-bonded material results in an improved product even when low-temperature glasses are used.

RESERVES

No significant domestic reserve of sheet mica has been demonstrated because little exploration is done in advance of mining, and concentrations of mica usually are mined promptly after discovery. The total reserve of muscovite sheet mica is estimated at 4 to 5 million pounds.

Quantitative estimates cannot be made for the reserve of scrap mica because it includes scrap dependent on sheet production, scrap produced directly from pegmatites, and scrap (flake) recovered from disseminated deposits such as mica schist. Resources of scrap mica occurring as small flakes in disseminated deposits are essentially unlimited (*26*).

There are no known domestic reserves of phlogopite mica, although a few occurrences have been reported.

Quantitative information on reserves or resources in foreign countries is unavailable. The major reserves of muscovite are in the Bihar and Madras areas of India and are considered to be very large. Other large reserves are in Brazil, Western Africa, the Rajputana area of India, and the Lake Baikal and Sayan Upland areas of the U.S.S.R. Argentina, Australia, Southern Rhodesia, and the South Enissey Range of the U.S.S.R. have smaller but substantial reserves.

Canada and the Malagasy Republic have the world's major reserves of phlogopite. Additional reserves are available in the Sludyanka River district and Alden area of the U.S.S.R., Ceylon, and Mexico.

SOURCES OF STATISTICAL INFORMATION

Government agencies and trade organizations compile statistics on various aspects of the mica industry. The Bureau of Mines collects statistics semiannually from fabricators of block and film mica and annually from producers of crude mica, from consumers of mica splittings, and from grinders of mica. Data on imports and exports are compiled by the Bureau from monthly data obtained by the U.S. Department of Commerce. World production data are compiled annually by the Bureau from foreign statistical sources. The National Electrical Manufacturers Association and the Wet-Ground Mica Association issue regular releases on transactions by member companies.

Data of the Bureau of the Census, U.S. Department of Commerce, on imports of mica follow the tariff classification, which in many respects differs from trade practices.

PRODUCTION, CONSUMPTION, AND TRADE

The United States leads the world in production of total mica (sheet plus marketable scrap), but the bulk of the product is scrap mica. India, ranking second in total mica pro-

duction, produces principally sheet mica and is the major supplier of this category (table 6).

The United States consumes more sheet mica, principally for electrical insulation, and grinds more scrap mica than any other country (table 7). Muscovite splittings and the lower qualities of muscovite block constitute the largest portion of sheet mica used. Comsumption of ground mica, as indicated by sales, comprises about 85 percent dry-ground materials and 15 percent wet-ground.

India furnished about 82 percent of the total imports of mica film and splittings in 1963 and about 21 percent of block mica. Brazil furnished about 63 percent of all block mica imports. The Malagasy Republic supplied almost all the phlogopite splittings. U.S. mica exports consisted mainly of ground mica.

Tariffs on mica, as described in the "Tariff Schedules of the United States, Annotated (1963)" are shown in table 9.

TABLE 6.—*World production of mica by major producing countries*

[Thousand pounds]

Country	1954-58 (average)	1959	1960	1961	1962	1963

[1] Includes First- and Second-quality film.
[2] Includes other-quality film.
[3] Includes punch mica.

SELF-SUFFICIENCY AND STRATEGIC CONSIDERATION

The United States is not self-sufficient in any category of sheet mica or in high-quality scrap mica.

Historically, sheet mica produced domestically has equaled no more than a small fraction of U.S. requirements for high-quality mica but instead has been principally punch and circle mica. The United States is almost completely dependent on foreign sources for strategic sheet mica. Of the five strategic categories only muscovite block mica has been produced in the United States in significant quantities and then only under the stimulus of above-market prices paid by the Government. Stained and better qualities obtained from processing domestic mica purchased by the Government in 1960 would have furnished 16 percent of the total fabrication of muscovite block and film of these qualities, irrespective of grades. The Government purchase program was terminated in June 1962.

Domestic production during World War II filled approximately 15 percent of the total block and film mica requirement of the United States. However, only 4 percent of the requirement for strategic-quality mica acceptable for stockpiling came from domestic production.

Virtually all mica splittings, the bulk of U.S. consumption of strategic sheet mica, and all mica films must be imported. As discussed in

TABLE 8.—*U.S. imports and exports of mica*

Year	Imports for consumption				Exports, all classes (short tons)
	Uncut sheet and punch (pounds)	Scrap (short tons)	Manufactured (short tons)	Total (short tons)	
1954-58 (average)	1,911,673	6,115	5,150	12,221	4,326
1959	3,220,412	4,644	5,042	11,296	5,102
1960	1,088,021	6,240	4,266	11,050	4,012

TABLE 9.—*Mica tariffs*

Description	Duty rate
Mica not manufactured (including split block mica and mica over 0.006 inch thick, not cut or stamped to dimensions, shape, or form) and mica scalings, mica cleanings, and other mica waste and scrap:	
Untrimmed phlogopite from which no rectangular piece over 2 inches long or 1 inch wide can be cut.	5 percent ad valorem.
Waste and scrap valued not over 5 cents per pound:	
Phlogopite	12.5 percent ad valorem.
Other	Do.
Split block mica	Free.
Other	4 cents per pound.
Mica splittings	Free.
Mica, not over 0.006 inch thick, not cut or stamped to dimensions, shape, or form.	Do.
Mica, not over 0.006 inch thick, cut or stamped to dimensions, shape, or form, whether or not perforated or indented, and whether or not dedicated to a specific use:	
Not perforated or indented:	
Fuse disks, split to thickness	25 percent ad valorem.
Other	40 percent ad valorem.
Perforated or indented	25 percent ad valorem.
Mica, ground or pulverized	12.5 percent ad valorem.
Built-up mica	17 percent ad valorem.
Articles not specifically provided for, of mica	25 percent ad valorem.

the section on alternate materials substitutes for mica splittings are closer to realization than for other categories of mica.

GOVERNMENT PROGRAMS

The defense program for mica since World War II has consisted of a purchase program for domestic mica, purchases of imported mica for the strategic stockpile, Commodity Credit Corporation (CCC) barter contracts for the supplemental stockpile, and exploration assistance, initially under the Defense Minerals Exporation Administration (DMEA), and subsequently under the Office of Minerals Exploration (OME).

In 1952 the Government began purchasing domestically produced block, film, and hand-cobbed muscovite mica at above-market prices. This program terminated, after a number of extensions, in June 1962.

The Government, through established importers, purchased mica produced in foreign countries. Each lot conformed to National Stockpile Purchase Specifications. Government inventories on June 30, 1964 are shown in table 10. Nonstockpile grade mica also is stockpiled.

TABLE 10.—*Mica in Government inventories*

[Short tons]

Grade	National strategic stockpile	DPA inventory	CCC stocks	Supplemental stockpile	Total
Muscovite block, Stained and better	3,331	1,323	144	784	5,582
Muscovite film, first and second qualities	598	51	23	51	723
Muscovite splittings	20,020			2,413	22,433
Phlogopite block	9				9
Phlogopite splittings	1,540			993	2,533

PRICES

Because of the wide range of qualities and grades of sheet mica, and because the differences between qualities often are slight, prices are negotiated between buyers and sellers. Duty-paid prices for imported full-trimmed mica in the range of qualities and grades constituting the bulk of the demand are about as follows: Block mica, $1.25 to $43 per pound; film mica, $5 to $24 per pound; and splittings, $0.20 to $4 per pound. Prices paid under the Government's purchasing program for domestic block mica in the equivalent range are $4 to $70 per pound.

During 1963 E&MJ Metal and Mineral Markets quoted prices for punch mica of $0.07 to $0.12 per pound and for North Carolina scrap mica of $30 to $40 per short ton.

Quotations in Oil, Paint, and Drug Reporter, during 1963, were as follows for carlots of dry-ground mica in bags at works in cents per pound: Paint, 100-mesh, 4; plastic, 100-mesh, 4; roofing, 20- to 80-mesh, 3. The same source quoted equivalent prices for wet-ground mica, as follows: Biotite, 6.5; paint or lacquer, 8.25; rubber, 8; wallpaper, 8.75; white, 5 to 10 microns, 8.25.

TAXES

No special taxes are imposed on the mica industry. Producers of mica are granted a depletion allowance of 23 percent on domestic production and 15 percent on foreign production.

RESEARCH

The bulk of the research on natural mica has been related directly to problems posed by the strategic and critical nature of sheet mica. A detailed review on research carried on by industry and government prior to 1960 was published by the Bureau of Mines (*26*).

Research on synthetic mica has been conducted by the Federal Bureau of Mines. Principal efforts were directed toward growing large single crystals, obtaining basic information on nucleation and the liquid state of fluorphlogopite, reconstituting improved inorganic paper from water-swelling compounds, and preparing machineable dielectrics by divitrifying synthetic mica glasses.

The U.S. industry-Government program to develop substitutes for natural mica was directed toward obtaining a suitable sheet material that could be obtained from synthetic mica. Efforts were directed principally toward inorganic bonding of sheets reconstituted from fluorphlogopite flakes and toward improving the properties of films formed from water-swelling micas.

Synthetic mica research sponsored by the U.S. Air Material Command was concluded in 1961. The objective of the program was to develop a commercially feasible technique for producing large area, single crystals of fluorphlogopite mica.

Evaluation of reconstituted natural mica as a substitute for natural mica in electronic tubes and capacitors was sponsored by the U.S. Army Signal Corps, and the Navy Bureau of Ships supported research on the use of synthetic mica for encapsulating electronic components.

OUTLOOK

Domestic production of good qualities and grades of sheet mica was at a high level prior to 1962 owing to the influence of the Government stockpiling program, which purchased sheet mica at a premium price. Expiration of this program in June 1962 caused a sharp reduction in production during 1962 and the following year. This reduction will probably continue until only a nominal quantity is produced annually.

Domestic sheet mica (block, film, and splittings) requirements will continue to be met largely by imports of muscovite from India and phlogopite from the Malagasy Republic. This pattern will continue unless interrupted by international conflict or the development of acceptable synthetic mica substitutes.

Action by the Indian Government early in 1964 establishing minimum prices for splittings and other types of mica may result in lower Indian mica production because fewer purchasers may be willing to pay the increased price. Any inability of Indian producers to find buyers may cause smaller and less efficient mining operations to be curtailed. If production decreases and price increases are maintained, major users may commence expanded efforts to find suitable substitutes for Indian mica in many industrial uses.

Consumption of the higher qualities of muscovite block and film during the next few years is expected to continue at the 1963 level. Continued demands of the expanding electronics industry will require block mica for the fabrication of electronic tubes and film mica for condensers.

The demand for built-up micas should increase slowly, at a rate dependent on the economics of the materials, technical improvements in reconstituted mica products, and the conversion of design engineers to the use of reconstituted material.

Ground mica production since 1961 has shown a strong pattern of increase which will probably continue. Increased consumption for roofing materials and paints can be expected as the building construction industry expands with the growing population. Other industries, such as plastics, welldrilling, welding, and rubber, also will continue to require ground mica. Substantial expansion of ground mica consumption will depend on the development of new uses.

PROBLEMS

SHEET MICA

A serious problem is the insufficient domestic supply of sheet mica that forces the United States to rely on distant and uncertain foreign sources to supply most of its requirements.

The inadequate market for the more plentiful classes of mica—block and film of the lower qualities, splittings, and scrap—and the impracticability of recovering and selling other pegmatite minerals hinder the development and exploitation of domestic mica deposits in particular. Lack of coproducts to share the costs of mining and recovery increases the cost and possibly decreases the supply of the higher qualities of block and film mica. The problem is accentuated by increasing demands for higher qualities and larger sizes of sheet mica and by partial displacement of more plentiful classes by other materials.

Numerous mining and processing problems result from the manner in which mica occurs. The often irregular distribution of mica in pegmatites complicates estimation of reserves. The necessity of recovering undamaged books of mica and the softness of the material create special rock-breaking problems. Large quantities of rock must be mined for each pound of usable sheet mica recovered which burdens the economics of the operation.

The large amount of skilled hand labor required to produce and qualify block, film, and splittings makes preparation of sheet mica uneconomical in the United States. This labor factor in combination with inadequate domestic resources prevents development of a mica processing industry that could serve as a base to overcome U.S. dependence on foreign sources of mica in wartime.

The lack of an accurate relation between the properties required in end-use applications of sheet mica and the specifications for visual quality of block and film mica may result in some unnecessary use of the highest qualities and failure to utilize all satisfactory lower qualities. The problem is made more difficult by the absence of practical, reproducible, scientific tests to evaluate sheet mica for specific end uses.

The lack of satisfactory bonding techniques is the major obstacle to using synthetic mica flake to produce a sheet material having suitable electrical and mechanical properties. The use of single crystals of synthetic mica in elec-

tronic applications is hindered by the present inability to obtain large crystals of synthetic mica with an orientation and yield that permit economic recovery.

SCRAP MICA

Greatly expanded production of reconstituted natural mica will be hindered by the lack of sufficient known supplies of suitable high-quality muscovite scrap mica.

Since scrap mica goes principally into the production of ground mica, the problems of the two are virtually inseparable. Ground mica for some uses, especially fillers, is subject to displacement by other materials unless more economical methods of recovering and grinding scrap are developed.

The lack of markets for scrap and ground mica, particularly of the lower qualities, creates a problem in utilizing all that can be produced readily.

The lack of standard specifications for ground mica deters the development of new markets and complicates the reduction of costs for grinding scrap.

MOLYBDENUM

By R. W. Holliday [1]

FIRST isolated as a metal in 1782, molybdenum was not used widely until the early years of the 20th century when it played a role in commercial development of the electric lamp. Later, during and after World War I, it became an important constituent of alloy steel.

A single mine, the Climax mine in Colorado, has produced more than half of the world molybdenum supply from 1925 to the present and the free world resource is predominantly in the Western Hemisphere.

Molybdenite (MoS_2) is the principal commercial mineral of molybdenum. Most production is from ores containing only a few pounds of molybdenite per ton. In the United States in 1963 byproduct molybdenite from copper and tungsten mines comprised 27 percent of the total output. Most of the remaining 73 percent came from the Climax molybdenum mine.

All molybdenum ores, including the byproduct ores, are concentrated by flotation. Virtually all of the concentrate is roasted to molybdic oxide. This oxide is added directly to steel and other alloys or it is converted to other products.

The known domestic reserve, of ores that are commercial under present conditions, is estimated to comprise a 37-year supply averaging 50,000 tons per year of contained molybdenum. However, the rate of growth in the industry during recent years indicates that annual requirements for consumption and export may exceed 50,000 tons by 1972.

BACKGROUND

The mineral, molybdenite, was identified as a sulfide of molybdenum in 1778 and the metal was isolated in 1782. More than 100 years later, in 1893, a 96-percent pure metal was produced and in the following year production of a molybdenum-bearing armorplate was reported (*6, 8*).[2] Commercial use as an alloy constituent of steel was announced prior to 1905 but the first real stimulus to its use in alloys came in the First World War when shortages of other alloying elements centered interest on molybdenum. Wide spread search for deposits, development of a flotation process for separating molybdenite from its ores, and applications research followed. Beginning about 1920, there was rapid growth in production and use.

Methods for producing ductile molybdenum metal in the form of wire, rod, and sheet by powder metallurgy techniques were developed in the years following 1907. The metal was an important factor in development of the electrical and more recently the electronics industries. Molybdenum has also been used for many years in chemicals and dyes.

Small quantities of molybdenum ore were mined in Norway about 1880. Australia and the United States were producing by 1900. Canada was a prominent producer in the years 1916–19.

The Climax deposit in Lake County, Colo., and the Questa deposit in Taos County, N. Mex., were among those exploited during the First World War, and by 1925, these two deposits were the source of about 75 percent of the world supply of molybdenum. In succeeding years as demand for molybdenum in making ferrous alloys and other uses grew rapidly, the Climax mining and milling facilities were expanded because the large disseminated deposit proved amenable to large-scale mining. The Questa vein deposit was not mined on a large scale and consequently, annual output from that source never exceeded more than a few hundred tons of molybdenum. However, at the end of 1963, mine and concentrating plant were being readied for production of 5,000 tons per year of molybdenum in concentrate from a large new low-grade deposit at the Questa property.

In 1933, the Greene Cananea Copper Co., a Mexican subsidiary of The Anaconda Company, started separating molybdenum from copper concentrate made from the sulfide ores of the

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Colorada deposit at Cananea. Molybdenum-bearing copper ores have since become an important source of molybdenum, and in recent years about one-third to one-half of the world annual output has been obtained as a byproduct of copper, largely from deposits in the United States, the U.S.S.R., and Chile.

World molybdenum production increased almost continuously from 500 tons in 1925 to 34,500 tons in 1943. Output declined to 11,500 tons in 1946, but rose to a peak of 45,800 tons in 1963.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

World production of molybdenum in concentrate was estimated at 45,800 short tons in 1963. Of this total the United States produced 71 percent; the U.S.S.R. produced 14 percent; Chile produced 7 percent; China produced 4 percent; Peru 1; Canada 1; and five other countries together produced the remaining 2 percent.

Ores containing molybdenum as the principal value accounted for more than 70 percent of the domestic output in 1963 and byproduct sources produced nearly 30 percent. Unconfirmed data suggest that about 50 percent of the U.S.S.R. production was from copper-molybdenum ores, about 30 percent from molybdenite ores, and about 20 percent from tungsten-molybdenum ores. Nearly all of the Chilean and Peruvian output was a byproduct of copper production.

Principal U.S. producers of molybdenum concentrate and producers of molybdenum products are listed in table 1. Of the producers of molybdenum concentrate, Climax Molybdenum Co., Division of American Metal Climax is by far the largest. This firm, from a single mine at Climax, Colo., produced more than half of the world output between 1925 and 1963. In 1963 Climax produced 73 percent of the U.S. total. The firm also operates plants in Michigan and Pennsylvania for converting concentrate to products including ingots, billets, and other mill products and research laboratories in Michigan.

The Molybdenum Corporation of America has been a leading producer of molybdenum products for many years. A plant at Washington, Pa. produces molybdic oxide and ferromolybdenum. A plant at York, Pa. produces molybdenum chemicals. The firm has operated molybdenum mines at various times over many years, but the first large-scale operation is scheduled for initial production at the Questa deposit in 1965. Current plans call for an output of about 5,000 tons of molybdenum in concentrate, per year.

Duval Corp. and Union Carbide Nuclear Co. produce byproduct molybdenite and convert the concentrate to molybdic oxide.

Kennecott Copper Corp. is the largest byproduct producer of molybdenite. The company recovers molybdenum in concentrate at its Arthur and Magna copper concentrating plants near Salt Lake City, Utah, and at Chino mines, Hurley, N. Mex., and Nevada mines, McGill, Nev. The firm also controls Braden Copper Co. which is a major producer of molybdenum in Chile.

Virtually all domestic producers of concentrate, except exporters, ship to one of the producers of molybdic oxide listed in table 1.

Annual productive capacity in Colorado is expected to increase some 5,000 tons by 1967 or 1968 through expansion at Climax and development at the company's Urad deposit in Clear Creek County. Annual capacity in New Mexico is expected to increase 5,000 tons by the end of 1965 from the Questa mine; and in Arizona 1,500 tons from copper mines.

The largest foreign, free world producers are Chile Exploration Co., Andes Copper Mining Co., both subsidiaries of Anaconda, and Braden Copper Co., a subsidiary of Kennecott; all in Chile. Southern Peru Copper Corp. began producing byproduct molybdenite in 1962 and produced more than 500 tons of molybdenum in concentrate in 1963. Planned development will increase Canada's annual production from about 500 tons in 1963 to perhaps 8,000 tons within the next several years.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Molybdenite (MoS_2) is the chief commercial molybdenum mineral occurring, usually disseminated in small quantities, in a host rock. Molybdenite concentrate is the mineral after separation from other constituents in the crude ore. Industry specifications for the concentrate vary widely although a 95-percent MoS_2 content is a usual basis for price quotations. National Stockpile Specification P–74–R5, dated July 15, 1963, listed the following chemical requirements for molybdenite concentrate:

		Percent by weight (dry basis) [1]
Molybdenum disulfide (MoS_2)	minimum	90.00
Copper (Cu)	maximum	.45
Lead (Pb)	do	.15
Phosphorus (P)	do	.04
Tin-plus-arsenic (Sn+As)	do	.15

[1] The free moisture content shall not exceed 4 percent.

TABLE 1.—*Principal U.S. producers of molybdenum concentrate and molybdenum products*

Company	Mine or mill site	Processing plant site	Major product
American Metal Climax, Inc.:			
Climax Molybdenum Co	Climax mine, Lake County, Colo.		Concentrate (MoS_2).
Climax Molybdenum Company of Michigan.		Coldwater, Mich	Metal powder.[1]
Climax Molybdenum Co		Langeloth, Pa	Molybdic oxide, ammonium molybdate, ferromolybdenum, sodium molybdate, purified disulfide.
American Smelting and Refining Company	Silver Bell mine, Pima County, Ariz.		Concentrate (MoS_2).
Do	Mission mine, Pima County, Ariz.		Concentrate (MoS_2). (Initial operation of molybdenum recovery unit scheduled for 1964).
Bagdad Copper Corp	Yavapai County, Ariz		Concentrate (MoS_2).
Duval Corp	Esperanza mine, Pima County, Ariz.	Mine site	Concentrate (MoS_2), molybdic oxide.
Do	Ithaca Peak mine, Mohave County, Ariz.		Concentrate (MoS_2). (Initial operation scheduled for 1964).
Fansteel Metallurgical Corp		North Chicago, Ill	Metal powder.[1]
General Electric Co.:			
Lamp Metals and Components Department.		Cleveland, Ohio	Ammonium molybdate, metal powder.[1]
Do		Dover, Ohio	Metal powder.[1]
Inspiration Consolidated Copper Co	Inspiration mine, Gila County, Ariz.		Concentrate (MoS_2).
Kennecott Copper Corp.:			
Chino Mines Division	Grant County, N. Mex		Do.
Nevada Mines Division	White Pine County, Nev		Do.
Utah Copper Division	Salt Lake County, Utah		Do.
Magma Copper Co., San Manuel Division	Pinal County, Ariz		Do.
Molybdenum Corporation of America		Washington, Pa	Molybdic oxide, ferromolybdenum.
Do		York, Pa	Molybdic oxide, ammonium molybdate, sodium molybdate.
Do	Questa mine, Taos County, N. Mex.		Concentrate (MoS_2). (Initial production from new plant scheduled for 1965).
M & R Refractory Metals Inc		Springfield, N.J	Metal powder (pellets), self-reducing molybdenum mix.
North Metal and Chemical Co		York, Pa	Sodium molybdate.
Phelps Dodge Corp., Morenci Branch	Greenlee County, Ariz		Concentrate (MoS_2).
Philips Elmet Corp		Lewiston, Maine	Metal powder.[1]
Republic Steel Corp		Canton, Ohio	Molybdic oxide.
SW. Shattuck Chemical Co		Denver, Colo	Molybdic oxide, ammonium molybdate, calcium molybdate, sodium molybdate.
Southern California Chemical Co		Los Nietos, Calif	Calcium molybdate.
Sterling Drug Company, Inc., The Hilton Davis Chemical Co. Division.		Cincinnati, Ohio	Sodium molybdate.
Sylvania Electric Products, Inc., Chemical and Metallurgical Division.		Towanda, Pa	Ammonium molybdate, metal powder (pellets).[1]
Union Carbide Corp., Nuclear Division	Pine Creek mine, Inyo County, Calif.	Mine site	Concentrate (MoS_2), molybdic oxide.
Universal Cyclops Steel Corp		Bridgeville, Pa	Metal powder.[1]
Vick Chemical Co., subsidiary of J. T. Baker Chemical Co.		Phillipsburg, N.J	Molybdic oxide, ammonium molybdate, sodium molybdate, molybdic acid.
Wah Chang Corp., Glen Cove Division		Glen Cove, Long Island, N.Y.	Molybdenum pellets, molybdenum spray powder, molybdenum carbonyl, metal powder.[1]
Do		Albany, Oreg	Metal powder.[1]
Westinghouse Electric Corp		Bloomfield, N.J	Do.[1]

[1] Produces wire, rod, sheet, or other mill products.

A purified molybdenite concentrate that contains more than 99.9 percent MoS_2 is required for use in manufacturing molybdenum disulfide lubricants.

Technical molybdic oxide (MoO_3) is produced by roasting molybdenite concentrate in air. It is used as a raw material for producing all types of molybdenum chemicals, for manufacturing ferromolybdenum, and for adding molybdenum to iron and steel alloys.

Specification P–74–R5 lists the following chemical requirements for technical grade molybdic oxide:

		Percent by weight (dry basis) [1]
Molybdenum (Mo)	minimum	60.00
Copper (Cu)	maximum	.50
Lead (Pb)	do	.15
Phosphorus (P)	do	.05
Sulfur (S)	do	.25

[1] The free moisture content shall not exceed 0.5 percent.

Purified molybdic oxide is produced from the technical grade by sublimation or by chemical means. It is used as a raw material for producing molybdenum metal powder, chemically pure molybdenum salts and compounds, and in special alloys.

Ferromolybdenum is a molybdenum-iron alloy produced in the electric furnace or by a thermite process. It is used to introduce molybdenum into iron or steel alloys and as a coating material on welding rods.

Specification P–74–R5 lists the following chemical requirements for ferromolybdenum:

		Percent by weight (dry basis)	
		Grade A	*Grade B*
Molybdenum (Mo)	minimum	60.00	60.00
Carbon (C)	maximum	2.50	.10
Carbon (C)	minimum	2.00	-----
Copper (Cu)	maximum	.50	.50
Phosphorus (P)	do	.10	.10
Silicon (Si)	do	1.00	1.00
Sulfur (S)	do	.20	.20

Molybdic oxide briquettes and calcium molybdate are other forms used for adding molybdenum to alloys.

Ammonium molybdate, as well as purified molybdic oxide, is used for the production of molybdenum metal powder and for various chemicals, fertilizers, and catalysts. Sodium molybdate is used in the production of fertilizers, pigments, and chemicals.

Molybdenum metal powder is used for production of substantially pure molybdenum mill products. It may also be used for adding molybdenum to special alloys.

TECHNOLOGY

Mineralogy and Geology

Molybdenite is the disulfide of molybdenum, containing about 60 percent molybdenum and 40 percent sulfur. Its specific gravity is 4.6 to 4.7 and it resembles graphite in appearance and softness. Its streak is bluish grey on paper and greenish grey on porcelain. Molybdenite yields sulfur fumes when ignited on charcoal. It occurs in pegmatites, aplites, contact metamorphic zones, quartz veins of the single-vein type, porphyry copper deposits, and in stockworks composed of myriads of intersecting veinlets.

The most important discovery to date, the stockworks at Climax, Colo., was formed by intrusion of a quartz-monzonite magma into granites, schists, and porphyry; solidification and fracturing of the quartz-monzonite and the surrounding granite and schist; injection of quartz-monzonite dikes, some of which contained molybdenite; and hydrothermal deposition of quartz, orthoclase, molybdenite, pyrite, and sericite. The hydrothermal solutions penetrated the smallest fractures depositing quartz-molybdenite veinlets that make the rock look like a breccia (*10*).

Quartz veins with molybdenite are widely distributed and two deposits of this type have yielded significant quantities of molybdenite. The Questa deposit in New Mexico and the La-Corne deposit in Quebec both produced consistently over many years. (A large, low-grade occurrence adjacent to the Questa deposit is similar to the Climax formation in that hydrothermal solutions deposited a network of quartz-molybdenite veinlets in a previously fractured and shattered rock complex.)

Most of the porphyry coppers in the Western United States contain small quantities of molybdenite disseminated, with the copper minerals, through large bodies of granitic rock.

Contact-metamorphic skarn or tactite zones containing some molybdenite or powellite are relatively common. Pine Creek mine, near Bishop, Calif., has produced molybdenum as a byproduct of tungsten since 1939.

Pegmatite and aplite with small quantities of molybdenite, are found throughout the world, but no appreciable production has resulted.

Molybdenum oxide minerals have yielded molybdenum, but production has been relatively insignificant. Wulfenite ($PbMoO_4$) is a secondary mineral formed in the oxidized zones of lead- and molybdenum-bearing deposits. Composition of the mineral is variable in that tungsten substitutes for molybdenum and calcium for lead. Powellite ($CaMoO_4$) is an alteration product of molybdenite, frequently associated with scheelite and containing up to 10 percent tungsten trioxide. Ferrimolybdite (long known as molybdite) and Ilsemannite are secondary oxidation products of molybdenite.

Mining

The caving method employed at the Climax mine produced 35,500 tons of ore per operating day in 1963. Essentially the ore body is undercut to induce caving of the ore, which flows by gravity through finger raises into concrete lined scraper drifts. The ore is then scraped into cars on the haulage level. The caving must be carefully controlled to avoid ore dilution and to prevent damage to mine openings.

The smaller vein-type deposits are mined by shrinkage, cut-and-fill, or other conventional methods adapted to existing conditions. The new development at the Questa deposit will employ open-pit methods. The Climax mining method was described in a Bureau of Mines publication (*6*).

Beneficiation

Ores containing molybdenite as the chief valuable mineral and copper sulfide ores containing byproduct molybdenite are beneficiated by flotation. Tungsten ores containing both molybdenite and powellite are beneficiated by a combination of flotation, tabling, and chemical extraction. Complex wulfenite-bearing ores can be concentrated by either gravity or flotation methods, but smelting, leaching, and precipitation are necessary to separate molybdenum from lead and other valuable metals (*6*).

The Climax flowsheet involves crushing, grinding, classification, and a preliminary flotation that produces a rougher concentrate of 8 to 10 percent MoS_2. Tailings from the rougher flotation are routed to the byproduct plant where Humphreys spirals and flotation cells produce a pyrite concentrate that is marketed and tailings that are further treated by tabling and magnetic separators to produce tungsten concentrate and tin concentrate.

The 8- to 10-percent rougher concentrate is

cleaned in additional flotation stages, with grinding and classification between stages, to produce the final concentrate.

Molybdenite is recovered from copper ores containing as little as 0.2 pound MoS_2 per ton.

Copper plants designed to recover molybdenum as a byproduct first produce a concentrate containing both copper sulfide minerals and molybdenite. Methods for separating molybdenite from the copper sulfide minerals and other impurities such as iron sulfides and gangue material in this concentrate vary in detail from producer to producer, but all employ selective flotation. At some plants the molybdenite in the first flotation concentrate is depressed along with some copper and iron sulfide and gangue material, producing a copper concentrate and a tail product that is the rougher molybdenite product. This tail material is filtered and given a light roast to tarnish the copper sulfide minerals before further processing. In other processes the first flotation concentrate is treated by adding lime and steaming to retard the copper sulfide so that a rougher molybdenite concentrate is produced during the second flotation. In either process the molybdenite materials are further cleaned through several conditioning reflotation steps, in which various reagents may be used to effect selective flotation. Recovery of molybdenite varies with the tenor of the crude ore and with the nature of the mineralization and ranges from about 15 to 80 percent.

A hydrometallurgical process for recovering molybdenum from oxidized ores was undergoing pilot plant tests in 1963 at Climax research facilities. Oxidized ores will not be a major source of molybdenum in the foreseeable future, but recent advances in recovery procedures indicate that they will be a significant increment of supply.

Manufacture of Molybdenum Products (*5, 7*)

The principal molybdenum products and their relationships to end uses are shown in figure 1.

Lubricant-grade molybdenum disulfide (MoS_2) is prepared by removal of silica and other impurities from the commercial-grade concentrate. Screening, grinding, leaching, volatilization, washing, and possibly other methods are employed, primarily for extraction of abrasive materials.

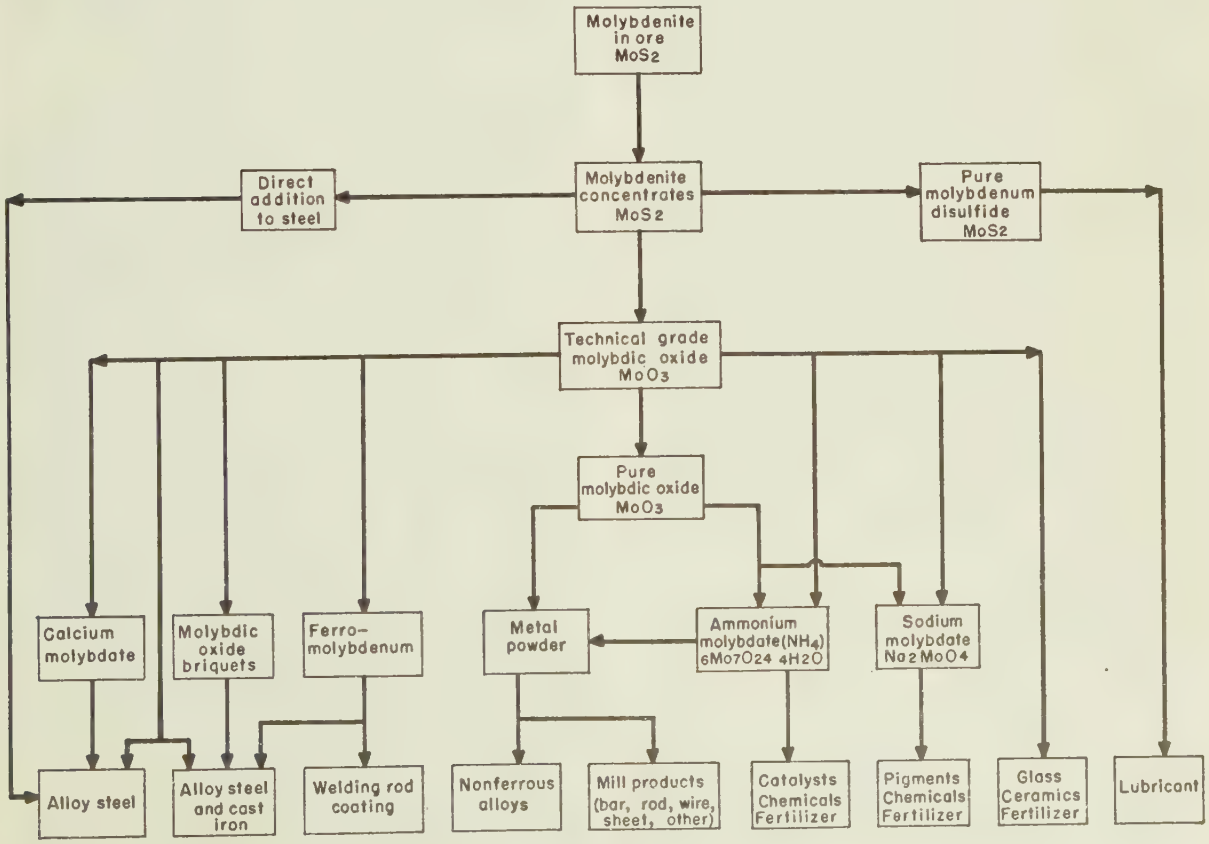

FIGURE 1.—Principal Molybdenum Products and Their Relationships to End Uses.

Technical-grade molybdic oxide is produced by roasting molybdenite concentrate. As the only purpose of the roast is to convert the sulfide, MoS_2, to an oxide, MoO_3, the oxide contains virtually all of the impurities present in the original concentrate. Usual practice is to roast the molybdenite concentrate in multiple hearth furnaces, operated on a heat gradient ranging from about 300° F on the drying to 1,250° F on the roasting hearths. The sulfur dioxide is discharged into the air. For some uses, the molybdic oxide is purified by sublimation or chemically to yield a product of about 99.95 percent MoO_3.

Molybdenum metal powder is produced by the hydrogen reduction of purified molybdic oxide or ammonium molybdate. (Ammonium molybdate is the purest commercially available molybdenum compound. It is produced by dissolving purified oxide in ammonium hydroxide. The solution is then filtered and evaporated, crystallizing out the pure compound.) For fabrication by powder metallurgy methods, the metal powder is compacted into ingots or bars and sintered in a vacuum or a hydrogen atmosphere. Smaller ingots are sintered by resistance heating but large ingots, up to several hundred pounds, are sintered by radiation or induction heating. The sintered piece is further shaped by hot rolling, swaging, or forging.

For larger ingots an arc casting procedure has been in use since about 1945. The process comprises vacuum or inert-gas arc melting in a water-cooled copper mold. The melting takes place in an arc, which operates between a consumable molybdenum electrode and a pool of liquid metal in the mold. Ingots weighing more than a ton can be produced in this way for subsequent extrusion, rolling, or forging (*1*). The consumable electrode is a product of powder metallurgy composed of molybdenum powder, a deoxidizing agent (usually carbon), and sometimes alloying additions.

Two grades of ferromolybdenum are produced, high-carbon and low-carbon. The high-carbon ferromolybdenum is produced in electric furnaces from a charge, consisting typically, of 900 pounds of technical grade molybdic oxide, 200 pounds of iron, 100 pounds of coal, and 160 pounds of lime (*8*).

Low-carbon ferromolybdenum is made either by the aluminothermic or the silicothermic reduction of molybdic oxide.

USES (*3, 6, 8, 9*)

Of the molybdenum consumed in 1963 in the United States, 69 percent was used in alloy steels, 14 percent was used in alloy cast iron and steel mill rolls, 4 percent in high-temperature alloys, 4 percent as metal, and 9 percent in chemicals and miscellaneous applications.

Molybdenum enhances the properties of steel both from its effect in solid solution in ferrite and from its effect in the carbide phase. Low-alloy steels designed for use without heat treatment frequently contain 0.10 to 0.25 percent molybdenum to increase the strength of the steels. Heat treatable low-alloy steels in most instances contain 0.10 to 1.50 percent molybdenum to promote uniform hardness and strength and to reduce softening on tempering at about 1,000° F, to increase strength and creep resistance at elevated temperatures, to reduce brittleness after tempering, and to retard embrittlement in those steels subjected to stress at temperatures of 600° to 1,000° F. Most of these heat treatable low-alloy steels contain less than 0.5 percent molybdenum, often with chromium, nickel, or both, but those designed for moderately high-temperature service often contain more than 0.5 percent molybdenum. Some corrosion-resistant austenitic stainless steels contain 2.0 to 3.0 percent molybdenum to enhance chemical resistance and class A type high-speed steels contain 5.0 to 9.0 percent molybdenum. In the latter steels molybdenum increases hardness and strength at the high operating temperatures developed during cutting operations.

Small additions of molybdenum to cast iron improve its tensile and impact strength, hardenability, and resistance to chipping.

Molybdenum metal has long been used by the electrical industry and more recently in electronics. It is used as filament supports and as mandrels for winding coiled tungsten filaments. Anodes, grids, shields, cathodes, glass-metal joints, and structural parts of electronic tubes employ molybdenum. Electric furnace heating elements, electrical contacts, and electrodes are made of molybdenum metal or molybdenum base alloy.

The missile industry uses molybdenum in high-temperature applications such as nozzles, leading edges, and numerous structural parts.

In the metalworking industry a wide range of uses includes boring bars, hot-work tools, resistance-welding electrodes, molds, thermocouples, and injection molding equipment.

Electrodes for use by the glass industry, weighing 25 to 50 pounds each, comprise an important use for molybdenum.

The nuclear-energy and the chemical industries require molybdenum for tubing, heat exchangers, heat shields, and structural parts.

Sprayed molybdenum has gained importance as a coating for surfaces subject to frictional wear such as shaft bearings and crankshafts.

A potential for growth in the use of molyb-

denum base alloys has emerged during the last decade with advances in fabricating procedures. A 70-percent molybdenum-30 percent tungsten alloy, for example, has been widely adopted by the zinc die casting industry for injection nozzles. One report indicated a life 50 times longer than that of hot-work or high-speed steels. TZM, a molybdenum-0.5 percent titanium-0.08 percent zirconium alloy is also one of the more promising materials of construction for high-temperature use. Growing use of molybedenum-rhenium alloys is due to improved ductility without significant loss of molybdenum's desirable high-temperature characteristics.

Molybdate chrome orange is a pigment used in paints, printing ink, and plastics. Molybdenum catalysts are used in reforming and desulfurizing of petroleum, in hydrogenation of coal, and in other processes. They are effective in reactions involving oxidation, hydrogenation, dehydrogenation, isomerization, cyclization, chlorination, dehydration and condensation, polymerization, and alkylation. Molybdenum disulfide, added to lubricating oils and greases, is widely used in applications requiring superior performance.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Principal byproducts of molybdenum are tungsten concentrate, pyrite, cassiterite, bismuth, and rhenium-bearing materials. The first three are produced at the Climax mine; bismuth is recovered at the LaCorne mill in Canada; and rhenium is recovered from the flue dust collected at some molybdenite conversion plants. Minute quantities of monazite and topaz occur in the Climax molybdenum deposit. These have not been recovered in commercial quantities but some research has been directed toward their recovery.

About 27 percent of the domestic molybdenum concentrate production in 1963 was from copper and tungsten mines. However, expansion at the Climax and Questa mines will reduce the future percentage of the byproduct component.

Tungsten concentrate produced from ores of many deposits contains molybdenum in varying quantities up to about 3 percent as an impurity. Some of this concentrate is used in high-speed steel when the molybdenum is desired, but for some other uses of tungsten, molybdenum is a harmful impurity.

ALTERNATE MATERIALS

There has been little, if any, direct substitution of other metals for molybdenum. Molybdenum is usually considered an alternate material to replace tungsten and other ferroalloy metals in some uses rather than as a metal for which others can be substituted. Molybdenum can replace tungsten in certain high-speed steels, and the reverse is technically feasible, but costs usually favor molybdenum. Boron steels may be used to a limited extent to replace molybdenum-bearing steels where hardenability is the only alloying effect desired. Chromium and manganese could also be substituted for molybdenum to impart hardenability.

Vanadium is also a potential substitute for molybdenum in some steels.

Composite materials, exemplified by the use of a thin molybdenum coating sprayed on piston rings to impart wear resistance, in a sense, can be classed as substitute materials. Honeycomb cores, laminations, fiber reinforced materials, and numerous other composites either replace molybdenum or reduce the quantity that might otherwise be used.

SECONDARY SOURCES AND RECOVERY

Molybdenum, high-speed steels, low-alloy molybdenum-bearing steel, and commercially pure molybdenum scrap are the major sources of secondary molybdenum, but data on the quantities recovered annually are not available. Molybdenum in high-speed steel scrap is reused in making high-speed or other types of tool steels. However, much of the low-alloy scrap goes into carbon steel melts where the molybdenum is diluted and lost to the secondary supply. This loss is due primarily to costs involved in the identification of the alloying elements in such scrap and to the cost of segregating scrap to eliminate contamination.

Relatively pure molybdenum scrap is an important source of molybdenum for nonferrous-molybdenum-bearing alloys, but the quantity of this scrap comprises only a small part of the total secondary molybdenum supply.

RESERVES

Much of the known world molybdenum resource is in the United States, but molybdenum mineralization is widespread and erratic. Many deposits in various parts of the world have not yet been fully explored, because molybdenum is relatively new in its role as an important industrial material. Furthermore, abundant supply from a single, large producer and a number of low-cost byproduct producers undoubtedly has slowed prospecting and exploration until recent years. Continued growth in

demand, however, has stimulated interest and investment, marking the present decade as one of significant expansion.

The known, commercial U.S. molybdenum reserve exceeds 1.5 million tons and potential sources may contain as much as 3 to 5 million tons additional. Proven ores at Climax, Colo., contain 1 million tons of molybdenum; copper and tungsten deposits may contain as much as 350,000 tons of byproduct molybdenum; other deposits under active investigation or development (including the Questa, N. Mex., and the Urad, Colo., deposits) may contain 500,000 or more tons of molybdenum depending on the cutoff grade used for classifying ore.

Domestic resources therefore can be expected to yield 1,850,000 tons of molybdenum from deposits that are now being mined or investigated. As a basis for comparison, this reserve can be regarded as a 37-year supply at an average annual output of 50,000 tons. Domestic production in 1963 totaled 32,500 tons.

Known molybdenum occurrences in Alaska, Arizona, Colorado, Montana, Nevada, New Mexico, North Carolina, and Washington; inferred reserves at operating mines; molybdenum in vanadiferous shales in Idaho, Montana, Utah, and Wyoming; molybdenum-bearing uranium ores in several States; and uranium-bearing lignite in the Dakotas provide reasonable assurance that more than 5 million tons of molybdenum are contained in domestic resources.

About 700 molybdenum occurrences are known in Canada, but few have been productive to date (*11*). Prior to 1963, production exceeded 500 tons only in 1944. Recent exploration has increased the known reserve sufficiently to justify new mine development, but no firm estimate of the total resource is available. Announced developments are expected to increase annual molybdenum output from about 500 tons in 1963 to as much as 8,000 tons in the next 2 to 4 years. Assuming that a minimum 10 year operation is needed for amortization the commercial reserve must contain at least 80,000 tons. One recent estimate suggests 250,000 tons (*5*).

Chile has the largest free world reserve (*9*) outside of the United States. The major portion is in porphyry-copper deposits although a number of small higher grade occurrences are known. Three large copper mines, El Teniente, Chuquicamata, and El Salvador, with some 2.0 to 2.5 billion tons of ore contain some 400,000 or more tons of byproduct molybdenum.

Three large deposits in Peru, the Toquepala, the Quelleveco, and the Cuajone contain minable reserves of copper ore exceeding 1 billion tons. One of these began producing byproduct molybdenum in 1962 and together they may contain 50,000 to 100,000 tons of molybdenum.

Other free world sources with production in 1963 are in Japan, Norway, Mexico, Republic of Korea, and the Philippines. Occurrences of varying potential are known in Turkey, Greenland, Yugoslavia, Australia, and other countries.

Although confirmation and detailed descriptions are lacking, there is little question that the U.S.S.R. molybdenum resource is substantial. More than 100 deposits are known and Russian writers have stated that the reserve is second only to that of China. Reserves in the Soviet Union may approach 1 million tons of contained molybdenum in ores of various economic grades. However, a large part of this total cannot readily be exploited at the present time for geographic and economic reasons.

A 1959 report indicated that 46.2 percent of U.S.S.R. output came from copper-molybdenum ores; 33.2 percent from molybdenite ores; 17 percent from tungsten-molybdenum skarns; and the remainder from miscellaneous types.

Reports of large deposits in mainland China have been published in recent years. However, claims that China has the largest molybdenum resource in the world are not supported by credible data. The Yang-Chia-Chang-Tzu mine in western Liaoning Province, in Manchuria, was estimated, in 1939, to have 8 million tons of ore containing 8 pounds of molybdenum per ton. This and other large deposits in which molybdenum is associated with copper, lead-zinc, or tungsten undoubtedly comprise a large potential. The Chinese claim that extensive molybdenum deposits have been discovered in the Chiń-ling (Tśin-ling) Mountains somewhere in Shensi and Honan Provinces.

CONSERVATION PRACTICES IN PRODUCTION AND USES

Mining and concentrating efficiency permit the exploitation of ores containing only a few pounds of molybdenite (MoS_2) per ton as the major commercial mineral. Some byproduct producers recover molybdenite from ores containing only fractions of a pound per ton. A new unit to recover molybdenum from oxidized ores is scheduled to begin operation at Climax in 1966. Commercial recovery of byproduct molybdenum from uranium ores was reported in 1963.

Recovery exceeds 91 percent of the molybdenite contained in crude ore treated at Climax. Recovery from the copper ores is much lower because of the very low content in the crude ores, but in some instances is estimated as high as 80 percent. Recovery of molybdenum from concentrate at conversion plants is on the order of 99 percent. Molybdenum-bearing scrap is an important source of molybdenum although

much of the molybdenum used in low-alloy steel is lost.

Rhenium is recovered as a byproduct from the flue dust of some molybdenite concentrate roasting plants but the process is costly and, therefore, not economic for all plants.

SOURCES OF STATISTICAL INFORMATION

In the United States, data on production, shipments, consumption, and stocks of both molybdenum concentrate and primary products are compiled and published monthly and in the Minerals Yearbook by the Federal Bureau of Mines. Production figures on some primary products are not published separately because such information would reveal individual company information. Export and import data are compiled by the Bureau of Census. Information on the total quantity of molybdenum consumed in steel and quantities of molybdenum type steels produced are compiled and published by the American Iron and Steel Institute.

Data on foreign exports and imports are published in the Statistical Summary of the Mineral Industry Overseas Geological Surveys (London); Statistical Yearbook of the United Nations (New York); and in monthly and annual publications of the Department of Mines of the respective countries. Statistical information on the expanding molybdenum industry of Canada is published by the Mineral Resources Division, Department of Mines and Technical Surveys, Ottawa.

PRODUCTION, CONSUMPTION, AND TRADE

World production of molybdenum in ores and concentrates, by countries, 1959–63, is given in table 2. World production for the period 1905–55 was published (*6*) and, for individual years, to date, in the Minerals Yearbook series.

In 1963 the United States provided 71 percent of the world's total new supply. Estimated production of the U.S.S.R. was 14 percent and that of Chile was 7 percent of the world total.

U.S. consumption of molybdenum in concentrate comprised about 54 percent of estimated world output in 1963. However, some of this was exported as molybdic oxide, ferromolybdenum, and other products for end-use consumption overseas. Reported consumption of products in the United States as shown in table 3, was about 41 percent of world concentrate output.

Molybdenum consumption data for many foreign countries are not available, but an estimate for 1963, based on supply available from stocks and new production, indicates that all other nations consumed some 26,500 tons compared with U.S. consumption of about 21,500 tons (2,500 tons of molybdenum released from the U.S. Government stockpile in June of 1962, was believed to have entered the market during 1963).

The United States is the major source of molybdenum for the free world. Exports of concentrate, molybdic oxide, and ferromolybdenum during the 1950–63 period were equivalent to about 50 percent of the U.S. consumption. Imports to the United States have been minor.

The U.S. tariff rates effective August 31, 1963, were for molybdenum ore, 24 cents per pound of contained molybdenum; for ferromolybdenum and unwrought metal, 20 cents per pound of contained molybdenum plus 6 percent ad valorem; for waste and scrap, 21 percent ad valorem; and for wrought metal 25.5 percent ad valorem.

TABLE 2.—*World production of molybdenum in ores and concentrates, by countries* [1] [2]

[Short tons]

STRATEGIC CONSIDERATIONS

The United States produced more than 70 percent of the world molybdenum output in 1963 and domestic mine-mill capacity is expected to increase by about 30 percent in the next several years. Chile is a major producer, and Canada is expected soon to become a major producer. Transportation of molybdenum is not a major problem because the tonnage involved is relatively small.

TABLE 3.—*Domestic consumption of molybdenum products by end uses in 1963*

[Short tons of contained molybdenum]

End use	Molybdic oxides [1]	Ferromolybdenum [2]	Molybdenum metal powder	Ammonium molybdate	Sodium molybdate	Other [3]	Total 1963
Steel:

Stocks at consumer plants, Dec. 31	1,692	875	11	7	13	139	2,735

[1] Includes technical and purified oxides.
[2] Includes molybdenum silicide and calcium molybdate.
[3] Includes thermite molybdenum, molybdenum pellets, purified molybdenum disulfide, and molybdenite concentrate added direct to steel.
[4] Includes quantities that were believed used in producing high-speed and stainless steels because some firms failed to specify individual uses.
[5] Includes magnets, other special alloys, friction material, lubricants, pesticides, refractories, packings, etc.

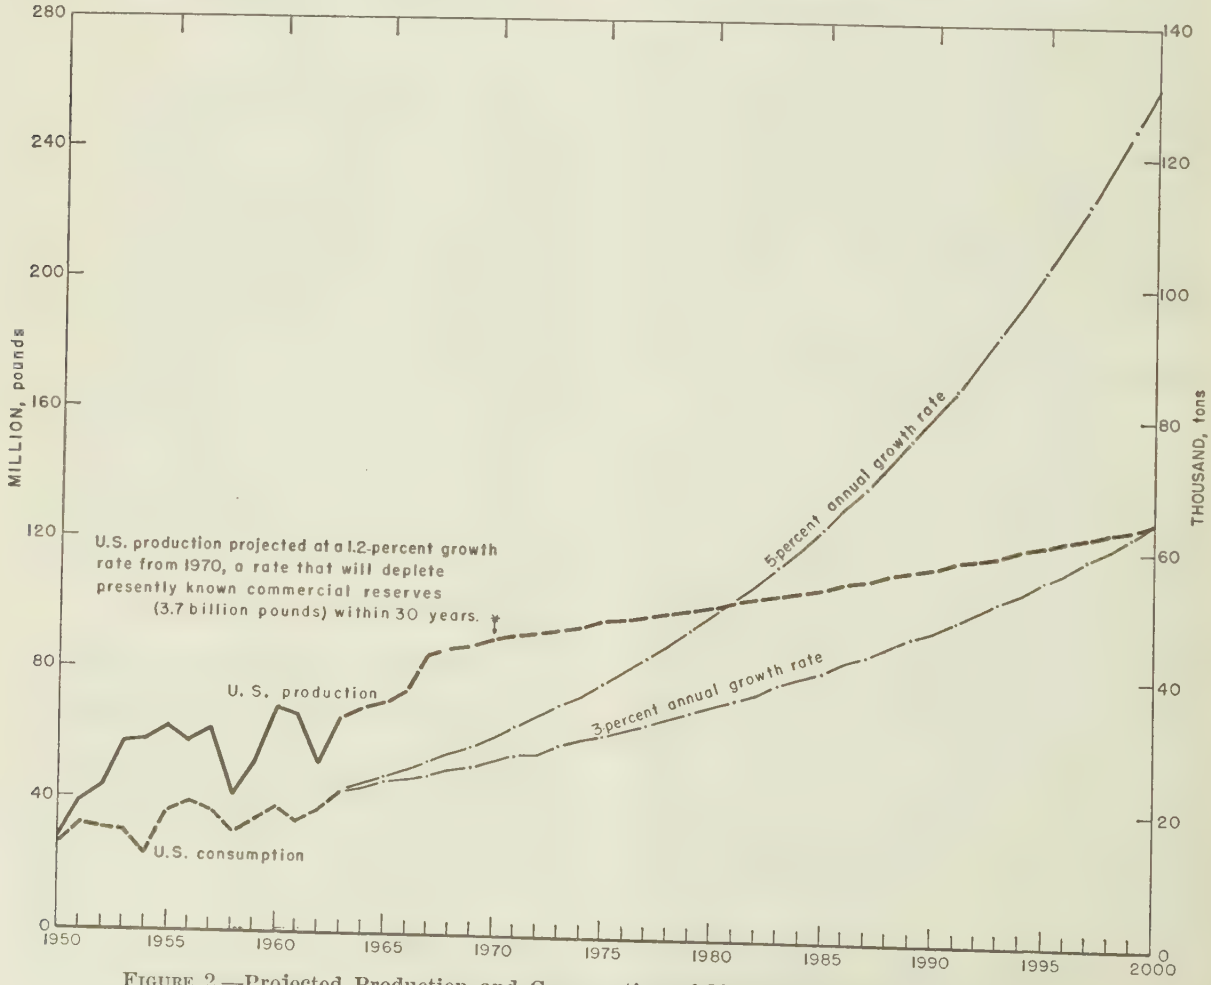

FIGURE 2.—Projected Production and Consumption of Molybdenum in the United States.

The national (strategic) stockpile contained 40,000 tons of molybdenum on June 30, 1964. Release of surplus material was expected to reduce this to 34,000 tons by the end of 1964.

Domestic ore resources, including potential ores that can be worked at sufficiently high prices, will not be depleted before the end of this century. However, a continued high rate of growth in demand will require continuing appraisal of the resource base and productive capacity.

GOVERNMENT PROGRAMS

To encourage exploration of domestic molybdenum deposits, the Office of Minerals Exploration, provides assistance to private industry, in the amount of 50 percent of the approved estimated cost, with the moneys to be repaid from production.

PRICES

The price of molybdenum has been notably stable over many years. The price of a pound of molybdenum contained in concentrate increased steadily from a low of 70 cents in 1932 to $1.40 in 1963. Price advances for ferromolybdenum, molybdic oxide, and other products paralled those for the concentrate.

TAXES

Producers are granted a depletion allowance of 15 percent on income from both domestic and foreign production.

RESEARCH

The Climax Molybdenum Co. has maintained a research department since 1924, and much of the rapid growth of the industry is attributed to its research in mining, milling, processing, and uses of the element in end products. Producers of byproduct molybdenum have increased overall recovery through improved flotation systems. Many consuming firms maintain research departments and have made significant contributions to solving processing and fabricating problems encountered and have developed new applications. Institutions have conducted research to devise means of protecting the pure molybdenum in oxidizing atmospheres at elevated temperatures and made other studies to expand knowledge of its properties and uses. The Government has sponsored much of the research on molybdenum conducted by industry and institutions, in addition to the work done by its individual agencies.

Bureau of Mines investigators have conducted mining and extractive-metallurgy research and have issued a series of reports providing thermodynamic data. Bureau research on molybdenum melting and casting procedures (2) and on the extraction of molybdenum from fused salts (4) was described in recent years.

In the last decade significant advances have been made in major problem areas: Difficulties in fabrication of arc-cast ingots have been largely overcome; quality of molybdenum sheet has been greatly improved and larger sizes are available; methods for protecting molybdenum against oxidation have markedly raised the temperature at which it can be used. Continuing research has added many new molybdenum alloys to the lists of available special property materials (7).

The Climax Molybdenum Co. and Battelle Memorial Institute have published data on the properties and uses of molybdenum and its alloys.

OUTLOOK

Inasmuch as the domestic steel industry accounts for about 80 percent of the U.S. molybdenum consumption, future trends in steel production will largely determine the future consumption of molybdenum. Two factors suggest that total domestic and export demand for molybdenum will increase at a faster rate than domestic steel production. One, alloy steel comprises an increasing proportion of total steel and molybdenum use per ton of steel is increasing. Two, foreign steel production, increased by 280 percent between 1950 and 1963. The consumption of metallic molybdenum, molybdenum-base alloys, and molybdenum compounds is also increasing but as the growth rate relates only to about 20 percent of total consumption it will not significantly influence the overall growth rate. However, a closer relationship has been shown in the postwar years between molybdenum consumption and real gross national product (RGNP). Domestic molybdenum consumption has averaged a 5-percent growth rate while RGNP has averaged slightly more than 3.5 percent. If this relationship holds, and a RGNP growth rate of about 3.75 percent is anticipated, future growth in molybdenum consumption can be expected to increase at least by 3 percent and probably by

5 percent annually as long as it is readily available at a real price only slightly higher than in 1964.

As shown in figure 2, domestic molybdenum production is expected to reach 45,000 tons by 1970, and will equal the projected consumption of 30,000 tons plus exports of 15,000 tons. However, in subsequent years, production in excess of 45,000 tons will be increasingly costly. Thus, although production will increase in response to demand there may be some slowing of the demand-growth rate because of tightened supply or higher price.

Increased production costs per unit of molybdenum will not be due to depletion of the overall reserve but primarily will be due to the difficulty of expanding productive capacity. Recovery of byproduct molybdenum which is relatively low in cost, will comprise a smaller proportion of total output, and mines which produce molybdenum as a principal product may have inherent limitations, as to size, for economic operation. Therefore, new plant, and development of less economic deposits, will be necessary.

During the 14 years (1950–63) U.S. exports of molybdenum were equivalent to about 50 percent of domestic consumption. On this basis, 15,000 tons of molybdenum will be available from the United States in 1970 plus 10,000 to 15,000 from other free world sources and possibly 10,000 tons from China and the U.S.S.R., for a total supply of 35,000 to 40,000 tons for foreign consumers.

Assuming a 3 to 1 ratio of foreign steel production to U.S. steel production, as in 1963, foreign demand for molybdenum in 1970 might approach a 3 to 1 ratio with U.S. consumption, or 80,000 to 90,000 tons. Therefore, although estimates of the future balance between foreign demand and supply are tenuous, there is reason to believe that any lag in the growth rate for domestic demand, below 5 percent, probably will be compensated by the export market.

PROBLEMS

The overall problem of maintaining balance between domestic supply and demand will not be critical in this decade and probably not before 1980. However, component parts of the problem need immediate and continuing study.

The need for more flexibility in production rates, to meet fluctuation in demand, was manifest in the shortages of 1962, 1963, and 1964. The question of equity between domestic and export demand, also evident in these shortages, involves political, economic, and national defense considerations.

Prudent use of molybdenum resources will be increasingly important in future years to assure a continuing supply of molybdenum for essential applications. For example, some molybdenum alloy, catalyst, or other molybdenum-bearing material might continue in use where a more plentiful substitute would perform as well. Another need is for economic methods of reclaiming molybdenum-bearing scrap now being lost by dilution in products where this metal is not needed.

Industrial, defense, and space programs have brought molybdenum applications technology to an advanced stage, but continued research to improve high-temperature strength, fabricability, oxidation resistance, and other properties are needed.

Extractive technology also is well advanced but research is needed for expansion of the resource base. Lower cost sampling, mining, and concentrating procedures are needed to permit exploitation of small or inaccessible deposits which currently cannot support plant amortization. Improved recovery from copper, uranium, tungsten, and other ores and economic extraction from vanadiferous shales are appropriate subjects for additional study.

NICKEL

By Glen C. Ware [1]

NICKEL is used in world production of ferroalloys in an amount exceeded only by chromium. When alloyed with other metals it imparts strength, toughness, hardness, and ductility together with resistance to oxidation and corrosion. Nickel is a component of a series of magnetic alloys and alloys for use in resistance heating elements. Metals are clad with nickel to protect them from corrosion and coated with it to gain luster and beauty.

Although nickel deposits are found worldwide, 90 percent of free-world supply is produced by 3 Canadian companies and a company in New Caledonia. The United States consumes about half of free-world production. Domestic production is derived from Nickel Mountain, an ore deposit near Riddle, Oreg. The ore, containing about 1.5 percent nickel, is expected to support the present production rate through the year 1978.

Canadian nickel is derived chiefly from pentlandite, a sulfide mineral associated with pyrrhotite and chalcopyrite. In the Sudbury area, as many as 14 products are obtained, chief of which are nickel, iron ore, copper, and the platinum-group metals. A new deposit opened at Thompson, Manitoba, contains less of precious metals, but a modern, highly efficient plant and an abundant reserve assure profitable operation and ability to expand to meet foreseeable demands for nickel. Garnierite is exploited in the only United States nickel plant. Although the output is small compared with U.S. demand for nickel, the operation is important as a possibility to expand domestic production if ample reserves should become available through discovery or improved benefication methods.

Laterite and serpentine deposits are widespread throughout the tropics and constitute the world's largest source of nickel. They are being exploited in Cuba, New Caledonia and the Celebes and being investigated in the Dominican Republic, Central America, New Guinea, and the Philippines. The difference in composition of the various nickel ores requires a variety of mineral dressing methods, and complex pyrometallurgical, chemical and electrolytic processes are needed to recover nickel.

During the period 1959–63 more than 80 percent of the primary nickel consumed in the United States went into the manufacture of alloys. The largest single application was to the manufacture of stainless steels where the use is expected to increase significantly.

During 1959–63 the consumption of nickel averaged 116,500 tons per year, an increase of 9 percent over that of 1954–58. Owing to newly developed uses, increased use in new product lines, and the availability of nickel, consumption is expected to rise sharply throughout the world.

One of the more important remaining metallurgical problems is that of achieving high recovery of nickel from laterite and serpentine ores. Other problems involve the efficient and economic separation and recovery of coproduct or byproduct metals from ores, scrap alloys, and spent catalysts. Among the many physical metallurgical problems in the development and utilization of new alloys are those connected with the preparation of extremely pure nickel and of high-strength, high-temperature alloys to withstand extreme temperature changes.

BACKGROUND

Coins of Asia Minor of the pre-Christian era contained nickel, and its alloys are mentioned in ancient Persian fables in which the mythological warriors fashioned their "Heaven-sent" blades from meteoric iron. By the ninth century A.D. the Chinese used a nickel, copper, and zinc alloy called paitung or "white-copper." Nickel began its Western history in Saxony, Germany, in the middle of the 18th century

[1] Commodity specialist.

when miners stumbled upon it while working with lodes of copper and silver ore. Smelting of this ore produced a hard white shiny metal, seemingly full of promise, but not being able to work the metal into useful articles, the superstitious miners named the ore "kupfernickel" after "Old Nick" and his mischievious gnomes whose duties were to plague the workers and bewitch the raw materials.

In 1694 W. Hiarne described kupfernickel as having the appearance of copper ore but yielding no copper. The Swedish scientist Axel Cronstedt identified nickel as an element, isolating it from a copper-nickel ore. Twenty-five years later Bergmann confirmed the discovery. In 1776 G. von Engestrom showed that paitung contained nickel, copper, and zinc. In 1781 Richter produced the first nickel pure enough to enable him to describe its physical and chemical properties with remarkable accuracy.

The use of nickel was limited largely to making German-silver alloys until Faraday developed electroplating. By 1844 plating was firmly established in England. A further impetus to greater use of nickel resulted from a change in policy toward token-money coinage. In 1860 Belgium adopted a composition of 75 percent copper and 25 percent nickel for some of its coins. The United States did the same in 1865, Germany in 1873, and Switzerland in 1879. Joseph Wharton's work with a malleable pure nickel enabled Switzerland to issue pure nickel coins 2 years later. At the same time Fleitmann pioneered in the development of nickel-clad steel.

Until 1870 nickel production was limited to small deposits in China, Germany, Greece, Italy, Norway, Sweden, and the United States. From 1853 to 1893 only about 2,000 tons of nickel was produced domestically at the Gap mine near Lancaster, Pa., and at Mine La Motte near Fredericktown, Mo.

In 1864, nickel silicate ore was discovered in New Caledonia by Garnier, after whom the mineral, garnierite, was named. Commercial mining in New Caledonia, began in 1874 and New Caledonia was the principal source of nickel until 1905 when Canada became the leading producer. The mine at Riddle, Oreg., was brought into operation in 1954.

The International Nickel Co. of Canada, Ltd. (Inco), the world's largest nickel producer, was formed in 1902 by a merger of the Canadian Copper Co. and the Orford Copper Co.

The free world capacity to produce nickel is estimated at more than 330,000 tons annually, Canada alone accounting for more than 250,000 tons. Inco has a rated annual capacity of 200,000 tons; Falconbridge Nickel Mines, Ltd., 37,500 tons; and Sherritt Gordon Mines, Ltd., 15,000 tons. The annual rated capacity of the Cuban plants seized by the present Cuban government is 50,000 tons, but production is reported to be about half this rate. The U.S.S.R. is estimated to produce about 100,000 tons of nickel per year.

Large scale smelting and refining of nickel ores became feasible when the Orford process to separate nickel and copper mattes was combined with the Mond process to refine nickel. By the Orford process sodium sulfide is heated with the matte to produce a melt from which a layer of copper-sodium sulfide separates and floats on a layer of nickel sulfide. After the melt has cooled the solid layers are separated with a blow of a hammer. In the Mond process the nickel sulfide is roasted to oxide which is reduced to pure nickel with hydrogen and carbon monoxide. A volatile nickel carbonyl is produced which can be decomposed by heat to produce nickel and regenerate carbon monoxide. Both of these processes, were reduced to practice in the last decade of the 19th century, and their application brought Canada into first position as a producer of nickel in 1905. Modern mineral dressing technology has replaced this method making it only of historic interest.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1963, the United States consumed 48 percent of the nickel produced in the free world, and contributed only 4 percent of world production. The Hanna Nickel Smelting Co., Riddle, Oreg., produced 10,700 short tons and 700 tons was a byproduct of copper. The Hanna company markets ferronickel recovered from ore mined by the Hanna Mining Co. The smelter has a capacity of about 14,000 tons per year. National Lead Co., Fredericktown, Mo., had recovered nickel from complex ore but the mine and refinery were closed in 1961.

Many companies, the largest ones at Cleveland and Cincinnati, Ohio, produce 3,000 to 3,500 tons of nickel salts annually using metal, residues, oxide, and scrap. Table 1 lists United States refiners and processors and their products.

The principal nickel producing countries in the free world during 1959–63 were Canada with 77 percent of the total free world production; New Caledonia, 13 percent; United States, 8 percent; and Republic of South Africa and Finland, 1 percent each. The total capacity of free world mines is estimated to be about 330,000 tons of nickel per year. Of this total, the capacity of Canadian producers amounts to about

250,000 tons. Table 2 gives estimates of nickel producing capacity of various firms and countries at yearend 1963. The expropriated U.S. Government facilities at Nicaro and those of the Freeport Sulphur Co. at Moa Bay, Oriente Province, Cuba are reported to be producing nickel at an annual rate of about 50 percent of their original combined capacity of about 50,000 tons of nickel.

TABLE 1.—*Refiners or processors of nickel in the United States in 1963*

Refiner or processor	Location of plant	Nickel products made
Allied Chemical Corp., General Chemical Division.	Marcus Hook, Pa.	Carbonate, salts.
American Metal Climax, Inc.	Carteret, N.J.	Sulfate.
American Smelting and Refining Co.	Perth Amboy, N.J.	Do.
Baker Chemical Co., J. T.	Phillipsburg, N.J.	Carbonate, salts.
Hall Chemical Co.	Wickcliffe, Ohio	Carbonate.

Shepherd Chemical Co.	Cincinnati, Ohio	Carbonate, hydrate, salts.

TABLE 2.—*Size and distribution of principal producers of nickel*

Country and producer	Location of mines	Refined nickel products (short tons of nickel)	
		Annual capacity end of 1963	Planned annual capacity by 1963
Canada:			
The International Nickel Co. of Canada, Ltd.	Sudbury, Thompson.	205,000	225,000
Falconbridge Nickel Mines, Ltd.	Sudbury	38,000	45,000
Sherritt Gordon Mines, Ltd. (refinery capacity).	Lynn Lake, Fort Saskatchewan.	15,000	15,000
New Caledonia: Société le Nickel.	New Caledonia	32,000	39,000
Japan: Refinery capacity (using imported ores).		25,000	30,000
United States: The Hanna Mining Co.	Riddle, Oreg.	13,000	14,000
Byproduct production from copper refining.		700	850
Other countries: Brazil, Finland, Morocco, Southern Rhodesia, and Republic of South Africa.		600	1,000

Supply of nickel to the United States comes chiefly from Canada, which supplied approximately 90 percent of the total U.S. nickel imports in the period 1959–63. Most of the nickel imports were supplied by Inco. Other Canadian suppliers were Falconbridge Nickel Mines, Ltd., and Sherritt Gordon Mines, Ltd. The supplier of New Caledonian nickel was Société Le Nickel, S.A.

The International Nickel Co. of Canada, Ltd., operates Creighton, Frood-Stobie, Garson, Levack, Murray and Clarabelle mines in the Sudbury district, Ontario, and the huge Thompson mine at Thompson, Manitoba. The firm also operates ore concentrators at Copper Cliff and Creighton, smelters at Copper Cliff and Coniston, and a refinery at Port Colborne, in the Sudbury district. It also operates a nickel refinery at Clydach, Wales, and a large rolling mill at Huntington, W. Va. It recently established a new research laboratory at Sterling Forest, N.Y. Inco's nickel plant at Thompson is a fully integrated complex. Activities at this recent development range from mining to production of nickel metal in various forms. Annual nickel-producing capacity at the Thompson complex has been expanded from the planned 38,000 tons to over 45,000 tons.

Falconbridge Nickel Mines, Ltd., operates the Falconbridge, East, Hardy, and Fecunis mines in the Sudbury district, a smelter at Falconbridge, Ontario, and a refinery at Kristiansand, Norway. In 1963, Falconbridge's total mine development advances amounted to 42,000 feet, and total diamond drilling totaled 344,000 feet. Drilling and other mine development programs were initiated by the Marbridge Mines Ltd., a firm jointly owned by Falconbridge and Marchant Mining Co., Ltd.

Sherritt Gordon Mines Ltd., operates mines at Lynn Lake, Manitoba, and a refinery at Fort Saskatchewan, Alberta. Other Canadian producers of nickel materials are Giant Mascot Mines, Ltd., Metal Mines Ltd., Raglan Nickel Mines Ltd., and McIntyre Porcupine Mines Ltd.

The largest nickel ore mining operation in New Caledonia is on the Thio Plateau. The refinery center is at Pointe Doniambo where nickel-sulfide matte and ferronickel are produced. The matte is shipped to Le Nickel's refinery at Le Havre, France, for conversion to refined nickel.

GRADES AND SPECIFICATIONS

Primary nickel products of smelters and refineries are chiefly metal, oxide, and ferronickel. Most primary nickel metal in the United States is sold as electrolytic cathodes, whole or cut into convenient sizes, containing 99.95 percent nickel. Nickel metal also is supplied in ingots, shot, briquets, pellets, and powder. National stockpile specifications for various forms of metal and oxide are given in table 3.

TABLE 3.—*Nickel purchase specifications for national stockpile* [1]

Constituent	Chemical requirements, weight-percent					
	Metal				Oxide	
	Electrolytic	Ingots	Briquets	Shot	Powder	Sinter
Nickel plus cobalt, minimum	99.50	98.50	99.50	98.90	76.50	[2]76.50
Cobalt maximum	1.00	1.00	1.00	1.00	1.00	1.10
Iron maximum	.25	.90	.25	.60	.50	3.00
Sulfur maximum	.02	.07	.02	.05	.05	.08
Carbon maximum	.10	.30	.10	.25	.10	.10
Copper maximum					.30	.30

[1] National Stockpile Specification P–36–R, Oct. 11, 1956.
[2] When the nickel plus cobalt content of sintered nickel oxide exceeds the minimum requirement the cobalt, iron, sulfur, carbon, and copper may increase proportionately.

NOTE. Physical requirements follow:
1. Electrolytic nickel shall be in the form of rectangular cathodes, cut or uncut, of any thickness or dimensions usual with the producer, except that all cathodes in a lot shall be of the same dimensions, which shall be not less than 4 by 4 inches nor more than 27 by 36 inches.
2. Nickel ingots and nickel briquets may be of any size and shape usual with the producer, but all ingots or briquets in a lot shall be of the same size and shape. Material shall have a clean surface, free from dirt, slag, or other foreign materials.
3. Nickel shot may be of any size usual with the original producer.
4. No particle size requirements shall apply to nickel oxide.
5. All sintered nickel oxide shall pass a 2-inch sieve. Not more than 10 percent by weight shall pass a ¼ inch U.S. Standard Sieve (A.S.T.M. Designation E 11). Sintered nickel oxide shall contain not less than 99 percent by weight of sintered material.

Ferronickel is an alloy of iron and nickel. Domestic ferronickel is cast into 50-pound pigs and contains 40 to 50 percent nickel, 49 to 59 percent iron, 0.5 percent cobalt, 0.10 percent chromium, 0.050 percent phosphorus, 0.015 percent carbon, 0.010 percent sulfur, and 0.30 percent copper. The compositions of some nickel alloys used by industry are given in table 4.

TABLE 4.—*Composition of commercial forms of nickel used by industry, in percent*

Constituent	"F" nickel shot and ingots	Nickel-copper-chromium-iron pigs	Nickel-chromium-iron pigs	Nickel-silicon granules

Cobalt content of 2 to 3 percent in engineering alloys imparts harmful effects if used for atomic energy applications, where the maximum tolerable amount is 0.2 percent. Cobalt content up to 7 percent imparts no seriously harmful qualities to nickel anodes. However, for fabricating engine valves, where cobalt interferes with the normal heat treatment cycle, 1 percent is the maximum that can be tolerated.

The National Bureau of Standards (NBS) has available three nickel oxide standard samples designated with the following numbers: NBS 671, NBS 672, and NBS 673. These standards are intended for use in checking and calibrating chemical and spectrochemical methods used in the analysis of high-purity nickel, particularly electronic-grade and electrolytic nickel. Four new high-temperature alloy standards designated as, Udimet 500, Inco 713–A, Inco 713–B, and Inco 713–C are available from the NBS. These samples are intended for use in optical emission and X-ray fluorescent analysis. Nickel content of these alloys ranges from 51.9 percent for Udimet 500 to 75.5 percent for Inco 713–A.

TECHNOLOGY

Geology

The nickel deposits fall into three general classifications—nickel-copper sulfides, nickel silicates, and nickel laterites and serpentines. Most of the nickel produced at present is from the huge Canadian deposits of the sulfides of nickel, copper, and iron, chiefly pentlandite $(NiFe)_9S_8$, chalcopyrite $CuFeS_2$, and pyrrhotite Fe_7S_8. These ores occur in large disseminated bodies and in small-to-moderate-size massive sulfide bodies. In addition to nickel, copper, and iron, ores contain varying quantities of cobalt, gold, silver, selenium, tellurium, and platinum-group metals.

The largest known deposits of nickel silicate ores, mostly garnierite, are in New Caledonia. Garnierite is a green hydrous nickel-magnesium silicate of variable composition $(H_2(NiMg)SiO_4 \cdot nH_2O)$. The intensity of its green color is directly proportional to the nickel content. In addition to the New Caledonian deposit, there are commercially significant nickel silicate deposits in South America, Indonesia, and the United States.

Nickeliferous laterite mantles are formed by weathering of ultrabasic rocks, notably serpentine. The content of weathered minerals decreases with depth down to unweathered rock without demarcation, and the deposits are referred to as laterite and serpentine. The typical composition of these mantles is about 40 percent iron, 1 percent nickel, 2 percent chromium oxide, and 0.05 percent cobalt. Laterite type deposits constitute the largest known potential resource of nickel in the world. Nickeliferous iron laterite deposits, measured in hundreds of millions of tons, occur in Cuba, the Philippine Islands, the Celebes Islands, and parts of Borneo. Smaller and lower grade deposits are found in Japan, Madagascar, U.S.S.R., Greece, Puerto Rico, and elsewhere.

Small quantities of native alloys of nickel and iron of terrestrial origin, have been found in New Zealand, Greenland, Oregon, and British Columbia. Similar alloys are also common constituents of meteorites.

Mining

Virtually all Canadian sulfide nickel ore is mined by conventional underground methods. Cemented sand fill is gaining wider application because it results in increased recovery of ore with less dilution. Silicate ores such as garnierite and laterite usually are mined from open-pits with power shovels and trucks as in Cuba and New Caledonia. However, at the Hanna open-pit operation, near Riddle, Oreg., broken ore is trammed down Nickel Mountain and generates power in the electric generators used to brake the tram in its descent from the mine 2,000 feet above the smelter.

The Hanna Mining Co. mines garnierite and several associated minerals which occur in altered peridotite. Ore containing an average of 1.2 percent nickel is dug largely without blasting from 40-foot minimum-width benches spaced at 20-foot vertical intervals. Thirty-ton trucks are loaded with 2½ to 3½-cubic-yard shovels. Boulders of residual rock are rejected. The ore is screened at the mine, and the minus-5-inch material is sent to the tramway surge pile. The oversize is crushed and visually classified into reject and ore. Efforts to blend the ore into a uniform feed to the melting furnaces begin at the mine and persist through all the subsequent operations.

At Canadian mines, where ore formation favors bulk mining, the "blast-hole" and "caving" methods are used. These procedures are more economical than earlier types of shrinkage mining. The blast-hole method has two advantages over shrinkage stoping: More economical distribution of powder and extension of diamond-drill holes to 40 to 100-foot depths. In early shrinkage stoping the holes were seldom drilled beyond 9 feet for each blast. Subsequently, when the powder is detonated at these lower depths, all the ore is torn from the ore face. The resulting large empty space, in turn, allows greater clearance for the broken ore to fall freely to the boxholes. More importantly, the blast-hole method provides safer working conditions for the miners. Since they are not exposed to openstope backs as in shrinkage stoping, they do their drilling in small, safe drift openings.

In the caving method the ore is completely undercut on the bottom of the stope area, and the vertical sides of the stope block are so weakened that the mass of ore gradually collapses of its own weight. When the characteristics of the ore body are right for caving the moving mass of ore is crushed and broken as it caves. The crushed ore is removed through draw holes under the caving block.

Mining practices for silicate and lateritic ores are simple since these deposits are relatively shallow, regularly formed layers covered with a thin, moderate overburden. These ores usually are soft and claylike and are excavated by bulldozers, shovels, and draglines. The first step is the stripping of the overburden, and the second is the collection of ore by power shovel or dragline and loading it into conveyors.

Metallurgy

Nickel is derived from two general types of ore, silicate and sulfide, requiring different extractive methods. Generally, silicate ores cannot be beneficiated by mineral dressing techniques, but sulfide minerals are readily floated or separated magnetically from matrix rock.

Typically an ore from the Sudbury district of Canada is crushed and a nickel concentrate is separated magnetically. The remaining crushed ore is ground and an iron concentrate is separated magnetically and pelletized for blast furnace smelting. The remaining sulfides of copper and nickel are separated by flotation.

The nickel flotation concentrate is treated by an ingenious method. It is roasted with a flux and melted into a matte, which, when cooled slowly, solidifies into a mass containing three separate phases; nearly pure nickel sulfide, copper sulfide, and a nickel-copper alloy containing most of the precious metal content of the ore. The mass is ground; the alloy is recovered magnetically and refined by electrolysis to recover nickel and a residue

containing the precious metals. The nickel and copper sulfides are separated by flotation. Copper sulfide is bessemerized to blister copper and refined by electrolysis. In older plants some nickel sulfide was sintered for sale as oxide; some was roasted for subsequent refining by the Mond process; and some was reduction roasted and cast into anodes. In newer plants the matte is cast directly into anodes for electrolytic refining in which cobalt oxide, elemental sulfur, and a precious metal concentrate also are recovered. The economy attending the use of nickel sulfide anodes in refining favors an increase in the proportion of cathode nickel in the market products. This trend is being hastened by the adoption by electroplaters of anodes consisting of titanium baskets filled with chopped cathodes, eliminating the cost of casting special nickel anodes.

Cuban plants use chemical extraction to recover nickel. The plant at Nicaro leaches with ammonium carbonate and ammonia and recovers basic ammonium carbonate. At Moa Bay sulfuric acid is used to extract the nickel and cobalt which are precipitated with hydrogen.

New Caledonia was the leading producer of nickel prior to the rise of the Canadian industry. In the early plants a nickeliferous silicate of iron and magnesia was smelted with gypsum to produce a matte which was refined to ferronickel in converters. Modern electric furnaces are now used to smelt the ore with coke breeze, producing a refined ferronickel suitable as a master alloy in making special steels.

The Hanna Nickel Smelting Co. smelts garnierite ore at Riddle, Oreg., by the d'Ugine process. The ore is melted in electric furnaces and poured into reaction ladles where reduction is accomplished by adding crushed ferrosilicon to the stream of molten ferronickel. Alloy containing more than 50 percent nickel is made for export, but the average is held to 48 percent to minimize loss of metal in the slag.

At the Sherritt Gordon Mines, Ltd., Fort Saskatchewan, Alberta, sulfide ore is leached with ammonia and oxygen. Copper is separated from the leach liquor with hydrogen sulfide. The liquor is further treated to separate nickel and cobalt which are reduced with hydrogen and recovered as powder. Silicate ores are amenable to this process if first given a sulfating roast. The powdered nickel and cobalt are ideal chemical starting materials and command premium prices. The company has developed a strip rolling process in which powder is compressed into strip, sintered and rolled into fully dense strip suitable for coin blanks or for fabrication into other useful forms.

USES

Nickel has hundreds of important, varied uses. Based on a 1959–63 average annual consumption of 117,000 tons, the largest users were ferrous alloys, 47 percent of the total; nonferrous alloys, 23 percent; electroplating, 15 percent; high-temperature and electrical-resistance alloys, 10 percent; and other uses, 5 percent. Stainless steel accounts for the largest single use of nickel, taking 32,000 tons annually during 1959–63 for the austenitic chromium-nickel types containing 6 to 22 percent nickel.

The austenitic stainless steels of the 300 series are the most important of the nickel-bearing stainless steels. Type 302 with 8 to 10 percent nickel and 17 to 19 percent chromium is a general purpose alloy with many applications. Type 301, an alloy with a lower nickel content than type 302, is used for structural members in aircraft, trucks, and railroad cars where high strength is required. For use at elevated temperatures nickel content of the alloys is increased to 10 to 22 percent and that of chromium, 24 to 26 percent. Higher amounts of nickel and chromium impart to the alloys superior resistance to high-temperature corrosion and scaling in addition to higher strengths.

The automotive industry is the largest single consumer of stainless steels. The largest tonnage goes into decorative trim and other ornamental applications, replacing chromium stainless which does not withstand the corrosive conditions in cities where salt or calcium chloride is used for snow removal or the air contains corrosive industrial gases. Stainless steel is used for structural purposes in trucks, buses, and trailers, but not in passenger cars.

The second largest use of nickel, taking an annual average of 27,000 tons during 1959–63, was for nonferrous alloys. These include nickel-copper, copper-nickel, nickel-chromium, nickel-molybdenum alloys, and superalloys. The most important alloys in the nickel-copper category are the various types of Monel metal. The basic Monel metal which contains about 66 percent nickel and about 32 percent copper, is strong, tough, ductile, and corrosion resistant. Its resistance to corrosion by foods and household cleaning solutions has led to widespread use in dairy and food manufacturing industries. The alloy retains its bright silvery luster in clean outdoor atmospheres; in polluted atmospheres it tarnishes but does not corrode. It is used for roofing and other architectural applications.

The most important nickel-chromium alloys known as Inconels and Illiums have typical compositions of 73.0 percent Ni, 15.0 percent Cr;

and 64.0 percent Ni, 22.0 percent Cr, respectively. The chromium gives these alloys more resistance to corrosion under powerful oxidizing conditions, and the high nickel content gives resistance to corrosion under reducing conditions. The first of the Inconel series had a composition of 76.0 percent Ni, 15.8 Cr, and 7.20 Fe. It was first used in the dairy industry and has since become widely used for such applications as furnace muffles, chemical and food processing equipment, gas turbines, and jet and rocket engines. Because recently developed Inconel alloys can withstand extremely high temperatures, the skin of the X–15 rocket research plane was made from Inconel alloy X–750. The Illium alloys resist corrosion by sulfuric and nitric acids over a wide range of concentrations and temperatures. The alloys are used in pumps, valves, tubing, and other equipment subject to severe acid corrosion.

Nickel-molybdenum and nickel-molybdenum-chromium alloys known as Hastelloys, were developed to resist corrosion by hydrochloric acid and later modified in composition to provide superior corrosion resistance to other mineral and organic acids. They are used primarily for industrial pumps, vats, distillation columns, and other industrial equipment for handling acids and alkaline bleaching solutions. Alloy C with a composition of 55 Ni, 17 Cr, and 17 Mo is one of the few alloys which will resist attack by wet chlorine gas and chlorine dioxide solutions.

The term superalloy was used after World War II to describe a family of high-temperature, high-strength alloys, nearly all containing nickel, and many nickel-based. When aluminum and titanium are added to the above alloys, compounds such as Ni_3Al and Ni_3Ti are formed which greatly strengthen the alloys by precipitation hardening. Most of these superalloys are used below 2,000° F.

An important step in extending the use of superalloys above 2,000°F. was made in 1962 by the E. I. du Pont de Nemours & Co., Inc. with the development of TD-Nickel, an alloy containing 98 parts nickel and 2 parts thoria. The thoria is dispersed uniformly in submicron-size particles. TD-Nickel is much stronger than standard superalloys above 2,000° F., tests showing an ultimate tensile strength of 10,000 pounds per square inch at 2,400° F., at which standard superalloys are virtually useless.

Electroplating accounted for 17,000 tons per year of the nickel used during 1959–63. However, since 1946 minor amounts of nickel have been used to plate various basic materials by techniques which do not require an impressed electric current. Among these methods are the Niphos process, immersion and electroless plating, and the vacuum or sputtering plating.

Nickel is used in electroforming in which a negative matrix is heavily coated with electrodeposited metal to produce useful objects such as fountain pen caps. Phonograph record master dies are electroformed on positive matrices so that they will reproduce positive copies, and they may be backed for strength and plated with chromium to harden the working surface. Highly detailed features can be produced precisely without the need of expensive tooling.

Nickel cast irons consumed an average of 5,000 tons of nickel per year during 1959–63. Nickel in cast iron improves its machinability and resistance to creep, and it imparts uniformity to the hardness of castings. The addition of chromium or molybdenum or both greatly improves the strength of nickel cast irons and their resistance to wear and corrosion. Major uses for nickel cast irons are cylinder blocks, cylinder liners and pistons, industrial melting pots, molds, and steel mill rollers.

Other uses of nickel include catalysts, magnets, and batteries. During 1959–63 an annual average of 1,600 and 850 tons of nickel was used for catalysts and magnets, respectively. The precise amount used for batteries is not known. The most important catalytic use of nickel is for hydrogenation of fats and oils. Nickel is an important constituent of the Alnico type of permanent magnets, used principally in loudspeakers. With the advent of cordless electrical appliances demand for nickel-cadmium batteries has grown. Nickel is used in the ceramic industry for preparing iron sheets prior to enameling and also in the preparation of carbides and other hardfacing materials, glass, lubricants, fuel additives, plastics, rubber, salts, and fungicides.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

A comparatively small quantity of nickel is obtained as a byproduct from cobalt ore, silver-cobalt ores, copper ores, platinum ores, and copper-lead ores. Usually, however, nickel is the chief value in the ores in which it is found associated with other metals and elements. The sulfide ores of the Sudbury district, Ontario, also contain copper, gold, silver, cobalt, tellurium, iron, and plantinum-group metals which are recovered as byproducts or coproducts of nickel processing. The nickel sulfide ores of the Lynn Lake region, Manitoba, contain mostly copper and cobalt, which are also recovered. The nickel silicate ores of Riddle, Oreg., contain minute quantities of cobalt, which are not recovered as a separate product.

Complete realization of the values in the ore is an important factor in the development of mining and metallurgy in the Sudbury area where the smelters and refiners recover as many as fourteen elemental products; they deliver sulfur dioxide to chemical plants to be liquefied or converted into sulfuric acid; and they return waste to the mine for fill. Inco produces iron ore, nickel, copper, cobalt, selenium, tellurium, sulfur, gold, silver, platinum, palladium, rhodium, ruthenium, and iridium.

ALTERNATE MATERIALS

High nickel alloys can be replaced substantially by nickel-chromium-molybdenum steels, boron-bearing steels, chromium-manganese-nickel stainless steels, and nickel-free stainless steels. Should the price of nickel rise significantly, considerable saving might be made by replacing high-nickel steels with case-hardened steel, lower nickel-content stainless steels and nonferrous alloys of lower nickel content. More extended use could be made of iron base alloys and iron-chromium-aluminum alloys in electrical resistors.

A copper alloy with 10 percent nickel and aluminum-base alloys can be substituted for cupronickel alloys for condenser tubes. Nickel can be conserved by replacing Alnico magnets, which contain 14 to 28 percent nickel, with magnets made of iron powder, bismuth-manganese, or barium-ferrite. It may be further conserved by reducing the amount of nickel in aluminum-base and other metal-base alloys. Nickel-plated and nickel-clad products can be used where only surface protection is needed.

SECONDARY SOURCES AND RECOVERY

The largest source of secondary nickel is stainless steel scrap, particularly the 300 series which contain 7 to 36 percent nickel. The second largest source is nonferrous alloy scrap such as cupronickel, nickel-silver alloys, and other nickel alloys. Spent catalysts and high-temperature alloys are important. Table 5 gives the consumption of new and old nickel by users and by the form in which it is used.

Nickel in scrap alloys is most effectively reused by including the scrap in the composition of more alloy, stainless steel going into stainless steel alloys, and other scrap into counterpart alloys. Other forms of nickel recovered from nonferrous scrap are metal, nickel-base and copper-base alloys, ferrous and high-temperature alloys, and various chemical compounds.

Very little of the nickel consumed in electroplating is recoverable as scrap except for small quantities in electrode sludge and spent plating solutions. Spent catalysts also are a small source of secondary nickel.

Insufficient data are available on the disposition of high-temperature alloy scrap. On account of various economic and technological reasons, only a relatively small quantity is treated for recovery of the more expensive constituents. In recent years large quantities of this type of scrap have been exported to Japan, West Germany, and other countries where either the scrap or its constituents are reclaimed. Table 6 gives the quantity of nickel recovered in the United States by type of scrap and by the form recovered.

TABLE 5.—*Consumption of new and old nickel, nickel-base, and nickel silver scrap in the United States*

[Gross weight, short tons]

	1962		1963	
	New	Old	New	Old
Smelters and refiners:				
Unalloyed nickel	704	260	753	294
Monel metal	483	1,166	505	979

Total	10,688	11,108	10,763

[1] Includes only nonferrous nickel scrap added to ferrous and high-temperature alloys.

RESERVES

The largest known potential resource of nickel in the world, conservatively estimated at 17 million tons of nickel content, is in the nickel-bearing laterite and serpentine ores in Cuba. The second largest known reserve is in New Caledonia with an estimated nickel content of

16 million tons. Reserves of proven and indicated nickel in the sulfide ore deposits of the Sudbury district and the newly-developed Manitoba areas in Canada total about 6 million tons of nickel content.

As of early 1964, reserves of proven and indicated nickel-bearing material in the United States were placed at about 71 million tons with a nickel content of approximately 500,000 tons. Of this amount, 360,000 tons of nickel was in silicate and nickeliferous iron ores and 140,000 tons in sulfide ores. About one-half of the sulfide ore is in Alaska. Most domestic sulfide deposits are too small to warrant establishment of a nickel smelting industry. Table 7 gives ore reserves of the major Canadian producers in 1963.

TABLE 7.—*Estimated reserves of major Canadian producers in 1963*

[Million tons]

Company	Ore	Nickel content (percent)
International Nickel Co. of Canada, Ltd.: Proven ore reserve	302	1.6
Falconbridge Nickel Mines, Ltd.:		
Proven ore reserve	27	1.6
Indicated ore reserve	24	1.2
Sherritt Gordon Mines, Ltd.: Indicated ore reserve	12	.9

Nickel-bearing laterite deposits are abundantly distributed in a wide belt of tropical and semitropical countries around the world. Large deposits are known in Cuba, Brazil, Venezuela, Puerto Rico, the Dominican Republic, Greece, Pakistan, India, the Malagasy Republic, the Republic of the Philippines, the Republic of Indonesia, and the French Pacific Islands (New Caledonia). Some of the largest deposits, such as those in the Republic of the Philippines, may contain more than 1 billion tons of potential ore (*1*).[2] The prospect for the discovery of additional nickeliferous laterite deposits is good, since many areas in the equatorial regions where laterite is found are relatively underdeveloped and have not been extensively prospected.

Puerto Rico has nickeliferous laterite and serpentine deposits estimated at least 100 million tons of ore with an average nickel content less than 1 percent. It is estimated that the Republic of the Philippines has a laterite reserve of about 120 million tons of these ores and a larger tonnage of lower grade nickel ore. Other nickel resources amenable to large-scale development are in Central and South America, Indonesia, and Africa.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Nodules on the ocean floor represent another potential source of nickel. Manganese dioxide nodules scattered over large areas also contain nickel, cobalt, copper, and iron.

SOURCES OF STATISTICAL INFORMATION

Annual data on production of nickel ore are obtained from domestic producers by the Bureau of Mines. Data on annual consumption by form and end use, and on stocks by form are obtained from about 1,030 consumers which account for about 99 percent of total consumption reported in 1963; corresponding monthly data are obtained from 200 consumers which account for about 94 percent of the consumption reported in 1963. World production data are compiled from Foreign Service dispatches and official publications of foreign countries, and figures on foreign trade are obtained from the Bureau of the Census.

PRODUCTION, CONSUMPTION, AND TRADE

Free world annual production of nickel increased from about 10,000 tons in 1900 to a record high of 301,000 tons in 1961 when the U.S. Government was purchasing it for the national stockpile. The total free-world nickel production in 1962 and 1963 was 287,000 and 271,000 tons, respectively.

Of the free-world nickel production in 1963, Canada produced 81 percent; New Caledonia, 12 percent; and the United States, 4 percent. Table 8 gives the world production of nickel from 1959 to 1963. Despite the decline in nickel production in 1963, U.S. industrial consumption was approximately 125,000 tons, about a 5-percent increase above the 1961–62 levels.

Of the total United States imports in 1963, 91 percent was nickel metal and 8 percent was nickel oxide. Canada provided 91 percent of the total imports and Norway, 7 percent. Since Norway's raw materials originated from Canada, the United States, in effect, imports 98 percent of its nickel from Canada. France and other countries provide the remaining 2 percent.

Exports of nickel-bearing material by the United States have been increasing. In 1963 this country exported 61,000 tons of nickel-bearing materials consisting principally of nickel and nickel-alloy scrap. Compared with the 1962 figure, this was an increase of 120 percent. Shipments to Japan were 67 percent of the 1963 total; to Canada, 12 percent; to Italy, 11 percent; and to Sweden, United Kingdom, and West Germany, 3 percent each.

[1] Comprises conper-nickel alloys, nickel silver, brass, bronze, beryllium alloys, magnesium and aluminum alloys; Monel, Inconel, and malleable nickel.
[2] Figures represent quantity of nickel used for production of anodes, plus cathodes used as anodes in plating operations.
[3] Figures do not cover all consumers.

STRATEGIC CONSIDERATIONS

In 1963, total domestic primary and secondary nickel production was approximately 22,000 tons, about 19 percent of U.S. consumption. There is little likelihood of improvement in this domestic supply position. Since nickel is a strategic and critical metal, it has been acquired for the national stockpile to insure a supply in the event of a national emergency. As of June 30, 1964 inventories totaled 219,278 tons of nickel, 166,914 tons in the national (strategic) stockpile and 52,364 tons in the Defense Production Act (DPA) inventory. Of the total amount, 50,000 tons was declared within the objective, and 169,278 tons was declared in excess. In addition to the inventories of the Federal Government, consumer stocks at yearend, 1963 amounted to 17,191 tons, up approximately 3,700 tons from that of yearend, 1962.

Alloy steels of 1 percent to about 5 percent nickel are used for military aircraft, ships, vehicles, weapons, ammunition and other military hardware. Stainless steels containing 7 percent to 30 percent nickel find a use in the production of aircraft engines, airframes, and ocean vessels. Nickel-base alloys, which are mainly high-temperature materials, are specified chiefly in gas turbines, jet engines, and other applications requiring alloys with high mechanical strength at elevated temperatures. Corrosion resistant nickel-base alloys are used in ships, storage tanks, and various processing equipment. A number of nickel alloys are used in plants and equipment in the metalworking, mining, oilfield, power, chemical, railroad, and other industries.

The United States depends almost entirely on the Canadian supply and to a lesser extent on the New Caledonian source for its needs of nickel. Since the seizure of American owned nickel plants by the present Cuban government, nickel shipment from Cuba to the United States has been suspended. Potential nickel supplies may come from Central and South American countries, the Caribbean area, the Philippine Islands, India, Indonesia, and Federation of Malaysia.

GOVERNMENT PROGRAMS

In October 1963 an Interdepartmental Disposal Committee was charged with the responsibility for determining criteria and procedures for the development of long-range programs to dispose of surplus material in the Government stockpiles. In November, work was begun on plans to dispose of nickel.

At the end of 1963 only the Hanna Nickel Smelting Co. held an unfulfilled contract to deliver nickel to the stockpile. However, by mutual consent, deliveries had been suspended.

The Government offers financial assistance up to 50 percent of allowable costs for exploration for mineral reserves of nickel. No assistance contracts are in effect.

PRICES

The price of nickel metal rose in June 1961 from its 5-year plateau of 74 cents per pound to 81¼ cents and declined again in May 1962 to 79 cents, its price at the close of 1963. Except for shaded prices of oxide in 1958 through 1960 the price of oxide nickel remained 3¾ cents per pound below that of the metal, but 1¼ cents reflects a U.S. import duty on the metal. Table 10 gives nickel prices for the metal and the oxide from 1951 through 1963.

TABLE 10.—*Prices per pound of nickel metal and nickel oxides in the United States*

Year	Date of change in price	Nickel metal, f.o.b. Port Colborne, Ontario, duty included	Nickel oxide sinter (nickel content) f.o.b. Copper Cliff, Ontario, no duty	Cuban nickel oxides (nickel content) f.o.b. Philadelphia	
				Powder	Sinter
1951	June 1	$0.56½	$0.52¾	$0.50¾	--------
1952	Unchanged	.56½	.52¾	.50¾	--------
1953	Jan. 14	.60	.56¼	54¼	--------

[1] Price f.o.b. port of entry, reduced by International Nickel Co. of Canada, Ltd., to compete with Cuban nickel oxide.

TAXES

Domestic nickel producers are granted a depletion allowance of 23 percent on income from domestic production and 15 percent on income from foreign production.

In addition to a 15 percent depletion allowance (of salable value of minerals), taxable income of operations outside the United States and within the Western Hemisphere are taxed at 14 percentage points below the U.S. corporate income tax rate. With an approximate rate of 48 percent for domestic operations, the rate for Western Hemisphere trading corporations is about 34 percent.

RESEARCH

The Bureau of Mines conducts research projects related to the conservation and production of nickel, which range from mineral exploration to electrolytic recovery of refined nickel (*2*, *3*, *6*, *8*, *13*). It makes theoretical studies of basic nature (*17*, *22*), including the properties of nickel and its alloys (*5*, *21*), and it investigates analytical methods (*10*, *19*). Much effort has been devoted to the beneficiation of ores (*18*) and to the recovery of nickel from them (*1*, *7*, *12*, *16*). The recovery of nickel from scrap receives attention (*9*, *11*).

The International Nickel Co. of Canada, Ltd. maintains facilities in which research is directed largely toward immediate commercial objectives, but basic studies are carried out. The company issues The Nickel Bulletin which contains abstracts of recent literature pertaining to nickel.

Falconbridge Nickel Mines, Ltd. officially opened a $1 million metallurgical research laboratory at Thornhill, Ontario, in 1963 with a staff of 50 scientists, engineers, and technicians. The Sherritt Gordon Mines, Ltd. has research laboratories in its metallurgical plant at Fort Saskatchewan, Alberta, Canada. A great many articles have been published dealing with chemical methods of extracting metals from ores, including laterites, and dealing with the production of metal powders and their fabrication into dense strip.

The Defense Metals Information Center, Columbus, Ohio, publishes reports pertaining to the properties of nickel and its alloys (*4*, *14*, *15*).

OUTLOOK

Total free world nickel producing capacity in 1963 was conservatively placed at about 330,000 tons annually, exceeding the current annual consumption rate in the free world by about 62,500 tons. The outlook is for continued free world excess capacity to produce nickel. There are ample reserves of sulfide ores in Canada and of silicate ores throughout the Tropics. There are feasible ways to exploit low-tenor ores of each type which will enable producers to meet any forseeable level of world demand. This may be expected despite the fact that, currently, increasing deliveries of nickel are steadily correcting the 20 to 25 percent excess capacity that was reported at the beginning of 1963.

The outlook on consumption of nickel for the United States and the rest of the free world is for continued steady increases resulting from general economic growth and from the development of new uses. It is probable that this country will continue to consume about 50 percent of the free world total, at least in the foreseeable future. The rate of increase in nickel use has in the past been held down by substitution of other metals as well as by replacing nickel-bearing materials of higher nickel content with lower content alloys. It is expected these practices will continue. However, countering this trend of reduction in the use of nickel by substitution is sales advertising by producers directed toward the ultimate consumer.

The recent discovery of huge nickel sulfide deposits in the Thompson, Manitoba, area and elsewhere in Canada has probably assured the continued dominance of Canadian sulfide ore as the major source of the free world nickel for many years. Intensive prospecting in other areas of Canada may result in the discovery of other nickel ore deposits. Thus, barring a major increase in the consumption rate, the United States and the rest of the free world is assured of adequate supplies of nickel from Canada for the next 50 to 70 years.

The prospect of finding nickel ore in large quantities in the United States is poor. With the possible exception of Alaska, most of the promising areas of the United States have been well prospected, and although a number of relatively small, low-grade deposits have been found, no commercial deposits have been developed except that at Riddle, Oreg., now mined by the Hanna Mining Co. The reserve at the Riddle mine is expected to last about 15 more years at the capacity production of about 14,000 tons per year with little prospect of finding more ore nearby.

PROBLEMS

Some of the unsolved problems in the technology of nickel are as follows: lack of knowledge of the theoretical basis of its metallurgy; need for an economic way to separate nickel and cobalt; economical methods to recover nickel from silicate and lateritic ores and from other minerals with a low nickel content; and economical reclamation of nickel from high-temperature and cryogenic alloy scrap, spent catalysts, and other nickel alloy materials.

Although nickel is widely used in many alloys to impart toughness, corrosion resistance, low-temperature ductility, and to improve high-temperature properties, the development of alloys is often done by trial-and-error procedures rather than by more scientific methods based on knowledge of the basic mechanisms of the alloying process. There is, then, need for more fundamental research in this field not only to gather information about various alloying processes, but more importantly, to synthesize the gathered information into a more unified explanation of these processes. With greater elucidation of the fundamental alloying mechanisms, the formulation of new alloys with the desired physical and chemical properties would be based on more reliable information, and results would be more certain.

Nickel ores usually contain some cobalt which is difficult to remove because of the chemical similarity of the two metals. Currently used methods are relatively complicated and often involve large circulating loads. The problem may be approached by three methods: separation of the two metals from the ore by the preparation of separate concentrates, separation during smelting by slagging off the cobalt, and separation from the electrolyte during electrolytic refining. Although the very close similarity in the chemical and physical behavior of nickel and cobalt minerals and compounds poses formidable difficulties to any of these approaches, some success has been attained recently in all of them. The third approach seems to be the most promising.

The problem with silicate and nickeliferous lateritic ores is twofold. In the first place, no economical method has yet been found for producing a physical concentrate from these minerals. This normally means that smelting or leaching plants must be built close to the ore deposits, since it is usually uneconomic to transport the ore over long distances due to its relatively low nickel and high moisture content. An intensive study of the application of mineral dressing techniques to these and other relatively low-grade minerals might lead to the development of a method by which a separation of some of the constituents could be made.

Secondly, present processes for the exploitation of silicate and nickeliferous laterite ores do not make full use of the potential of these ores as sources of iron, cobalt, and other contained metals. The ammonia leach process used at the formerly U.S. Government-owned Nicaro plant in Cuba recovered less than 80 percent of the nickel and less than 10 percent of the cobalt. The tailings were too high in nickel, chromium, and cobalt to be suitable for use as iron ore.

The acid leach process used at Freeport Sulphur Company's former plant at Moa Bay recovered over 95 percent of the nickel and cobalt, and the 50-percent iron content of the tailings was also to have been recovered by a direct reduction process. The process, however, is not usable on the serpentine fraction of the lateritic ores, which may make up one-third of the total weight of the ore and may be the richest in nickel content.

NITROGEN

By Richard W. Lewis [1]

NITROGEN has a key role in the life cycle of plants and animals. When man devised methods to "fix" atmospheric nitrogen he achieved independence from the inadequate supply of naturally derived nitrogenous materials. The atmosphere is the main source of nitrogen supply. Other sources include natural nitrates, coal, and natural organic materials, such as cotton seed, tankage, bone meal, and guano.

Ammonia, the most important nitrogen compound, is produced synthetically in vast quantities by reacting nitrogen with hydrogen in the presence of a catalyst. It is the basic compound from which a host of other nitrogen compounds are made. Most of the nitric acid consumed in the United States is made by oxidizing anhydrous ammonia.

The fertilizer industry is the largest consumer of nitrogen compounds. Ammonium sulfate, ammonium nitrate, and ammonium phosphate are components of mixed fertilizers and are produced by neutralizing the respective acids with ammonia. These compounds, as well as ammonia, both anhydrous and in solution, are sometimes applied directly to the soil or to irrigation waters to supply nitrogen to growing crops.

The largest single industrial use of ammonia is for explosives. It is the basic ingredient for the production of sodium nitrate, ammonium nitrate, nitrocellulose, nitroglycerine, trinitrotoluene (TNT), and other explosives.

The only important commercial source of natural nitrates is Chile. Strong competition in the world markets by synthetically produced nitrates has made it increasingly difficult to mine and sell natural nitrates profitably.

Nitrogen as a liquid or as a gas has shown a rapid increase in industrial importance. Large volumes are produced annually in air-separation plants by a simple process of liquefaction and fractional distillation of the atmosphere.

The reserves of nitrogen in the atmosphere, coal deposits, and natural mineral deposits assure ample supplies for all time. The quantity available for agricultural and industrial uses is limited only by the production capacity of the processing facilities.

The demand for nitrogenous fertilizer materials will continue upward to assist in meeting the increasing needs for agricultural products. Further growth is expected in the use of ammonium nitrate for field-compounded explosives. Also, increased use by industry of high-purity nitrogen, liquid and gas, is anticipated.

Problems of the nitrogen industry include providing an adequate supply of nitrogen compounds to meet fluctuating seasonal demands and reducing operational costs to meet foreign competition.

BACKGROUND

SIZE AND ORGANIZATION OF THE INDUSTRY

Until the 18th century, organic nitrogen materials, primarily animal and plant wastes produced at or near the point of use, accounted for supplemental nitrogenous plant food. From the 18th century until the 1920's, the nitrate deposits of Chile were virtually the only commercial source of nitrogen. Since then, the chemical industry, by nitrogen fixation, has supplied the major part of the world's nitrogen requirements.

The four main sources of nitrogen today are—(1) the atmosphere, (2) coal, (3) natural nitrates, and (4) organic materials.

The first commercial nitrogen fixation plant was established in Norway about 1900 and used the arc process. Nitrogen and oxygen in the air were combined by an electric arc to form nitrogen oxides, which were absorbed in water to form nitric acid. The cyanamide

[1] Commodity specialist.

process, first used commercially in Italy in 1906, makes calcium cyanamide by reacting calcium carbide, prepared from coke and limestone, with atmospheric nitrogen. The Haber-Bosch process, developed in Germany between 1905 and 1913, produces synthetic ammonia by combining nitrogen and hydrogen in the presence of a catalyst at elevated temperatures and pressures. Research in every major country was stimulated by the success of the Haber-Bosch process, and a number of variations were developed to produce ammonia from nitrogen and hydrogen.

The first successful domestic synthetic ammonia plant was built at Syracuse, N.Y., by the Atmospheric Nitrogen Corp. in 1921. A modification of the Haber-Bosch process was used. This plant was followed by others which soon were contributing large quantities of nitrogen compounds to supply the growing demand. To insure adequate supplies of nitrogen compounds during World War II, the Government constructed 10 synthetic ammonia plants with a total rated capacity of 863,000 short tons of nitrogen equivalent per year. The plants were operated by the Government in the latter part of the war, after which all except the Tennessee Valley Authority (TVA) plant at Muscle Shoals, Ala., were sold or leased and now are operated by private industry to produce nitrogen compounds.

The synthetic nitrogen compound industry in the United States was expanded rapidly between 1951 and 1958. At the beginning of 1959 the industry was comprised of more than 40 companies and the TVA, which were operating about 55 synthetic ammonia plants in 28 States and Puerto Rico. Total annual rated capacity was nearly 5 million short tons of nitrogen equivalent. In addition, there were about 80 coking plants in 21 States with a total productive capacity of more than 250,000 tons of nitrogen equivalent per year as a byproduct. During the next 5 years an even greater expansion of the industry took place, and by December 31, 1963, 79 ammonia plants were in operation, having a combined capacity of about 8.2 million short tons per year. The production of byproduct ammonia from coking plants, however, declined slightly. In 1963, 59 of the 66 coking plants in operation recovered a total of 185,301 tons of ammonia, of which 86 percent was converted into ammonium sulfate.

The growth of the elemental nitrogen (gaseous and liquid) industry has been phenomenal. The average annual domestic production for 1953–57 was 141,000 short tons, whereas in 1963 over 2 million tons was produced. This production did not include the output of a large number of small "make it yourself" units in use throughout the Nation.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Nitrogen is a colorless, odorless, and generally inert gaseous element making up 78 percent of the air by volume. This nitrogen is referred to as atmospheric nitrogen and is represented chemically by "N."

Fixed nitrogen is nitrogen that is chemically combined with one or more other elements and is present in all living things, both plant and animal. Sodium nitrate ($NaNO_3$) or soda-niter and potassium nitrate (KNO_3), sometimes referred to as niter or saltpeter, are the only natural occurring nitrogen minerals of importance. (*12*).[2]

Although more than 250,000 nitrogen-containing compounds are known, only a few are important in the fertilizer and chemical industries. These include anhydrous ammonia (NH_3), ammonium nitrate (NH_4NO_3), ammonium sulfate ($(NH_4)_2SO_4$), monoammonium phosphate ($NH_4H_2PO_4$), diammonium phosphate ($(NH_4)_2HPO_4$), calcium cyanamide ($CaCN_2$), nitric acid (HNO_3), urea (NH_2CONH_2), and the two natural nitrates. Recently synthetic potassium nitrate has become more prominent.

Aqua ammonia, as the name implies, is anhydrous ammonia dissolved in water to form ammonium hydroxide (NH_4OH). Commercial grades usually contain 20 to 25 percent nitrogen.

Grade regulations for mixed fertilizers, including nitrogenous fertilizers, are under State control. Summaries of these regulations are published annually (*2*). Grades and purity specifications for nitrogen and nitrogen compounds for industrial use are varied and established by the individual manufacturer.

TECHNOLOGY

Nitrogen Fixation Processes

The atmosphere is the major source material from which nitrogen is extracted and "fixed" for use in the fertilizer, chemical, and explosive industries. Three basic processes may be used to fix atmospheric nitrogen: The arc process which produces dilute nitric acid; the cyanamide process which produces calcium cyanamide; and the synthetic ammonia process which produces ammonia. Other methods were developed for fixing nitrogen but were little used and are of no importance.

The arc method (*7*) has no commercial importance in the United States chiefly due to

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

the large investment and the electrical energy requirements per ton of product. However, it uses directly the cheapest and most plentiful of raw materials, air and water, and produces directly a very desirable form of fixed nitrogen, nitric acid.

The cyanamide process (*6*) involves four steps to produce calcium cyanamide: The production of lime by calcining limestone; the manufacture of calcium carbide in an electric-arc furnace by reacting lime with coke; the separation of nitrogen from the atmosphere by the fractionation of liquid air; and the reaction of the calcium carbide with the nitrogen to produce cyanamide. Calcium cyanamide, early in the century was used extensively as a fertilizer. Today, however, it represents only about 2.5 percent of the nitrogenous fertilizers consumed in the world.

The synthetic ammonia method is currently by far the most important and most used method. Although there are several processes in general use today, all may be considered as modifications or variations of the original Haber-Bosch process. They have in common the following three main steps:

1. Preparation of hydrogen and nitrogen.
2. Purification and compression of the gases.
3. Conversion of the gases into ammonia.

Nitrogen necessary for ammonia synthesis may be obtained from producer gas, or when hydrogen is cheap, sufficient air can be mixed with hydrogen and the oxygen burned out to give a hydrogen-nitrogen gas mixture. The most used method, however, is by fractional distillation of liquid air which produces a nitrogen of high purity.

Hydrogen is obtained principally from natural gas in the United States but also is produced from coal by water-gas reaction, water by electrolysis, coke-oven gases, and byproducts of caustic-chlorine and ethylene production and petroleum refining.

The process of ammonia synthesis consists essentially of passing nitrogen and hydrogen over a catalyst (usually iron oxide) at high pressures and temperatures. The product is ammonia, mixed with nitrogen and hydrogen, from which ammonia is recovered by absorption or refrigeration. Unreacted nitrogen and hydrogen are returned to the process.

Process requirements for manufacturing ammonia and selected nitrogen compounds for raw materials, process and cooling water, power, and catalysts have been published by the Bureau of Mines (*5*). For example, about 1,500 kilowatt-hours of electricity is required to produce 1 ton of ammonia, compared with 5,100 kilowatt-hours to produce 1 ton of elemental phosphorus.

Coking-Plant Nitrogen

The gas from coking coal is a mixture of ammonia, carbon dioxide, hydrogen, methane, water vapor, coal tar, and small quantities of various hydrocarbons. After passing through a tar separator, the gas is passed through water, sulfuric acid, or phosphoric acid to recover aqua ammonia, ammonium sulfate, or ammonium phosphate (*13*, *14*).

Natural Nitrate Deposits

Small deposits of soluble nitrate minerals are widely distributed in the United States. Nitrate deposits have been found in 23 States. Most occurrences are in the arid and semiarid parts of the Western United States. Three types of nitrate deposits are known—cave, caliche, and playa. Cave nitrates are the most numerous and contain the widest variety of nitrate salts, including potassium, sodium, calcium, and (more rarely) magnesium and ammonium. Caliche and playa deposits are composed chiefly of sodium nitrate. The domestic deposits are discussed in detail in various Geological Survey reports (*4*, *8*, *10*, *11*).

Nearly all the known nitrate deposits in the United States are too small and low-grade to support a domestic nitrate industry, although small-scale production has been reported. Production from one cave deposit began early in 1957 in the Grand Canyon, Ariz. The guano was mined by a suction hose and carried across the canyon on a 1½-mile aerial tramway. There, it was packaged for sale as an organic nitrogenous fertilizer. This venture is not currently in operation.

The only commercially important large nitrate deposits in the world are in Chile, in an area 10 to 50 miles wide and 450 miles long between the Coast Range and the Andes Mountains in northern Chile. The nitrate-bearing ores contain 5 to 30 percent sodium nitrate and occur in slightly dipping beds a few inches to several feet thick overlain by an overburden of loose sand and gravel or consolidated conglomerate. The nitrate ore is mined by both hand and mechanical mining. Open-pit mining usually is employed, but some underground mining is done when the overburden exceeds 30 feet in thickness.

There are two main methods of extracting the nitrate from the ores—the Shanks process and the Guggenheim process. Both are solution and recrystallization methods. The Shanks process was the first method used to recover marketable nitrate and was applied only to ore containing more than 15 percent $NaNO_3$. The Guggenheim process, which was developed in 1925, permitted treating ore down to 8 per-

cent $NaNO_3$, with recovery of nearly 100 percent of the nitrate, by using countercurrent leaching at a lower temperature. The Guggenheim process requires closer temperature control and more plant facilities than the Shanks process.

With the development of synthetic processes, many chemical products became competitors of Chilean nitrate; however, natural nitrates contain minor quantities of magnesium, iodine, boron, calcium, potassium, lithium, and strontium, which contribute slightly to the minor plant-food-element supply of the soil. Despite available and cheaper synthetic nitrogen, sales of Chilean nitrate have been maintained relatively high.

Guano deposits in Peru, an important source of nitrogenous materials before 1900, are now controlled by the Peruvian Government. Guano obtained from them is consumed largely in Peru.

Organic Nitrogen

Raw materials for the organic nitrogen industry include byproducts of slaughter houses (blood), rendering plants (animal tankage), tanneries (process tankage), fish processing plants (fish scrap), cottonseed and other seed mills, and processed sewage. Substantial quantities of nitrogen also are added to the soil through manures and cover crops.

USES

Nitrogen compounds are essential to the fertilizer and explosives industries and have many important applications in the chemical industry. Ammonia is the major nitrogen product, and many other compounds and salts are made from it for use in the fertilizer, chemical, and explosives industries.

The nitrogenous material used for fertilizers can either be applied directly or as mixed fertilizer containing two or more plant-food elements. The principal compounds now used as fertilizer, in order of importance, are ammonium nitrate and ammonium nitrate-limestone mixtures, sodium nitrate, anhydrous and aqua ammonia, ammonium sulfate, calcium cyanamide, calcium nitrate, and urea.

Industrial uses of nitrogen compounds are many and varied. Ammonia is used in manufacturing paper, plastics, and synthetic fibers and in refrigeration, metal treatment, water purification, and oil refining. Nitric acid is one of the more valuable chemical reagents. It is an important solvent and basic chemical and is used extensively in making explosives and dyes. Many other nitrogen compounds are important to both the fertilizer and chemical industries, one of the most interesting being the increasing use of prilled ammonium nitrate in explosives. However, most of the domestic production of ammonium nitrate is used in fertilizer.

Elemental nitrogen has a wide diversity of uses in industry including chemicals, drugs, electronics, food processing, metals, and oil-well drilling.

The ammonia industry consumes the largest amount of nitrogen. This amount, however, is not reported in the production of pure nitrogen since it is used captively as produced.

The largest use of pure nitrogen is as a blanketing gas medium in the electronic and metal industries. Liquid nitrogen consumption is increasing in food processing and as a refrigerant for food transportation. Also, more liquid nitrogen is being consumed each year for use in rockets and missiles.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Nitrogen production from coking operations, less than 5 percent of the U.S. output of inorganic nitrogen compounds, is directly geared to the steel industry. The demand for steel governs the quantity of nitrogen made available from this source. The proportionate output of aqua ammonia, ammonium sulfate, and ammonium phosphate depends on the requirements of the fertilizer market.

The quantities of nitrogen, phosphate rock, and potash consumed in mixed fertilizers are closely related.

Elemental nitrogen production is closely associated with oxygen in that the two are obtained simultaneously from the atmosphere in air-separation plants.

ALTERNATE MATERIALS

There is no substitute for nitrogen as a plant food. However, there are many nitrogenous fertilizers from which to choose—price, physical characteristics, and agronomic factors being considered. There is no substitute for nitrogen in the production of ammonia which is the major consumer.

Although a number of explosive compounds containing no nitrogen are known and used, it would be difficult to substitute for all nitrogenous explosives.

Some substitutions are possible, although not economical, for elemental nitrogen in a few of its uses. Helium or argon may be substituted for nitrogen as a blanketing gas in some metallurgical operations.

RESERVES

The mass of the atmosphere has been estimated at more than 5 quadrillion tons containing about 4 quadrillion tons of nitrogen, or about 148,000 tons for every acre of land area. Each day, lightning fixes about 60,000 tons of nitrogen, which reaches the earth in the form of nitric or nitrous acids; however, most of this tonnage falls on nonagricultural areas. The nitrogen content of the air is replenished constantly (primarily through decomposition of organic materials), providing a never-ending source.

The quantity of nitrogen in coal ranges from less than 1 to 3 percent. The domestic recoverable reserve of coal is estimated at about 830 billion tons, containing 5 to 25 billion tons of nitrogen. At present, only about one-sixth of the total nitrogen in coal is recoverable. The nitrate reserve in Chile is estimated to be slightly under 1 billion tons and is the only important commercial source of natural nitrates in the world.

SOURCES OF STATISTICAL INFORMATION

World statistics on fertilizer materials, including nitrogen compounds, usually are collected on a crop-year basis. The crop-year is not the same for all countries; however, most countries report data for 12-month periods ending June 30.

Statistics on estimated world production and consumption of agricultural nitrogen are compiled and published by the Food and Agricultural Organization of the United Nations (*3*). Aikman (London), Ltd., compiles and publishes estimated world production and consumption data on agricultural and industrial nitrogen compounds (*9*). Both reports are for crop-years ending June 30. A canvass on consumption of nitrogenous fertilizers is conducted by the Agricultural Research Service, Department of Agriculture, and statistics are published for annual periods ending June 30 (*15*). Data on production, shipments, imports, and exports of certain nitrogenous fertilizers and chemicals are collected by Bureau of the Census. Some data are published monthly, and all are published on a calendar-year basis (*1*).

Statistics on production, sales, and stocks of ammonia, ammonium sulfate, and ammonium phosphates at coke-oven installations are collected and published monthly by the Bureau of Mines. Data from all sources are published in the Nitrogen chapter of the Minerals Yearbook, volume I, on whatever basis the material is available.

Statistics on nitrogen compounds in explosives are included in the Bureau of Mines annual Mineral Market Report, Consumption of Industrial Explosives. The Bureau of the Census publishes periodic data on explosive materials in Industrial Organic Chemicals, Census of Manufactures.

PRODUCTION, CONSUMPTION, AND TRADE

Table 1 gives U.S. production of nitrogen from synthetic ammonia plants, coking plants, and air-separation plants. Major nitrogen compounds produced during 1959–63 are given in table 2. Imports and exports of nitrogen compounds are shown in table 3. Table 4 presents world production and consumption of nitrogen compounds for both fertilizer and technical purposes for the fiscal years ending June 30, 1959–63.

From 1959 to 1963 ammonia nitrogen production increased 68 percent, while elemental nitrogen became the fastest growing industrial gas with production in 1963 nearly eight times that of 1958.

Peacetime consumption of fixed nitrogen has been about 75 percent for agricultural uses and 25 percent for industrial uses. In 1963, it is estimated that 80 percent of consumption went

into fertilizer materials. World consumption during 1963 is estimated at 17.5 million short tons with the United States consuming slightly more than 5 million tons. Thus, there has been no appreciable overproduction, and further expansion of the productive facilities are quite likely. Most of the increased demand for nitrogen compounds has been due to increased use of fertilizers with a larger proportionate use of nitrogen.

No consumption data are available for liquid and gaseous nitrogen, but it can be assumed that practically all produced was used. The spectacular rise in demand for pure nitrogen is due chiefly to the growth of markets that did not exist a few years ago. Greater amounts are being used annually for such uses as frozen food processing and transportation, oil well stimulation, and in environmental testing of space vehicles and components.

In general, the U.S. foreign trade situation is slowly changing due to heavy foreign competition. The trend during the past 5 years has been for increased imports and decreased exports. The increased imports are especially

noticeable for anhydrous ammonia and urea, in spite of the great expansion of domestic facilities.

All fertilizer nitrogen compounds and urea enter the United States duty free. The tariff rates on the more important compounds for nonfertilizer use are as follows:

Anhydrous ammonia	Rate Aug. 31, 1963	1.25 cents per pound.
	Statutory	2.50 cents per pound.
Ammonium phosphate	Rate Aug. 31, 1963	0.6 cent per pound.
	Statutory	1.5 cents per pound.
Ammonium sulfate	Rate Aug. 31, 1963	8.5 percent ad valorem
	Statutory	25.0 percent ad valorem.

STRATEGIC CONSIDERATIONS

Nitrogen compounds, including natural nitrates, are not on the Government's list of strategic and critical materials, but they are ingredients of several explosives and thus are important war materials. Nitrogenous fertilizers are essential to maintain and expand the agricultural output of the United States. The capacity of the atmospheric and coke nitrogen industries is sufficient to meet the expected demand in wartime.

GOVERNMENT PROGRAMS

In peacetime, the domestic nitrogen industry operates without any special controls. During wartime or periods when the supply was extremely short, the U.S. Government, the Food and Agriculture Organization of the United Nations, and other organizations have regulated imports and exports, and the U.S. Government has controlled the domestic use of nitrogen compounds.

TABLE 5.—*Yearly price ranges of major nitrogen compounds, per short ton*

Compound	1959	1960	1961	1962	1963
Ammonium nitrate, fertilizer-grade, 33.5 percent N (nitrogen):					
Canadian, carlots, f.o.b. shipping point, bags	$63.00–$68.00	$64.00–$68.00	$64.00–$70.00	$64.00–$70.00	$64.00–$70.00
Domestic, f.o.b. works, bags	63.00– 68.00	64.00– 68.00	64.00– 67.00	64.00–70.00	64.00– 70.00
Ammonium nitrate, domestic with dolomite, 20.5 percent N, bags, carlots, Hopewell, Va	44.50– 48.00	48.00	44.00– 48.00	44.00– 48.00	48.00
Ammonium sulfate, standard granular, bulk, f.o.b. works	32.00	32.00	32.00	28.00– 32.00	28.00– 30.00
Anhydrous ammonia, fertilizer, tanks, works, freight equalized east of Rockies	84.00– 88.00	84.00– 92.00	84.00– 92.00	84.00 –92.00	84.00– 92.00
Cyanamide, fertilizer-mixing grade, 21 percent N, granular, bags, Niagara Falls, Ontario	57.00	57.00	57.00	57.00– 59.00	59.00
Sodium nitrate, domestic, crude, carlots, works, bulk	40.50– 44.00	44.00	44.00	44.00	44.00
Sodium nitrate, imported, crude, carlots, port warehouse, bulk	40.50– 44.00	44.00	44.00	44.00	44.00
Urea:					
Industrial, 46 percent N, bags, carlots, ton lots, f.o.b. plant	[1] 125.00	[1] 98.00–125.00	98.00–100.00	100.00	100.00
Agricultural, 45 percent N, bags, carlots, delivered	[1] 103.00–100.00	[1] 100.00–103.00	[2] 87.25–100.00	[3] 93.25– 96.00	89.00– 96.00

PRICES

The prices of nitrogen compounds are quoted per short ton of material. In general, prices of major nitrogen compounds were rather steady showing only a slight increase during 1959–63. Urea was an exception, and the drop in prices was due principally to low cost foreign imports.

TAXES

Producers of natural nitrates are granted a depletion allowance of 15 percent on both domestic and foreign production. Numerous domestic producers of atmospheric nitrogen were granted accelerated tax amortization certificates from 1951 through 1956 for expansion and new facilities.

RESEARCH

Since the Atmospheric Products Company first attempted to fix nitrogen in an electric arc furnace in 1902 at Niagara Falls, N.Y., industry in the United States has been conducting research to improve and develop methods of fixing nitrogen. The Chilean Nitrate Educational Bureau, Inc., New York, N.Y., conducts experiments and demonstrations to promote the use of Chilean nitrate.

The Federal Government began active research on nitrogen during World War I, by building two nitrogen-fixation plants at Sheffield, Ala. Plant No. 1 produced ammonia by direct synthesis. Plant No. 2 produced calcium cyanamide.

After World War I, the Government organized the Fixed Nitrogen Research Laboratory under the Department of Agriculture to investigate and improve nitrogen fixation processes. The Plant Industry Station, Department of Agriculture, Beltsville, Md., has taken over this organization, and current activities are concerned mainly with agricultural problems.

The two Government plants at Sheffield, Ala., were closed at the end of World War I and were idle until 1933, when they were turned over to the TVA. Fertilizer research by TVA has been expanded considerably since 1933. Besides the phosphate facilities (see Phosphate Rock Chapter), the Wilson Dam research center includes a synthetic ammonia plant, nitric acid plant, ammonium nitrate plant, and various ammoniators and other fertilizer processing facilities. In addition to basic and pilot-plant research, use tests and cooperative experimental fertilizer applications are being conducted in a number of States.

OUTLOOK

The agricultural demand for nitrogenous fertilizers will continue to increase. The two most important basic factors influencing this increasing use are population growth, anticipated to be about 1.6 percent annually for the next 10 years, and a higher standard of living. The standard of living is directly related to gross national product, which is expected to have a growth rate of 3.8 percent compounded annually for the next 10 to 20 years. In addition, the continued removal of land from agricultural use leads to demands for more fertilizer to increase production per remaining acre.

Domestic production and consumption of high-purity nitrogen was greatly increased during 1959–63 with production in 1963 about 3.7 times that reported for 1959. Demand and production capacities are expected to increase in the next 5 years at a steady but slower pace. It is estimated that the demand for nitrogen by 1970 will have increased to 175 to 200 billion cubic feet.

Further automation of production plants, new and improved methods for manufacturing nitrogen compounds and fertilizers, and better storage and handling equipment will tend to reduce production cost. Also, the trend in the use of higher analysis nitrogen materials will continue, thereby reducing transportation costs per unit of contained nitrogen.

PROBLEMS

The removal of nitrogen compounds from the soil by crops, solution, and erosion presents an obstacle to providing agricultural products needed for the rising standard of living of an ever-growing population.

The fluctuating demand for nitrogenous fertilizers resulting from seasonal requirements, weather, and farm incomes produces problems in production, storage, and transportation. Other problems are encountered when attempting to produce better nitrogenous fertilizers more economically. The industry is concerned with the increasing imports of foreign low-cost ammonia and urea.

New and improved utilization of ammonium nitrate explosives with appropriate safety precautions remains an important problem to the nitrogen industry, as well as to the mining and construction industries.

OIL SHALE

By L. W. Schramm [1] and J. D. Lankford [1]

VAST deposits of oil shale, a sedimentary rock containing organic matter, comprise the second largest fossil fuel resource in the United States. It is exceeded only by coal and is more plentiful than petroleum and natural gas, which together furnished about three-fourths of the fuel consumed domestically for energy. By far the most important oil-shale deposits in the United States are those of the Green River formation in Colorado, Utah, and Wyoming, which represent a resource of about 2 trillion barrels of oil in place. Liquid fuels of all types, fuel gases, and a wide variety of chemicals can be produced from shale oil, a pyrolysis product obtained by heating oil shale. Interest in the oil-shale deposits of the Rocky Mountain region have risen to a high level since 1963.

The organic material, kerogen, in oil shale is a solid substance which is intimately associated with a mixture of minerals that in most oil shales make up a preponderant share of the rock. Kerogen undergoes a chemical transformation from 800° to 1,000° F to give a major pyrolysis product of oil; secondary products are gas and a carbonaceous residue which remains associated with the inorganic matter. Shale oil obtained in this manner is a mixture of hydrocarbons and hydrocarbon derivatives containing oxygen, nitrogen, and sulfur. By appropriate processing techniques, this oil can be converted to products similar to those from petroleum.

Although oil-shale industries have existed at various times in at least 10 countries, most of them have been discontinued because of competition by lower priced petroleum products. The largest industrial oil-shale operations today are in Estonia and Manchuria.

The economic outlook for commercial production of shale oil in the United States has been improved by technologic advances achieved through research and development during the past two decades. Concurrently, wage increases and the mounting costs of equipment and supplies have tended to hinder shale-oil competition with petroleum. Shale-oil's entry into the domestic market as a supplement to petroleum will be determined by economics—not by a petroleum shortage because petroleum supplies are vast.

Cooperative research and development work by six oil companies and a research foundation is in progress at the Government's oil-shale facility near Rifle, Colo. Recently, the in situ approach to shale-oil extraction has received much attention, although little field testing of this technique has been undertaken. One company has begun work on a project to mine and retort oil shale which is widely reputed to be commercial. The company announced that the plant will be designed to produce about 55,000 barrels per day of crude shale oil.

A major portion of the oil-shale deposits in Colorado, Utah, and Wyoming are on lands in the public domain and are under the jurisdiction of the Department of the Interior. Appropriately, therefore, the Department is engaged in a program for development and implementation of public policies to insure orderly development and conservation of the oil shale and the other natural resources on and beneath the surface of the federally owned oil-shale lands.

BACKGROUND

Commercial production of liquid fuels from oil shales began in France in 1838 and in Scotland in 1850. Subsequently, industries were established and flourished at various times in Australia, Estonia (U.S.S.R.), Sweden, Spain, Manchuria, Kwangtung (China), South Africa, and Germany. Most of these have been discontinued, and today industrial operations

[1] Chemical engineer.

of appreciable size exist only in Spain, Estonia, Manchuria, and Kwangtung. Much research and development work has been done on Brazilian oil shale in anticipation of future industrial operations.

The Spanish industry is processing about 3,000 tons of oil shale per day for an oil yield of roughly 2,100 barrels. Estonian oil shale (*20*)[2] has a high oil yield, generally about 50 gallons per ton. U.S.S.R. shale-oil production in 1963, mostly in Estonia, has been estimated at 55,000 barrels of oil per day. Part of the Estonian shale is used to produce gas, which is pipelined to Leningrad area.

Manchurian oil-shale operations are thought to be the largest in the world on the basis of tonnage of shale mined and processed. However, the Manchurian shale has a relatively poor oil yield, averaging only about 15 gallons per ton, and oil production is estimated to be between 30,000 and 40,000 barriels per day. Operations in the Chinese Province of Kwangtung are relatively new and are thought to be small.

In Canada and the Eastern United States a small shale-oil industry was operating in 1860 but disappeared when petroleum became plentiful following the Drake discovery oil well in Pennsylvania. Interest in oil shale in the United States was renewed shortly before the 1920's, and numerous experimental projects were undertaken. From 1914 to 1927, a small intermittent, commercial operation was conducted by the Catlin Shale Products Co. near Elko, Nev. However, an oil-shale industry of significant size has never existed in the United States.

Research and development on oil shale in the United States have been conducted sporadically by industry, Government (*2*), universities and others for many years, and there has been sustained interest since World War II.

Intermittently, from 1918 to 1930 the Bureau studied oil-shale retorting, shale-oil refining, and the chemistry of shale oil. During 1944–55, the Bureau conducted mining, retorting, and refining investigations on a pilot plant and demonstration scale near Rifle, Colo. This work was authorized by the Synthetic Liquid Fuels Act (Public Law 290, 78th Cong., April 1944), and subsequent amendments. Laboratory and bench-scale research has been conducted continuously since 1944 at the Bureau's Laramie Petroleum Research Center, Laramie, Wyo., and still is in progress. The Rifle facility, inactive since 1956, was leased to the Colorado School of Mines Research Foundation by the Department of the Interior in 1964 for research and development work. Pilot-plant operations to develop oil-shale-processing technology are being conducted at the Rifle installation under the sponsorship and technical direction of Socony Mobil Oil Co. and Humble Oil & Refining Co. Several other oil companies (Sinclair Research, Inc., Phillips Petroleum Co., Pan American Petroleum Corp., and Continental Oil Co.) are observer participants, and the research and development program is financed by all 6 participating companies.

In 1957, a large experimental retort was erected on Union Oil Co.'s property near Grand Valley, Colo., and was in use for more than a year. The company reported that the retort operated successfully at up to 1,200 tons of shale per day, and that several thousand barrels of crude shale oil from this operation was processed through the gilsonite refining plant near Fruita, Colo. The refined motor fuel products met standard specifications and were sold in regular commercial channels.

In 1963 and 1964 interest increased sharply and recently has risen to a high level. A few manifestations of such interest are articles published recently (*13*, *14*), higher prices for oil-shale lands than those prevailing a few years earlier, expressions by oil companies and others of interest in leasing federally owned oil-shale lands, and an announcement of plans for a commercial venture by Colony Development Co., which is owned by The Oil Shale Corp., Standard Oil Co. of Ohio, and Cleveland Cliffs Iron Co. and will be on oil-shale land owned by the Dow Chemical Co. According to the announcement, the capacity of the installation will be about 55,000 barrels of shale oil per day, and the capital investment is expected to be about $100 million. An initial semiworks unit is scheduled for operation in 1965, and the announced goal for initial production by the commercial plant is 1967.

TECHNOLOGY

The oil-shale technologies developed in various countries of the world (*9–11*, *19*) in general have followed the pattern of mining and crushing the shale, then retorting the crushed shale to obtain crude shale oil, and refining the oil into usable products, mainly liquid fuels. An exception to this general pattern is the Ljungström in situ process, a method of applying electrical heating to oil-shale beds, used in Sweden prior to curtailment of the oil-shale industry there. A unique feature of the Estonian oil-shale industry is that fuel gas is manufactured from some of the oil shale. The characteristics of oil-shale deposits and the

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

properties of oil shales differ greatly from one deposit to another. Because of these and other differences, such as certain economic conditions in one locale versus another, the technology used for one oil-shale deposit often is not suitable for another, or it may require modification before it can be applied successfully to the shales from another deposit. In the United States and some of the other countries having oil-shale resources, the technology derived from research and development has not yet been translated into industrial experience.

Occurrence and Geology

Oil shales are distributed widely throughout the world and occur in sedimentary formations from Cambrian to Recent. They vary greatly in richness, thickness, and rock characteristics. In the United States they occur in at least 30 States (*6*), and, in some instances, in sediments of several different geologic ages within the same State, as shown in table 1. Based on potential oil yield, the most important oil shale occurs in the Green River formation of Eocene (Tertiary) age, which covers approximately 16,500 square miles in adjoining portions of Colorado, Utah, and Wyoming. The other domestic oil shales are of secondary importance as they commonly yield less than 15 gallons of oil per ton and occur in beds less than 25 feet thick.

TABLE 1.—*Oil shales of the United States*

Geologic age	State
Quaternary	Idaho.
Tertiary	Arkansas, California, Colorado, Montana, Nevada, Texas, Utah, Wyoming.
Cretaceous	Colorado, Idaho, Maryland, Montana, South Dakota, Texas.
Triassic	North Carolina, Alaska.
Permian	Idaho, Montana, Ohio, Utah, Wyoming.
Carboniferous and Devonian.	Alabama, Arkansas, Georgia, Illinois, Indiana, Kansas, Kentucky, Maryland, Missouri, Michigan, Montana, New York, Ohio, Oklahoma, Pennsylvania, Tennessee, Texas, Utah, Virginia, West Virginia.
Ordovician	Illinois, Iowa, Nevada, Tennessee, Wisconsin.

The Green River oil shales were formed by the deposition of organic and mineral matter in large shallow lakes that became compact, laminated sediments up to several thousand feet thick. These oil shales or marlstones contain widely varying amounts of organic material and, consequently, yield different amounts of oil by pyrolysis. In Colorado, the Green River formation covers about 2,600 square miles, but the principal oil-shale measures occur in the Parachute Creek member within 1,350 square miles in the Piceance Basin. Although the oil shales in the center of the basin are buried under 1,000 feet or more of overburden, a section nearly 2,000 feet thick has an average assay value of 25 gallons per ton. Sections of this richness become progressively thinner toward the basin margin. Near the outcrop facing the Colorado River, the beds having an average assay of 25 gallons per ton generally are less than 100 feet thick. The Green River formation covers about 4,700 square miles in Utah and 9,200 square miles in Wyoming. The oil-shale deposits in these portions of the formation have not been as thoroughly investigated as those in Colorado. However, present information indicates that, although the deposits in Utah and Wyoming extend over larger areas, generally they are leaner, thinner, and less uniform.

Properties of Oil Shale and Shale Oil

Oil shales consist of solid, largely insoluble organic material intimately associated with a mixture of minerals. Green River oil shale is somewhat resilient, is resistant to fracture, has a Moh's hardness of about 5, and has little porosity or permeability. Detailed analyses giving the compositions, oil yields, and other chemical and physical properties of several grades of the shale have been published (*15*, *18*). Mahogany-zone oil shales have similar characteristics over a wide area; the average composition is shown in table 2.

Kerogen, the organic constituent, is a mixture of high-molecular-weight compounds of carbon, hydrogen, nitrogen, oxygen, and sulfur. According to Himus (*11*), the composition of kerogen in oil shales throughout the world range within the following wide limits: Carbon, 66 to 88 percent; hydrogen, 7.2 to 12.8 percent; nitrogen, 0.1 to 3.1 percent; sulfur, 0.1 to 8.8 percent; and "oxygen plus errors," 0.18 to 24.7 percent. Kerogen is essentially insoluble in alkaline, acidic, and organic solvents. Chloroform or aqueous solutions of chlorohydrate cause it to swell slightly, but only about 10 percent dissolves.

The kerogen in Green River oil shale is believed to be predominantly a heterocyclic material connected to or associated with smaller amounts of hydrocarbon material consisting of straight and branched chain paraffins, cyclic paraffins, and aromatics. A study of low-temperature thermal extracts obtained from this kerogen at 77° to 662° F (25° to 350° C) indicates that it contains approximately 5 to 10 percent straight and branched chain paraffin structures with 25 to 30 carbon atoms, 20 to 25 percent cycloparaffin structures with 3 to 5 rings per molecule, 10 to 15 percent aromatic structures with 3 to 5 rings per molecule, and 45 to 60 percent heterocyclic material containing oxygen, nitrogen, and sulfur.

TABLE 2.—*Composition of oil-shale sections averaging 25 gallons of oil per ton in the Mahogany zone of Colorado and Utah*

	Weight-percent
Organic matter:	
Content of raw shale	13.8
Ultimate composition:	
Carbon	80.5
Hydrogen	10.3
Nitrogen	2.4
Sulfur	1.0
Oxygen	5.8
Total	100.0
Mineral matter:	
Content of raw shale	86.2
Estimated mineral constituents:	
Carbonates, principally dolomite	48
Feldspars	21
Quartz	13
Clays, principally illite	13
Analcite	4
Pyrite	1
Total	100

Shale oils produced from Green River oil shale by the Bureau's Gas Combustion retorting process, the older NTU (Nevada, Texas, Utah) process, and the process of the Union Oil Co. of California, have similar compositions. The gravity of these oils generally ranges from 18° to 21° API. They have a high pour point (about 75° to 90° F), high viscosity (about 300 Saybolt Universal Seconds at 100° F) and contain less than 10 percent naptha. They contain about 0.75 percent sulfur and about 2.0 percent nitrogen. Shale oil is unlike petroleum in that it contains appreciable quantities of nitrogen compounds and rather large quantities of unsaturated compounds. Composition data are fairly extensive on the naphtha fractions (*5*) but are rather meager on higher boiling range fractions.

Mining

A low-cost underground mining method was developed and demonstrated by the Bureau (*6*) at its oil-shale facility near Rifle, Colo., during 1944–56. A "selective mine" was opened first to obtain specific shales from any of the nine beds within the principal oil-shale section, commonly referred to as the Mahogany Zone, for retort testing, and to determine whether theoretical studies on safe roof spans were applicable. A "demonstration mine," sometimes referred to as an underground quarry, then was opened in a 73-foot minable section of the Mahogany Zone to demonstrate the feasibility of a room-and-pillar mining method, to develop and test equipment, and to determine whether low mining costs and high recovery were possible.

Although a mining method having a top heading and two benches was used during the early phase of the mining work, a two-level operation was adopted later—a top heading 39 feet high and a single bench 34 feet high. Head and side space was sufficient to permit the use of large portable diesel and electrically driven mining equipment, thereby obtaining a high output per man-shift. An average of 150 tons per man-shift was achieved for sustained periods during normal operating tests.

Special equipment developed for mining the high faces included drilling jumbos, explosives-loading platforms, scaling rigs, and a mobile compressor and utility station. An electric shovel with a 3-cubic-yard dipper was used to load the broken shale. Diesel-powered end-dump trucks, of 15- to 22-ton capacity, were used for haulage. Room openings and roof-supporting pillars were both 60 feet square. An extraction ratio of 75 percent of the rock in place was attained, leaving supporting pillars which comprised the remaining 25 percent.

Drilling proved to be a major cost item. At first only percussion drills were available, and most of the research on drilling and costs was based on this type of drill. To improve efficiency when drilling vertical holes in the bench mining operation, a hydraulically operated rotary drill mounted on a tractor was developed. For horizontal holes, another rotary drill was developed, but closing of the mine prevented comprehensive testing. A 45-percent semigelatin dynamite was adopted as a standard explosive after much experimental work. Subsequently, new explosives have been developed, and current thinking is that the use of ammonium nitrate explosive mixtures probably would result in lowered blasting costs.

Test-room data indicated a progressive roof deterioration over a period that could result in failure. The minimum roof life was more than 2 years before roof failure would be expected, whereas, in normal retreat-type commercial operations, a unit mine area would be mined out in less than 60 days and then closed to entry. This period of open entry, which is much shorter than 2 years, would leave a substantial margin of safety for a retreat-type mining operation.

In the early 1950's, cost estimates based on data developed at the demonstration mine were made by the Bureau and industry groups in cooperative studies. The estimates ranged from 48 to 56 cents per ton for mining and crushing oil shale and conveying the crushed material to retort stockpiles. These estimates included labor, supplies, depreciation, local taxes and administrative overhead, but not depletion, interest on investment, expenditures for offsite facilities or cost of oil-shale land. These figures

pertained only to costs and therefore did not include profit or income taxes. During the years since estimates were made, labor rates and equipment prices have increased, but it is believed that the escalating effect of these increases on oil-shale mining cost has been largely offset by technologic advances. Changing to rotary drilling in the mine heading as well as in benching; blasting with a more economical explosive, such as an ammonium nitrate-oil mixture; use of better drilling, haulage, and loading equipment; and other improvements based on recent advances in quarry and open-pit mining engineering can be expected to lower costs substantially. Accordingly, mining oil shale on a large scale probably still could be achieved at close to 50 cents per ton.

The optimum size of a single room-and-pillar mine currently is envisioned at about 30,000 tons per day. Mining a continuous section 100 feet thick at this rate, with 75 percent extraction, would deplete an area of about 1,050 acres in 20 years. This amount of oil shale would produce almost 120 million barrels of oil if the average assay were 25 gallons per ton and if overall retorting efficiency were 90 percent of assay.

The room-and-pillar mining method may be adaptable to shales other than those of the Mahogany Zone and to areas far separated from an outcrop by gaining entry to the shale through vertical shafts. Open-pit mining probably will be practical in some areas where the ratio of overburden to shale is not excessive.

Crushing

The Bureau has obtained substantial data on crushing Colorado oil shale using different types of equipment including jaw, gyratory, impact, and roll crushers. Experience and data were accumulated on two- and three-stage size reduction throughout the testing and development program conducted at its oil-shale project near Rifle, Colo. In addition, data were derived from a number of crushing tests of short duration which were conducted cooperatively between the Bureau and several industrial machinery companies. As a result of these studies and operating experience, valuable information was acquired and relationships were derived on oil-shale properties as functions of type of crushing equipment and retorting processes. For example, a significant property of oil shale from the richer strata of the Mahogany Zone is that it is tough and resilient and tends to form slabs, which produce operating troubles especially when crushed in a jaw-type crusher. For some processes, such as the Gas Combustion (*3*) retort pioneered by the Bureau, a large amount of very small particles is not desirable and crushing equipment for preparing its oil-shale feed should be chosen that minimizes fines production.

Although the crushing step is not considered as a critical problem, a number of factors will be important in designing commercial crushing plants and in selecting the most suitable equipment. The cost of crushing is a relatively small part of the overall cost of producing liquid fuels from oil shale. In 1955, the cost of reducing mine-run shale with a maximum particle size of 60 inches to minus 3-inch particles was estimated to be about 15 cents per ton.

Retorting

Heating is the only practical means known to produce shale oil from oil shale. From 800° to 1,000° F, the organic material, kerogen, which is a solid substance, undergoes a chemical transformation by pyrolysis, in effect a thermal cracking. The major pyrolysis product is oil; secondary products are gas and a carbonaceous residue which remains on the retorted shale.

Three retorting processes designed for processing the oil shales of Colorado, Utah, and Wyoming have progressed through various stages of pilot-plant development, and offer promise for commercial application. One of the three processes was developed by the Bureau, another by the Union Oil Co. of California, and the other by The Oil Shale Corp. (now a part owner of Colony Development Co.); the processes are known as Gas Combustion, Union, and TOSCO, respectively. Another, known as the Entrained Solids retorting process (*16*), has been developed by the Bureau through laboratory and small pilot-plant experimentation, and shows considerable promise of finding commercial application in processing oil-shale fines (particles smaller than about one-fourth inch) that probably will be removed by screening from the feed to Gas Combustion and perhaps other retorts. In situ retorting may become an important shale-oil extraction method, but the technology is still in an early stage of development.

In the Bureau Gas Combustion process, a bed of oil-shale particles, ranging in size from about one-fourth inch to 3 or 4 inches, moves down through a vertical retorting vessel while gas flows up through the bed. Air mixed with gas is injected into the central portion of the retort, and combustion of the gas provides much of the heat for retorting. Some of the residual carbon in the retorted shale burns also, providing additional heat. Oil vapors from the retorting zone condense as small droplets to form a mist in the upper portion of the moving bed of particles. The mist is carried out of the

780–887 O—65——41

retort by the effluent gas stream, and is then separated from the gas by suitable agglomerating equipment such as centrifugal separators. Part of the gas is recirculated through the retort to provide the major fuel for the Gas Combustion process. The process was studied by the Bureau in three sizes of pilot plants, the largest of which was operated at about 200 tons of shale per day. Further development has been initiated at Rifle under the previously described leasing arrangement with private organizations.

The Union Oil Co. process uses a vertical, continuous, retort which is underfed with shale and has a countercurrent gas flow from an internal-combustion zone. Crushed oil shale, with pieces ranging up to the size of a double fist, is forced upward from the bottom of the retorting vessel by means of a ramlike piston that serves as a "rock pump." Air and combustion gases flow downward through the shale bed. As the shale moves upward, it passes progressively through a zone where downward flowing gases and products are cooled and shale oil is condensed; a retorting zone, where gases from combustion heat the shale to pyrolysis temperature; a combustion zone, where combustibles and residual carbon on the retorted shale are burned; and finally a cooling zone, where the incoming air absorbs some of the heat content of the retorted shale. The hot spent shale spills over the top of the retort into a chute and passes from the system.

In the TOSCO retorting process, oil shale, crushed much finer than the feed to the Union and Gas Combustion retorts, is introduced continuously, along with hot ceramic balls, into a horizontal, kiln-type, rotating drum. The shale is heated to retorting temperature (about 900° F) through direct contact with the heat-carrying balls. Oil vapors and product gas released by the pyrolysis are withdrawn from the rotating drum and enter a recovery system, which includes a "soaking" drum where additional cracking occurs as well as condensing and collecting equipment. The ceramic balls leave the drum and are reheated after a part of their heat content is given to the shale. The retorted shale is sent to equipment where the residual carbon is burned off, and the heat so generated is used to reheat the ceramic balls. This process is a greatly improved evolvement of the Aspeco retorting system, a process that was conceived in Sweden by Olaf Aspegren. Under a contract with The Oil Shale Corp., the Denver Research Institute assisted in the development of the TOSCO process in a 25-ton-per-day pilot plant.

Many retorting processes have been proposed, but they either have been rejected because they were inoperable or were lacking in one or more of the essential characteristics for successful application to the oil shales of Colorado, Utah, and Wyoming—or they have faded into the background because research and development work on them has not been pursued far enough to demonstrate their merit. The Socony Vacuum Oil Co. (now Socony Mobil Oil Co.) studied the application of their patented Thermofor catalytic cracking equipment to oil-shale retorting. Standard Oil Development Co. (now Esso Research & Engineering Co.) conducted retorting tests in a modified two-vessel fluid catalytic cracking pilot plant. The Bureau experimented with several processes (*1*), namely, Hayes, NTU, Pumpherston, Royster, Gas Flow, Counterflow, and Thermal-Solution, but discontinued work on these in favor of the Gas Combustion process.

The most recent work on oil-shale utilization involves studies by oil companies of in situ retorting using interconnections between wells in shale formations resulting from oil-well fracturing techniques. Such interconnected wells would serve as input and producing wells for underground combustion which would provide heat to retort the oil shale underground. Shale oil then would be liberated and withdrawn from one of the wells.

Sinclair Research, Inc., a subsidiary of Sinclair Oil Corp., initiated work in 1964 on an in situ oil-shale retorting test in the Piceance Creek area in Rio Blanco County, Colo., where the oil-shale beds are hundreds of feet thick. Sinclair operated a pilot in situ project (*8*) in the early 1950's at Haystack Mountain, near Debeque, Colo., where the oil-shale beds are thinner and relatively near outcrop areas. Other oil companies and the Bureau have conducted laboratory and bench-scale work to obtain data for application in the development of in situ retorting methods and techniques, and several companies have conducted field investigations of a preliminary character.

Refining

Shale-oil refining research and process development in the United States have been focused to a large extent on adapting petroleum refining techniques to shale-oil processing and to a limited extent on developing new processes especially suited to the characteristics of shale oil. This approach was taken in the interest of utilizing existing oil industry methods and equipment and thereby achieving a flexibility that will permit movement of shale oil products when they become available into regular petroleum channels.

Shale oil produced in retorts designed to obtain a high-percentage yield of oil contains only

a small quantity of distillate in the gasoline-boiling range. Both straight-run distillate and residual fuel oils can be prepared directly from crude shale oil, but the distillate fuels usually require treatment to meet specifications.

Gasoline and diesel fuel were obtained by thermal cracking and low-temperature chemical treatment in the Bureau's experimental refinery (*12*) at Rifle, Colo. The shale gasoline met the specifications then in effect for regular-grade gasoline and was burned in automobiles used on the project. Shale diesel fuel produced in the experimental refinery was tested in several types of diesel-powered equipment and in railroad locomotives, and it was regularly used in the diesel equipment on the project. Performance was satisfactory and comparable to that obtained with regular commercial diesel fuel. In a commercial shale-oil refinery, tar bases and tar acids removed from the lighter distillate fractions by washing with sulfuric acid and caustic solutions, as was done at Rifle, would be produced in rather large quantities. These tar acids and bases would have byproduct value.

Hydrogenation, re-forming, desulfurization and nitrogen removal, catalytic cracking of reformates, and other modern refining processes have been studied on a laboratory scale at the Bureau's research facility in Laramie, Wyo. (*7*).

Crude shale oil contains waxes and high-viscosity materials which cause it to have a high pour point (90° F); therefore, it is not pumpable at ambient temperatures. Vis-breaking, a mild thermal cracking, or coking, a more severe thermal cracking, produces shale oil suitable for pipeline transportation. Recycle cracking of crude shale oil produced a yield of over 50 percent gasoline-boiling-range naptha in the experimental refinery. Thermally cracking crude shale oil to yield coke and a coker distillate boiling lower than the original crude may be advantageous as feedstock preparation for subsequent refining in operations such as hydrogenation, catalytic cracking, desulfurization and nitrogen removal. Re-forming the gasoline fraction by either thermal or catalytic processes improves its octane rating. Cracking of crude shale oil or its high-boiling fractions at elevated temperatures or in the vapor phase results in highly aromatic products. This aromatic oil may be hydrogenerated readily to premium-grade gasoline or aromatic chemicals.

Hydrogenation is an effective means of removing sulfur, nitrogen, and oxygen from shale oil and of stabilizing the more reactive unsaturated components, thereby reducing their gum- and color-forming tendencies. Excellent yields of high-quality jet, diesel, and distillate fuels can be produced by this method of refining. Hydrogenated oils also are satisfactory charging stocks for catalytic cracking and reforming processes and may be suitable for use in manufacturing lubricants. Laboratory investigations have demonstrated that without any treatment such as hydrogenation to remove nitrogen, shale-oil stocks are unsatisfactory feed materials for catalytic cracking processes currently used in the petroleum refining industry because nitrogen compounds in shale oil "poison" (have a deactivating effect on) cracking catalysts.

Several overall shale-oil refining procedures made up of various combinations of unit operations such as those mentioned have been evaluated and could be used to produce a full range of liquid fuels.

Waxes having properties similar to petroleum waxes can be separated from shale-oil fractions by conventional dewaxing processes. Shale-oil asphalts and road oils were used to surface roads at the Bureau's facility near Rifle, Colo. Shale-oil pitch was used experimentally and found satisfactory as a blending agent with coal at a Utah steel mill to produce metallurgical-grade coke. Shale-oil coke was found to offer promise for use in blast furnaces and in the manufacture of electrodes and carbon brushes.

USES

Shale oil will be utilized in much the same manner as petroleum and will become a supplemental source of liquid fuels. Gasoline, jet fuel, diesel fuel, and fuel oils are expected to be the major shale-oil products. Properties of these products obtained from shale oil closely resemble those of their petroleum counterparts and will meet the same specifications. Shale-oil fuels are expected to merge into the use pattern of petroleum fuels (see Petroleum chapter of this bulletin). Chemicals similar to many of the petrochemicals manufactured from petroleum, particularly olefinic, aliphatic, and aromatic hydrocarbons such as naphthalene, also may be produced from shale oil. Some inorganics such as sulfur and ammonia also are expected to be byproducts of an oil-shale industry. However, shale oil probably will not be a significant source of lubricants, inasmuch as petroleum stocks better suited for this purpose are plentiful and require less processing.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Because shale oil differs in composition from most natural crude oils in some respects, its refining may result in byproducts not commonly obtained from petroleum, at least not in as large quantities. Among these are chemicals such as tar acids and tar bases, which normally are con-

sidered as coal tar derivatives, but also are obtainable from some shale-oil distillates under particular types of treatment.

Byproducts may be produced in conjunction with oil-shale retorting plants as well as shale-oil refineries. Large volumes of low Btu gas will be obtained from internal-combustion retorts. Other retorts will produce gases rich in hydrogen, hydrocarbon gases, carbon dioxide, and hydrogen sulfide. Decarbonization of the heavy oils to produce the desired distillate materials will result in large amounts of coke if coking is utilized as an initial processing step. Coke would not be a major product if the crude were hydrogenated. Among the hydrocarbon gases are ethylene, propylene, and other olefins of interest to the chemical industry. All retorting processes will discharge spent shale. Although no large-tonnage uses for this inorganic material are foreseen, it may find local uses in special situations such as for low-cost fill. However, the problems and expense that may be involved in disposing of spent shale in large quantities are expected to more than outweigh the credit that may accrue because of such limited uses.

RESOURCES

Estimates of oil in place in the principal known oil-shale deposits of the world are given in table 3. Only a portion of these shale-oil resources can be regarded as likely to be economically recoverable in the near future using present technology. Some of the beds are too lean to be of commercial interest any time soon, and the application of mining methods presently considered suitable would not remove all the oil-shale from the deposits. At the same time it should be remembered that the presently known resources represent only part of the world's total shale-oil potential. Investigations of some of the known deposits have been limited, and additional deposits may be discovered in the future. However, it is believed that the estimates shown in table 3 portray the order of magnitude of shale-oil potentials of the known deposits in the countries listed, with the possible exception of Canada. Whereas only the Albert shale deposits in New Brunswick are included in the estimate, there are reports in the literature of several other deposits in Canada.

The oil shales of the Green River formation in Colorado, Utah, and Wyoming are by far the most important deposits in the United States. Some of the other States have substantial shale-oil resources, but the deposits usually are relatively low grade, are not as well defined nor as amenable to low-cost mining and processing, and therefore are less attractive economically than the Rocky Mountain deposits as a shale-oil resource potential.

TABLE 3.—*Estimates of the major known shale-oil resources of the world in oil shales assaying 10 gallons per ton or more* [1] [2]

Country or area	Oil in place, million 42-gallon barrels
Argentina	400
Australia, including Tasmania	270
Balkans and other Central Europe [3]	340
Brazil	800,000
Burma	2,000
Canada (Albert shale in New Brunswick) [4]	50,000
Chile	20
China:	
Fushun, Manchuria	2,100
Other deposits	26,000
England	1,000
France	425
Germany, West	2,000
Israel	20
Jordan	45
Sicily	35,000
Luxembourg	700
New Zealand	560
Republic of the Congo	100,000
Republic of South Africa	130
Scotland	580
Spain	280
Sweden	2,500
Thailand	800
United States:	
Colorado, Utah, and Wyoming	2,000,000
Central and Eastern States	200,000
U.S.S.R.:	
Estonia and adjacent Leningrad Area	22,000
Other European U.S.S.R.	13,000
Siberia	80,000
Total [5]	3,340,170

[1] Estimates are based on oil-shale formations thick enough to be considered minable in the future; most of the shale-oil resources are in thick oil-shale sequences.

[2] Based on a comprehensive treatment of the subject by Donald C. Duncan and Vernon E. Swanson of the Geological Survey in "Organic-Rich Shale," prepared as a chapter of a treatise on world energy resources. The manuscript of the shale chapter was in the review process preparatory to publication at the time this table was prepared. Many references to published information on the subject are contained in the manuscript.

[3] Countries included are Bulgaria, Yugoslavia, Albania, Greece, Czechoslovakia, Austria, and Switzerland.

[4] This is an order-of-magnitude estimate for the richer oil-shale sequences in the Albert Formation. Deposits of oil shale also are known to exist in Newfoundland, Nova Scotia, Ontario, Quebec, Saskatchewan, and Manitoba.

[5] Rounded total, 3.3 trillion barrels; energy equivalent, 19×10^{18} Btu. Nominally, shale oil of average composition is assumed to have an energy equivalent of 5.9×10^6 Btu per barrel. The gross heating value of crude shale oil produced by the modified Fischer assay retort from a composite oil-shale sample representative of the Mahogany Zone in Colorado is 18,510 Btu per lb, and the specific gravity of this crude shale oil is 0.916 at 60°/60° F (Bureau of Mines Report of Investigations 4825, 1951, p. 25). Accordingly, the gross heating value of this particular shale oil is 5.93×10^6 Btu per barrel.

Source: Geological Survey.

Analyses have been made by the Bureau (*17*) on more than 90,000 core and drill-cutting samples of the oil-shale deposits in the Green River formation. The samples were provided for the most part by companies engaged in evaluating oil-shale properties and drilling for oil and gas. The data provided by these assays are the principal source of oil-yield information used by the Geological Survey and others for resource evaluations. In Colorado, Utah, and Wyoming the shale-oil equivalent of beds richer than 10 gallons per ton and at least 15 feet thick is estimated at about 2 trillion barrels. Accord-

ing to the Geological Survey, the oil potential of the principal oil-shale deposits in Colorado's Piceance Basin includes about 500 billion barrels in shale yielding more than 25 gallons per ton and about 800 billion barrels in shale yielding between 10 and 25 gallons, or a total of 1.3 trillion barrels in combined high- and low-grade oil shale.

In Utah and Wyoming, estimates of oil in place in shale formations at least 15 feet thick assaying 25 gallons per ton or more are 120 billion barrels and 43 billion barrels, respectively. Utah's oil shales in beds at least 15 feet thick that will yield an average of 15 gallons per ton are estimated to represent about 320 billion barrels. In Wyoming, the shale oil in beds richer than 10 gallons per ton is estimated at 370 billion barrels.

The percentage of in-place oil that may be recovered economically depends principally on such major factors as extraction ratio achieved in mining, amount of fines discarded, if any, and retorting efficiency. In areas amenable to mining by underground methods developed by the Bureau at Rifle during 1944–55, it is estimated that about two-thirds of the in-place oil could be recovered using those mining and processing techniques that were demonstrated there.

GOVERMENT PROGRAMS

A major portion of the oil-shale deposits in Colorado, Utah, and Wyoming are on lands in the public domain which are under the jurisdiction of the Department of the Interior. Jurisdictional responsibilities apply not only to the land but also to the minerals and other natural resources on and beneath the surface of the land.

Prior to 1920, disposition of publicly held oil-shale lands had been governed by mining laws, and many claims had been filed under the U.S. mining law of May 10, 1872, but had not been brought to patent. Under the Mineral Leasing Act of February 25, 1920, oil-shale deposits in the public domain were made subject to leasing, rather than to location as mineral placer claims as formerly, with the exception that valid oil-shale mining claims existing on that date could legally be brought to patent. The federally owned oil-shale deposits and the lands containing such deposits were withdrawn from lease or other disposition by Executive Order 5327 of April 5, 1930, to allow clarification of the status of land ownership and title. This order has not been lifted since then, and it has not been possible to lease Federal oil-shale deposits, although later the order was modified to permit petroleum and natural gas operations and exploitation of sodium minerals such as the trona deposits in Wyoming near the town of Green River.

As a guarantee of oil for the Navy in future emergencies, the Government has segregated and held apart for such purpose certain sections of the public domain containing oil shale. Approximately 62 square miles of oil-shale land on the public domain in Colorado (Shale Reserve No. 1) and approximately 150 square miles in Utah (Shale Reserve No. 2) were reserved for the Navy by two Executive orders in 1916 and subsequent modifying orders. By an Executive order in 1924, approximately 35 square miles of land in Colorado (Shale Reserve No. 3), adjacent to the naval reserve that had been established earlier, were reserved primarily for the purpose of providing sites for plants to process naval-reserve oil shale and space for disposal of the resulting spent shale.

The Department is engaged in a program (*4*) for the development and implementation of public policies to insure orderly development and conservation of the federally owned oil-shale deposits, and to foster the most beneficial use of all oil-shale lands. A group of distinguished citizens from outside the Government, known as the Oil-Shale Advisory Board, have been appointed by the Secretary of the Interior to assist the Department in developing background and solutions to the many-faceted oil-shale policy problems. Implementation of sound policies will greatly aid oil shale's contribution to the Nation's long-term economic growth, add substantially to the national security, and permit wise use of the land, mineral, and water resources.

TAXES

Under present tax laws, a depletion allowance of 15 percent of the value of the oil-shale rock as mined can be deducted from the taxable income of a commercial oil shale operator in figuring income tax liability (provided that amount does not exceed 50 percent of taxable income computed without allowance for depletion). Oil shale, as petroleum and all minerals, is a natural resource which is entitled to a depletion allowance. The depletion-allowance provisions of Federal tax laws reflect a recognition of the wasting-asset nature of the extractive mineral industries. Allowable percentage depletion rates range from 5 to 27.5 percent.

Imports of petroleum and its products are likely to have an economic relationship to a shale-oil industry analogous to their relationship to the domestic petroleum industry. Accordingly, in the future, Government policies regarding petroleum imports may be expected

to have a significant bearing on a shale-oil industry.

RESEARCH

Methods, procedures, and equipment for mining oil shale, extracting shale oil, and processing the oil have been developed to varying degrees of refinement in many countries. The existing oil-shale technologies in various parts of the world are products of research and development, combined in most instances with industrial oil-shale operating experience. Patents relative to oil-shale and shale-oil processing number over 2,000, and new ones continue to be issued.

In the United States, there has been substantial oil-shale research and development, most of which has occurred during the past 20 years. Oil companies and other industrial firms, the Bureau of Mines, educational institutions, and individuals have engaged in this work. The overall objective of most such efforts has been to effect technological improvements that would lower the cost of producing liquid fuels from oil shale.

The in situ approach to shale-oil extraction, now receiving much attention, offers promise at least in concept of becoming an extremely valuable tool for extracting oil from the oil shales of the United States. It may prove to be applicable to deep-lying oil-shale beds and deposits that are hundreds of feet thick, such as those in the center of the Piceance Basin. Mining of oil shale from such deposits probably would be expensive and difficult. In situ retorting also may be found applicable to oil-shale beds that are too thin or too lean to be attractive for mining. However, the technology is in an early stage of development, and time and effort will be required to establish the feasibility of the in situ method and to define its capabilities and limitations.

The oil-shale program at the Bureau includes both basic and applied types of research. These investigations may be grouped principally in the following broad categories: (1) studies of the structure and composition of kerogen and its chemical and physical properties; (2) developing information on the characteristics of the Nation's oil-shale deposits, with emphasis on those of Colorado, Utah, and Wyoming; (3) obtaining scientific and engineering information needed to solve problems encountered in the development of retorting and refining processes; (4) laboratory studies that provide technical information and data which may be used in developing in situ oil-shale retorting methods; (5) shale-oil processing studies, especially the application of hydrogenation techniques in combination with other petroleum refining processes; and (6) evaluation of shale oil as a source of chemical products.

Some preliminary studies have been made jointly by the Bureau and the Atomic Energy Commission to obtain information needed in the planning of experiments tentatively contemplated and designed to assess the possibilities of using nuclear explosives in connection with in situ oil-shale operations. As yet no field experiments involving nuclear devices have been initiated. Part of one concept of using a nuclear explosive would be to create an underground cavity by a nuclear device. Subsequently, the cavity would become filled with broken rock from caving, and this rock-filled cavity then might be retorted in place, much as in a batch-type conventional retort such as the NTU. The oil retorted from the shale then could be withdrawn from the base of the cavern.

A continuing growth of the fund of basic scientific oil-shale knowledge can be expected to lead to advances in mining and processing techniques and to new and improved products. This knowledge embraces such aspects as constitution and structure as well as the chemical and physical properties of oil shale and its organic and inorganic constituents. The chemical reactions involved in the conversion of kerogen to shale oil and refined products also constitute an important aspect of this branch of scientific knowledge.

OUTLOOK

The oil shales in the Green River formation of Colorado, Utah, and Wyoming, the world's largest concentration of hydrocarbons, someday are expected to be a source of shale oil that will constitute an important supplement to petroleum. However, the time of entry of shale oil into the fuels market and the growth rate of future shale-oil production are conjectural.

Commercial shale-oil production in the United States can be expected whenever there is sufficient economic incentive. Before large amounts of capital are committed for this purpose, the public and industry must have assurance that shale-oil products can supply some of the demand for liquid fuels as well and as profitably as counterpart fuels can be produced from domestic petroleum or other fossil-fuel resources. Shale-oil production is not expected to be brought about by shortages in other forms of energy, but by the respective economics. Do-

mestic petroleum reserves alone are regarded as adequate for the foreseeable future.

The current economic position of shale oil is only vaguely defined; however, there is a general belief that oil from oil shale would not be much more costly than domestic petroleum. The view that shale oil can enter the domestic market before many years is reflected by the current high level of activity and interest in oil shale. Further research and development are needed to fill gaps in present technical knowledge and to lower mining and processing costs. Such research and development may take several years. Furthermore, approximately 3 years will be required for design and construction of commercial plants after a decision is made to proceed with commercial development.

It is unlikely that hydrocarbon resources other than petroleum will retard oil-shale development appreciably. Some of the oil to be produced from Canadian tar sands may be marketed in the north-central United States. However, if the governments of the Canadian Provinces continue to follow their present policy of limiting production of oil from the tar sand deposits, the quantities of oil from this source entering the United States during the relatively near future will be small. Also, it is believed that California rather than the Northern States will provide the first large market for shale oil, though eventually the north and eastern industrial sections of the Nation may provide the largest market.

Tar-sand deposits in the United States are smaller than those in Canada and have received comparatively little attention, although experimental operations of short duration in the past have been conducted from time to time, especially on deposits in Utah and California. However, interest has been growing in shallow tar sands, or heavy-oil deposits, in Oklahoma, Kansas, and Missouri, where such resources may be quite large although not well defined. Oil from these deposits is not expected to affect the potentially large west coast shale-oil market initially.

The anticipated increase in demand for petroleum products can be expected to favor expansion of shale-oil production, once it has started. Between now and the end of the century, the demand for liquid fuels is expected to rise to about three times its current level in the United States and to increase still more rapidly in the rest of the free world.

Eventually, oil shales may be used to provide gaseous as well as liquid fuels. However, economic considerations indicate that commercial production of fuel gas from oil shale to supplement natural gas is much farther in the future than production of shale oil to supplement petroleum.

PROBLEMS

Aside from the need for additional knowledge in resources and technology, some of the principal problem areas associated with the Rocky Mountain oil-shale deposits are those involving economic and legal matters and questions of public policy. These problem areas include a need for measures to insure conservation and multiple use of the several natural resources in the geographic areas in which the oil-shale deposits lie, anticipated economic effects of industrial development, and shale oil's competitive position with respect to other fuels.

Information is lacking and questions have been raised on the validity of many of the oil-shale mining claims that were filed prior to enactment of the Mineral Leasing Act of February 1920 but not patented. The Department of the Interior's authority to lease a large share of the oil-shale lands on the public domain will not be clear until the validity and various legal and title questions on the multitude of unpatented mining claims have been settled.

In the field of resources, problems in the realm of conservation from a technical standpoint are among the most difficult. Many of the oil-shale lands contain additional known or potential resources, both mineral and nonmineral, and the present and future values of these also must be considered. Among these resources are the land itself, as well as the subsurface oil and gas, sodium minerals, and ground water. Included to an increasing extent as the Nation's population grows are a number of items having esthetic and intangible values upon which it is difficult to place monetary worth such as freedom from air pollution, retention of outdoor recreation areas, and prevention of undue disruption of wildlife habitat. Strip mining could spoil the land surface for other uses. High-grading and other unwise mining and plant practices could waste large amounts of oil shale, result in enormous spoil piles, and create problems in stream and air pollution. In situ mining could adversely affect the extraction of other minerals, and caving of underground mines could affect the surface and impair recovery of sodium minerals that in some places lie above the oil-shale deposits.

Variation in the thickness and richness of the deposits, which relate to the expense of mining

or in situ processing at various locations, is a matter for consideration in the formulation of policy on leasing. Under the Mineral Leasing Act of 1920, a tract up to 5,120 acres, regardless of location, could be leased if the Executive withdrawal order of 1930, mentioned earlier, were not in effect. However, the oil shale beneath an acre of ground in the central portion of the Piceance Basin contains the kerogen equivalent of more than 10 times as much oil as that of an acre toward the basin margin.

The cost per barrel of producing shale oil by mining and retorting will be substantially lower for an operation on the order of 50,000 barrels per day than it would for a small operation such as 5,000 barrels a day. Accordingly, it is doubtful that small-scale operations would be economic or practical. The capital requirement for an economic-scale shale-oil production facility in the 50,000-barrel-per-day range would be as great as $3,000 per barrel of daily capacity, which is out of reach of most small operators. The exact amount involved would vary substantially depending on land costs, type of plant built, related facilities, and degree of processing beyond the point of producing crude pipeline oil.

The great thickness of some of the deposits and interbedding of high- and low-grade layers of oil shale will make these deposits difficult to mine underground in a way that will yield full recovery. In the mineral industries there often has been a tendency during the early stages of developing an orebody to focus mining plans on high-grade seams; selective extraction of rich beds of oil shale may jeopardize later recovery of associated lower grade beds.

Efficient and economic recovery of shale oil from the thick but deeply buried deposits in the central portion of the Piceance Basin will require development of in situ processing technology or of suitable mining methods. Such mining methods must be low cost and must be applicable to deposits some of which are up to 2,000 feet thick and overlain in some areas by more than 1,000 feet of overburden.

Ascertaining an optimum rate at which industrial oil-shale development should proceed will involve factors that vary widely in scope and include local, national, and international considerations. Among these will be the effects of future shale-oil production rate on the orderliness of commercial oil-shale development, the economics of the oil-shale industry, the economics of the petroleum and natural gas industries, the local and national economies, and the position of the U.S. energy complex in the economies of nations around the world. Tax treatment, leasing regulations, and other measures are all policy considerations that may bear on acceleration, retardation, or stabilization of the rate of industrial oil-shale development.

The supply of water in the Rocky Mountain States, a semiarid region, is limited. Eventually, lack of water in sufficient quantities easily could prove to be a limiting factor in the extent of oil-shale development and in the attainable production capacity. Significant quantities of water will be essential for the oil-shale mines and extraction plants even if the bulk of the shale is processed by retorts which have no need for cooling water and even if most of the refining is done out of the area, such as on the west coast or other points of end use. In addition, large amounts of water will be needed by the cities and towns that will grow in the vicinities of the future mines and retorting plants and by satellite industries. Such water needs are expected to be larger than shale plant industrial uses.

Additional work on the two-level room-and-pillar mining system, or an alternate method, is needed to assure adequate safety in future underground oil-shale mines. Rotary drilling of horizontal blast holes, initiated during the latter stages of the Bureau's operations at Rifle, requires further development and testing to provide the techniques, experience, and data needed for design of commercial rotary drilling machines. Likewise, studies are needed to investigate the cost-reduction potential of new explosives such as ammonium nitrate-oil mixtures. Earlier studies showed dynamite to be the largest single supply expense for mining.

Further development of retorting processes, including the operation of prototype plants, can provide process and engineering improvements leading to greater throughput, better efficiency, and reduced overall costs. The benefits of this work would be magnified in proportion to the growth of the future industry. Along this line, development work on retorting has been renewed at the Rifle facility by industry under the lease arrangement mentioned earlier. The results of this work will be published by the Bureau later under the terms of the lease agreement. In the meantime, the Bureau has engineers stationed at Rifle to observe all operations and obtain all testing and operating data.

Further assessment of the Green River deposits is needed, especially in Wyoming and Utah, where samples to date have been sparse. Oil-shale deposits other than those of the Green River formation, in other States, also should be appraised more fully as only meager data now are available.

PEAT

By Eugene T. Sheridan [1]

PEAT is partially decomposed vegetable matter that has accumulated under water or in a water-saturated environment. It is the initial stage in the transformation of plant materials into coal. When peat is buried beneath deposits of clay, sand, limestone, or other sedimentary beds and subjected to heat and pressure, usually by movements of the earth's crust, its physical and chemical properties are changed, and it becomes coal. The nature of the original vegetation, the conditions of its deposition as peat, and the subsequent geologic history all influence the characteristics of the resultant coal.

There are known peat deposits in at least 35 States, and total U.S. reserves have been estimated at approximately 14 billion tons. The bulk of the reserves are in 4 States—Florida, Michigan, Minnesota, and Wisconsin. Approximately one-half of the total, however, is in Minnesota.

Although used for fuel in other countries, peat cannot compete in U.S. fuel markets but is produced for use in agriculture and horticulture, principally as an amendment for soil improvement.

Markets for peat have increased steadily in the United States in recent years and, within the past decade, domestic production has more than doubled, reaching nearly 600,000 tons in 1963. In addition, 261,000 tons of peat, most of which was used for soil improvement, was imported.

The domestic industry in 1963 consisted of 113 active operations in 23 States. The principal producing States were Michigan, Indiana, Pennsylvania, California, and Washington which, collectively, produced about three-fourths of the total output.

World production of peat in 1963 was estimated at 170 million short tons, of which an estimated 60 percent was used for agricultural purposes and the remainder for fuel. The U.S.S.R. was the leading producer with an estimated 95 percent of the world output.

BACKGROUND

The earliest recorded use of peat for fuel dates back to the dawn of history. The Romans mentioned its use at the time of their conquest of northern and western Europe. They observed that the people of those regions dug soil from the marshlands with their hands, after which they dried and burned it to cook their food and to keep themselves warm. Thus, for centuries, peat has been burned for fuel, particularly in Ireland. In more recent times, peat has been used as fuel for heating and cooking in other northern European countries that, lacking deposits of coal, used wood as a domestic fuel until the forests were cleared for farming. Within the past few decades, peat has been developed as an industrial fuel in Europe, and a number of countries, particularly the U.S.S.R. and Ireland, now burn large quantities of peat to generate electric power.

Small quantities of peat were used for fuel in some areas in the United States almost continuously from the time of settlement until the beginning of the 19th century. But as transportation systems were improved, coal came into general use, and the use of peat for fuel was discontinued. No peat has been sold commercially for fuel in the United States for several decades.

The advantages of using peat in certain agricultural applications were recognized in the 20th century, and a peat industry engaged in producing peat for agricultural and horticultural purposes began to emerge around 1904. At this time there were about a dozen companies producing a few thousand tons of peat annually.

[1] Supervisory mineral specialist.

Since then the industry has expanded greatly, and in 1963 there were 113 active operations that produced more than one-half million tons of peat.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

There were 113 active peat operations in 23 States in 1963. Production, however, was concentrated mainly in California, Indiana, Michigan, Pennsylvania, and Washington. Collectively, these States had one-half of the total operations and about three-fourths of the total output.

Most of the active operations are in 15 States in the northeastern and north-central parts of the United States, in California and Washington on the west coast, and in Florida. Small quantities of peat are produced also in Georgia, South Carolina, Colorado, Idaho, and Montana.

Individual operations vary greatly in size, but all but a few are relatively small. Of the number active in 1963, about three-fourths produced less than 5,000 tons, and most of the remainder had outputs ranging between 5,000 and 15,000 tons per year. Only a few operations are large and well-mechanized and had individual annual outputs that approached 100,000 tons. The geographic distribution and relative size of active peat operations in 1963 are shown in tables 1 and 2.

TABLE 1.—*Geographic distribution of peat operations in the United States in 1963*

Region	Number of operations	Production (short tons)
New England	5	4,941
Middle Atlantic	61	410,292
South	10	32,160
Midwest	21	48,616
West	16	82,521
Total	113	578,530

TABLE 2.—*Relative size of peat operations in the United States in 1963*

Size	Active plants		Production	
	Number	Percent of total	Short tons	Percent of total
Under 500 tons	25	22.1	5,062	0.9
500–999 tons	18	15.9	12,678	2.2
1,000–4,999 tons	44	39.0	108,552	18.7
5,000–14,999 tons	16	14.2	123,816	21.4
15,000–24,999 tons	5	4.4	88,484	15.3
25,000 tons and over	5	4.4	239,938	41.5
Total	113	100.0	578,530	100.0

Although five plants contributed 42 percent of the peat production in 1963, only one company had two active operations, and the industry was operated strictly as private enterprise. The industry receives no price supports or subsidies, and competition for markets is very keen.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Peats differ greatly in chemical and physical properties, and an adequate classification system that will identify peats according to their specific properties has not yet been devised. Peat has been classified in a variety of ways, however, and a number of descriptive terms are used to identify peats of different origin and quality. Some terms, such as "turfy," "fibrous," and "pitchy," describe texture; others, degree of decomposition; and still others, botanical origin. All, however, are very general and rather inadequate for classification purposes.

In Europe, the terms "white" and "brown" peat are used to denote a relatively undecomposed variety whose botanical origin is mainly sphagnum mosses. This type, used conventionally as a soil conditioner, is almost universally prepared by hand cutting and air drying. The more decomposed types, used generally for fuel, are referred to as "black" peat.

European peats are named also according to the manner in which they were harvested, such as cut peat, machine peat, milled peat, and hydropeat. These terms are applied particularly to the decomposed peats that are produced mainly for fuel. Other European terms are "high moor" and "low moor" peat, used generally for denoting the degree of decomposition.

For statistical purposes, the Bureau has classified peat into three general types—Moss peat, reed-sedge peat, and peat humus. Peats of the sphagnum, hypnum, and other mosses group are classified as moss peat, while those of the reed-sedge, shrub, and tree group are classified reed-sedge peat. Any peat so decomposed that its botanical identity is lost is classified as peat humus.

Although there are no established standards for differentiating peats, the sale of peat in the United States is governed by Federal trade regulations that define the requirements for labeling a product "peat" and state the manner in which the terms "peat moss" and "moss peat" may be used. Established by the Federal Trade Commission in 1950, the regulations define peat as any partially decomposed plant matter that has accumulated under water or in a water-saturated environment. It is unlawful to label a product "peat" unless 75 percent of the ma-

terial, by dry weight, is composed of peat as defined, and the remainder is composed of normally associated soil materials. A product labeled "moss peat" must conform to this definition and the peat must have been formed from sphagnum, hypnum, or other mosses. The term "peat moss," a misnomer generally applied to all types of peat, is subject to the requirements of "moss peat" except when the kind or kinds of peat of which the product is composed are conspicuously stated in conjunction with the term "peat moss."

Government purchases of peat are subject to Federal specifications, developed by the Federal Supply Service, General Services Administration. The current specification, Q–P–166e, May 10, 1961, classifies and lists the requirements for the following four types of peat: (1) Sphagnum moss peat, (2) other moss peats, (3) humus peat, and (4) reed-sedge peat.

TECHNOLOGY

Excavation and Preparation

Although virtually all peat is excavated by machinery in the United States, extraction methods and equipment differ greatly because of the various sizes of operations and the differences in physical characteristics of deposits. In general, most operators employ conventional types of excavating and earthmoving machinery, or conventional types with modifications, for extracting peat. These vary from power shovels, bulldozers, draglines, and front-end loaders, used on drained bogs, to clamshells and dredges for submerged deposits. However, a few producers have specially designed equipment similar in some respects to the types used at some of the large operations in Canada and Europe.

Peat is prepared for sale by shredding and screening and, in a few instances, by artificial drying. Processing equipment consists of a variety of screens, shredders, grinders, hammermills, and gas- and oil-fired dryers.

The following illustrate the variety of production methods employed at peat operations in the United States: In eastern Michigan, reed-sedge peat is extracted simply by loosening the top surface with disk harrows, windrowing with a V-shaped wedge, and when dry, pushing the air-dried peat with bulldozers to the edge of roads built laterally across the bog at intervals of 500 feet. Peat then is loaded into trucks by front-end loaders and transported to a storage pile at the processing plant. Before harvesting, the water level of the bog is lowered by perimeter and lateral ditching, and clay roads are built to provide a firm operating surface for trucks and loaders. The other equipment has special wide-track treads that enable it to operate upon the bog.

Preparation at this operation includes grinding and screening with hammermills, shaker screens, and belt conveyors for carrying peat and refuse. The operation also has four packaging lines consisting of automatic weighing hoppers, bag-sewing and sealing machines, and conveyors for moving and loading packaged peat, interconnected with the processing equipment. This equipment can handle various sizes of bags and each line can package and load from 12 to 28 bags per minute for shipment. One line is used exclusively for mixing and packaging potting soils, a mixture of peat, sand, and vermiculite.

In Indiana, a large deposit of moss peat is harvested by means of tractor-drawn earthmovers that scrape peat from the surface of the bog after it has been loosened by a tractor-drawn spiked harrow. The earthmovers and tractors are conventional roadbuilding and land-grading machines, modified for use on peat bogs by the installation of specially designed rubber wheels and caterpillar tracks. Prior to harvesting, the water level of the bog is lowered by ditching and trenching, but this equipment can operate only when the weather is relatively dry. This operation employs two earthmovers, each with a capacity of 4 cubic yards of peat. When full, they unload at the top of a storage pile, after which the peat is hauled by trucks to a preparation plant for shredding and artificial drying. Shredding is done by a Lindig soil shredder (standard farm machinery), and drying, by an oil-fired, horizontal, rotary kiln. This plant also has automatic packaging equipment, similar to the types employed by the operations in Michigan.

In Minnesota, a deposit of moss peat is harvested with vacuum harvesters. These are mobile machines that lift previously loosened peat by vacuum from the surface of the bog to a large tank mounted on the machine. When full, the tank is hydraulically elevated, and the peat dumped into wagons that haul it to the preparation plant. Here the peat is double-screened to remove roots, then moved by conveyor into an oil-fired, horizontal, rotary kiln. When dry, it is pulled from the dryer by suction into a storage hopper, then flows to a grinder, is again screened, and carried by conveyor to hoppers above specially designed packaging machines.

Production and preparation methods in Europe are more complex and on a much larger scale. In the U.S.S.R., where annual output is estimated at 160 million tons, peat is produced by a number of mechanized processes, of which

the principal ones are known as the machine-peat, milled-peat, and hydropeat methods. All employ a variety of large, specially designed, equipment such as ditchers, bagger elevators, milling machines, windrowing machines, and vacuum loaders, depending upon the process used. These methods of production are used also in a number of other European countries, including Ireland, Sweden, Denmark, and Finland. Processing generally includes only air drying, but, in some instances, peat is briquetted for domestic fuel, mechanically dewatered, or ammoniated for fertilizer use.

Combustion, Carbonization, and Chemical Processing

Although peat has a high moisture content when extracted, it can be air dried and burned at about the same efficiency as lignite. Peat with a moisture content of 25 percent has about one-half the heating value but twice the volume of the same weight of coal. It also has about twice the volatile content but only about one-half the fixed carbon of coal. Therefore, a conventional furnace burning peat would be required to handle about four times the volume of coal necessary for the same quantity of heat produced. Furnaces suitable for burning peat, however, can be designed with a larger grate area, greater forced draft, or a precombustion chamber.

As with other solids hydrocarbons, peat heated in ovens or retorts in the absence of air yields a solid residue, tars and tar oils, and gas. Attempts to carbonize peat economically have been relatively unsuccessful, however, and generally have been limited to laboratory and pilot-plant study.

Except for a few commercial processes for reacting peat with ammonia, such as the Humon process of Austria, the chemical processing of peat has been confined, also, to laboratory investigations.

USES

Virtually all peat consumed in the United States is used for agricultural and horticultural purposes. This applies also to imported peat, although a small quantity of the imported peat (currently 2 percent) is used for poultry and stable litter. Ninety-six percent of the domestic peat sold in 1963 was sold for general soil improvement. This peat was used chiefly by landscape gardeners and contractors for landscaping and as a base for building lawns; by homeowners for mulching and improving lawns and garden soils; and by nurseries and greenhouses. The remainder was sold for use in potting soils and mixed fertilizers; for packing flowers; for preparing seed inoculant; for golf course greens; and as a medium for growing mushrooms and earthworms.

Peat is used in Europe both for fuel and for soil improvement. For centuries peat has been cut from bogs in the shape of small blocks, air dried, and burned as domestic fuel. It still is used in this form in some countries, and large quantities also are briquetted for use as domestic and industrial fuel. But peat's greatest potential as fuel is its use for electric-power generation. Large quantities are burned in powerplants in the U.S.S.R. where it has been reported that in 1956, 30 peat-fired stations produced 11 billion kilowatt-hours of electricity, about 6 percent of the total electric energy generated. Ireland also uses large quantities of peat for fuel, consuming about 3 million tons in five peat-fired power stations in 1963.

RESERVES

The peat resources of the United States have been surveyed extensively, and known reserves are estimated at approximately 14 billion short tons of air-dried peat. The reserves are widely distributed with deposits occurring in 35 States. Approximately nine-tenths of the total, however, occurs in Florida, Michigan, Minnesota, and Wisconsin.

Table 3 shows the geographic distribution of reserves. The major deposits occur in two general areas—the northern, with about 80 percent of the total, and the Atlantic coastal, with 19 percent. The northern region covers, roughly, the area north and east of the 41st parallel and 97th meridian and includes all of the New England States, Illinois, Indiana, Iowa, Michigan, Minnesota, New Jersey, New York, Ohio, Pennsylvania, and Wisconsin. The Atlantic coastal region includes all of Florida and the coastal areas of all States south of New Jersey.

More than one-half of the U.S. reserve is in Minnesota where known deposits cover more than 5 million acres, and the recoverable reserve (deposits at least 5 feet in depth) has been estimated to be nearly 7 billion tons. Although deposits occur in virtually all parts of the State, more than three-fourths of the reserve is in four northern counties—Beltrami, Koochiching, Itaska, and St. Louis.

Wisconsin, with reserves estimated to total 2.5 billion tons, has the second largest peat resource. There are peat deposits in virtually all sections of Wisconsin, and it is estimated that peat lands cover approximately 1 million acres, with deposits ranging up to 20 feet in depth and 32,000 acres in area.

[2] Includes Delaware, Maryland, South Carolina, and Georgia.
[3] Excludes Florida.

Michigan, the third-ranking Northern State, has a resource estimated at 1 billion tons. Michigan's deposits are well distributed throughout the State, but the largest and most extensive are in the north where some bogs cover more than 25 square miles and range in depth from 2 to 20 feet.

Several other Northern States have important deposits of peat, although the known reserve in each is less than one-half billion tons. In New York, peat lands cover approximately 800,000 acres and reserves are estimated to total 480 million tons.

All of the New England States have peat, but the largest and most extensive deposits are in Maine. Maine's reserves are estimated to total 100 million tons, of which about one-half occurs in the coastal areas and near the lower courses of major streams.

The reserve in Florida is estimated to be 2 billion tons, and there are important deposits in virtually all parts of the State. The most extensive are in the Everglades, a vast marsh area, where it is estimated that about one-half of the reserve occurs.

Some peat occurs in the Dismal Swamp area of Virginia and North Carolina, and in California, but the combined estimated reserve of both areas is less than 1 billion tons, about one-half the quantity that occurs in Florida. There are also small deposits in the coastal areas of Alabama, Georgia, Louisiana, and Texas; in Washington and Oregon on the west coast; and in Colorado, Idaho, and Montana. Less than 1 percent of the total U.S. reserve is in these States.

SOURCES OF STATISTICAL INFORMATION

Statistical data on peat are based upon annual Bureau of Mines surveys of producers. Information regularly collected includes production, sales, and use data; size of deposits; harvesting equipment used; and kind of preparation (shredding, kiln drying) prior to sale. Foreign trade statistics are collected monthly by the Bureau of the Census, U.S. Department of Commerce.

In 1958, the Bureau of the Census included peat in its periodic mineral industry survey and collected and published operational data such as employment, wages and salaries, cost of supplies, capital expenditures, and the cost of purchased machinery installed during the year. The Bureau of the Census conducted a similar survey covering the calendar year 1963, and data are being compiled presently for publication.

PRODUCTION, CONSUMPTION, AND TRADE

Peat production in the United States has increased greatly in recent years, with output in 1963 nearly three times greater than that of a decade ago. Production in 1963 was 578,530

tons, of which more than one-half was produced in Michigan, Illinois, Indiana, and Iowa. Most of the remainder was produced in California and Washington on the west coast, and in Florida, New Jersey, New York, and Pennsylvania in the East. Michigan, the chief producing State, contributed 44 percent to the total output.

Twenty percent of the production was moss peat; 53 percent was reed-sedge peat; and 27 percent was humus. Twelve percent was air dried and sold as extracted. The remainder was prepared for sale by shredding, screening, and, in a few instances, artificial drying. Approximately 54 percent of the total output was "cultivated." This is a method of reducing the moisture content by loosening the surface layer of a bog with a disk or spike harrow before the peat is removed.

Most of the peat produced in 1963 was sold, and consumption of domestic peat was approximately one-half million tons. An additional 261,000 tons of peat was imported, making apparent consumption in the United States in 1963 approximately 750,000 tons.

World production of peat was estimated to total 170 million tons. U.S. production was less than 1 percent of the world total.

Tables 4, 5, and 6 show production and consumption data for 1963 on domestic operations.

The quantities of peat imported by the United States have remained relatively constant in recent years, but imports have accounted for an increasingly smaller part of the total supply as domestic production has increased steadily. Imports currently represent about one-third of the total peat consumed annually.

About four-fifths of the peat imported in 1963 was produced in Canada. Most of the remainder was shipped from West Germany, although nine other European countries, Guatemala, Mexico, and Japan also exported small quantities of peat to the United States.

To conform with U.S. tariff regulations, imported peat is classified according to use into two grades: Poultry and stable, and fertilizer. Generally, the poultry and stable grade is imported for use as poultry and animal litter, whereas fertilizer grade is imported for various

types of soil improvement. Of the total imports in 1963, 98 percent was classified fertilizer grade and entered the United States duty free. A duty of $0.25 per long ton was levied on peat classified poultry and stable grade.

Table 7 shows imports of peat moss, by kinds and by countries, in 1963. No peat is exported from the United States.

MARKETING AND PRICES

Before 1955 most domestic peat was sold locally in bulk because packaging materials in which peat could be packaged and shipped economically had not been developed. (Unlike the moss peats of Canada and Europe, most of the peat produced in the United States has a texture that makes it unsuitable for baling.) With the advent of synthetic films, inexpensive moistureproof containers became available, and large quantities of domestically produced peat are now packaged and distributed in virtually all parts of the United States.

More than one-quarter million tons, or 51 percent of the total peat distributed in 1963, was sold in packages. Packaged peat usually is distributed through normal wholesale and retail channels and is available in retail outlets such as garden centers, hardware, drug and variety stores, and food supermarkets in virtually all parts of the country. Bulk peat usually is sold directly to consumers by the producer.

There is no standard unit of measurement for selling peat in the United States, but most peat sold in bulk is air dried and sold by the cubic yard. Packaged peat, which can be either air- or kiln-dried, is sold by both volume and weight. Most packaged peat is sold on a weight basis, however, principally in units of 25, 50, and 100 pounds. Preferred containers are polyethylene-lined paper bags. Some peat is packaged also in heavy-gage synthetic bags and burlap bags with synthetic-film liners.

Prices of domestic peat vary greatly, but, in general, the sales value depends chiefly upon the kind of peat, the degree of processing, and whether the peat is sold in bulk or packaged. In most instances, the value of packaged peat is about double that of bulk peat. Packaged peat usually has undergone more processing, and more labor and equipment are required to produce the packaged product.

The values of domestic and imported peats are shown in table 8. For domestic peat, the values are equivalent to the total amount producers realized from sales, f.o.b. plant, except that for packaged peat the cost of bags or containers was not included. The average price per ton for all domestic peat sold in 1963 was $9.92. The average plant price of bulk peat was $6.88 per ton while the unit price of packaged peat was $12.87.

The average value of $47.29 per ton of imported peat was about five times greater than that of domestically produced peat, but the values are not comparable because they were assigned at different marketing levels. Values assigned to imported peat were established at the port of embarkation and were approximately equal to prices paid by importers, less

TABLE 8.—*Quantity and value of domestic peat sold in the United States, and the quantity and value of peat imported*

Year	Domestic peat			Imports		
	Short tons	Value	Average value per ton	Short tons	Value	Average value per ton
1957–59 (average)	342,711	$3,556,551	$10.38	267,525	$12,300,753	$45.98
1960	430,664	4,456,510	10.35	263,887	13,509,015	51.19
1961	492,798	4,672,933	9.48	252,437	13,178,474	52.21
1962	566,441	5,185,627	9.15	267,678	12,868,168	48.07
1963	546,621	5,422,877	9.92	261,331	12,357,557	47.29

transportation and other miscellaneous charges. In some instances, ocean freight and other nondutiable charges such as insurance may have been included inadvertently.

In contrast to most packaged domestic peats which are more decomposed, have a relatively high moisture content, and are sold by weight, imported peats are light and fibrous, usually are pressed into bales or compacted into synthetic-film containers, and are sold on a volume basis. To indicate respective densities, each 100 pounds of a typical air-dried imported peat will measure approximately 12 bushels, whereas 100 pounds of a typical air-dried domestic peat will measure only 3 or 4 bushels. However, a few U.S. operations produce peat with properties similar to the imported types. In 1963, a 100-pound bag of domestic reed-sedge peat could be purchased at retail in the Washington, D.C., area for $1.69; a 7½-cubic-foot bale of imported peat, weighing from 80 to 100 pounds, had a retail price of $4 to $5 in the same area.

EMPLOYMENT AND PRODUCTIVITY

Employment in the peat industry is seasonal, as production and processing at most operations cease during the winter months. Of the 113 active plants that reported production to the Bureau for 1963, 656 employees worked a total of 942,430 man-hours, or an average of 1,437 hours per employee during the year. On the basis of an 8-hour day, the total number of man-days worked during the year was 117,804. Related to production, this was an output of 4.91 tons per man-day for 1963.

RESEARCH

Most of the research on peat is conducted in a number of northern European countries where peat is used in large quantities for fuel. Most of these countries consider peat a major organic raw material and, in addition to developing peat as a fuel for heating and electric-power generation, they have attempted to find practical methods for converting peat to metallurgical fuel, for using peat for the production of town gas, as a source of chemical materials, and as a base for enriched fertilizers.

The Soviet Union undoubtedly conducts the greatest amount of research on peat. In addition to having a large number of laboratories and experiment stations that are concerned solely with the development and use of peat, the U.S.S.R. has established several peat institutes, which not only train engineers and technicians, but conduct large-scale investigative programs ranging from basic research to applied research and development.

The Moscow Peat Institute, which was established in 1930 under the Ministry of Higher Education, is the principal Soviet institution for the training of technical personnel for the peat industry. This establishment not only graduates from 250 to 300 peat engineers per year, but also conducts a broad research program encompassing such areas in 1962 as the hydraulics and hydrotechniques of peat installations, classification and characteristics of peats, radioisotope techniques in the study of the physical and mechanical properties of peat, technology and equipment of hydropeat installations, and the chemical technology of peat.

The All Union Institute in Leningrad is the central research organization of the Soviet peat industry. This institute, which was founded in 1935 and is an agency of the Ministry of Power Stations, has three prime objectives: (1) The full mechanization of the peat-for-fuel industry as well as the mechanization of plants for the production of chemicals and other by-products from peat, (2) the development of new methods of producing and dewatering peat, and (3) the modification and improvement of existing techniques of winning peat. The institute has several departments that include a number of laboratories, a design department, shops, and library.

Peat in Ireland is produced under the auspices of Bord na Mona, a statutory corporation set up by the Irish Parliament in 1946 to develop peat resources, with particular emphasis on peat for electric-power generation. An important part of the Bord na Mona organization, an experimental station at Droichead Nua, County

Kildare, was established to develop improved methods for winning and utilizing peat. Although the work of the experimental station was designed originally to develop more efficient harvesting methods and improved burning equipment for power generation, research programs have been expanded, and this organization now engages in research aimed at developing peat as a raw material for the production of chemicals, coke, and waxes.

Austria, Finland, France, Germany, Holland, and Sweden also have active peat research programs. Most are concerned with developing improved techniques for using peat as a fuel, but, as in Ireland, these countries are attempting also to use their peat resources as a base for developing new products and establishing new industries.

There has been little emphasis on peat research in the United States because of the abundant supply of other fuels and other raw material sources of chemicals. Minnesota, however, has sponsored several research projects on peat in an attempt to find ways of economically using Minnesota's vast peat resources. Through the Iron Range Resources and Rehabilitation Commission, a State agency, a "Chemical Products from Peat Project" was established at the University of Minnesota in 1954. This project, which has been engaged in developing basic knowledge of the peats of Minnesota from the standpoint of eventual economic use, has conducted investigations ranging from basic through applied research, including studies such as the use of peat as a binder for pelletizing taconite, and the application of peat to agriculture and horticulture.

The Bureau of Mines made several studies many years ago on the potential of peat as a source of energy, but concluded that peat could not compete economically in the United States with other fuels.

OUTLOOK

The outlook for the U.S. peat industry is expected to be one of continued growth. Since 1945 the number of producers has more than doubled and domestic output has increased more than five times. Including imports, annual consumption is rapidly approaching 1 million tons. Consumption in the United States should continue upward because peat is in demand by homeowners, landscape gardeners, nurseries, and greenhouses in most parts of the country, particularly in urban and suburban areas. In past years, animal manures were used extensively as a source of organic matter for soil improvement. These, however, have become virtually unavailable in many areas, and peat generally has become accepted as an economic and lasting substitute when used in conjunction with other fertilizer materials.

Consumption of domestic peat for special agricultural and horticultural uses other than general soil improvement (potting soils, packing flowers, mushroom beds, and so forth) has increased moderately in the past decade and should continue upward, probably at a rate consistent with population increases. The use of peat as a filler for mixed fertilizers, however, has been decreasing steadily and probably will continue to decline.

Despite the large-scale use of peat for fuel in a number of European countries, peat cannot compete as a fuel in the United States with other fuels that are available at lower cost in virtually all areas. Peat, therefore, will not be used for fuel in this country in the forseeable future, except possibly in minor quantities in local areas if more efficient production and processing methods are developed.

PROBLEMS

Expansion of the peat industry in some States is limited by the remoteness of their operations from established markets. Generally speaking, it is uneconomical to transport most of the types of peat used for soil improvement long distances because peat is a bulk item with a relatively low value. Therefore, to be competitive, a peat operation must be located in an area where markets exist, or in an area from which peat can be shipped to markets at low rates of transportation. Several States presently producing peat have a market disadvantage because of their geographical location. This disadvantage possibly may be overcome by developing more economical and more efficient harvesting and drying methods.

A continuing problem of both producers and consumers is the lack of an adequate classification system for identifying the various types of peat. The present and most generally accepted system, which groups peats according to botanical origin, is overlapping and does not recognize their different chemical and physical properties.

This problem currently is being resolved by American Society for Testing and Materials Committee D–29, which was organized in 1963 to stimulate research and formulate definitions, methods of test, and specifications relating to peats, mosses, humus, and related products.

PERLITE

By Timothy C. May [1]

PERLITE is a siliceous rock containing 3 to 5 percent water. When it is crushed and heated, the rock expands to a mass of glass bubbles, producing a lightweight aggregate with many sealed cavities, which retard the conduction of heat and sound when used as loose fill or as aggregate in concrete and building plaster. Other uses include filter aid, horticultural applications, oil well cementing and grouting, filler, catalyst support, and abrasives.

Substantial commercial production started in 1946, and in 1963 404,000 tons of crude perlite was mined. The output of expanded perlite in 1963 was 272,000 tons, valued at $14.5 million. Production of crude perlite came from seven Western States, the major portion from New Mexico.

The principal industry problems are keeping pace and gaining a share of the fast growing market, high transportation costs of crude perlite to eastern markets, health hazards, and minimizing production of fines.

The domestic reserve of perlite is adequate to meet foreseeable requirements.

BACKGROUND

Perlitic obsidian reportedly was expanded and used for the manufacture of abrasive bricks in Germany before 1925. In 1940 perlite was expanded experimentally in a kiln at Las Vegas, Nev., and used with gypsum for building plaster. About 1941, crude perlite from Picket-Post Mountain near Superior, Ariz., was flash-popped in an experimental gas-fired furnace. This led to a series of small plants experimenting with the treatment and use of expanded perlite (*5*) [2]

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1946 the first commercial output was reported by five companies, totaling 4,200 tons from four mines in the Superior, Ariz., district and one near Beatty, Nev. In 1947 a property on the Deschutes River in Wasco County, Oreg., started producing. The post World War II building boom stimulated demand, and other perlite mines were opened. In less than a decade perlite changed from a lithologic curiosity to an important building material.

Perlite from a deposit in northern Ireland is largely shipped to England for expanding. A mine in Sardinia sends its ore to Milan, Italy, for processing. Otherwise very little foreign perlite mining is reported.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

In commercial usage the term "perlite" refers to any naturally occurring glass of igneous origin that will expand, when quickly heated, to yield a frothy, light-colored mass of glass bubbles. The term is also applied to the expanded product.

The petrological definition of perlite is restricted to volcanic glass which has a concentric, or "onion," structure of fracturing (*5*). This structure of fracturing is also known as perlitic.

Other characteristics of commercial crude perlite are 3 to 5 percent water of composition, waxy to pearly luster, transparent to translucent at thin edges, rhyolitic in composition. It is essentially an amorphous aluminum silicate of volcanic origin. An average analysis, in percent, of 10 perlites from 6 currently producing States follows (*1*):

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

	Percent
Moisture loss at 105° C	0.2
Total moisture loss after ignition at 800° C	3.83
Aluminum oxide (Al_2O_3) (including any phosphorus pentoxide or manganese oxide)	13.08
Calcium oxide (CaO)	.72
Iron oxide (Fe_2O_3)	.89
Magnesium oxide (MgO)	.18
Potassium monoxide (K_2O)	4.44
Silicon dioxide (SiO_2)	73.2
Sodium monoxide (Na_2O)	3.31
Sulfur trioxide (SO_3)	.04
Titanium dioxide (TiO_2)	.09

Before expanding, crushed and sized crude perlite ore has a bulk density ranging from 65 to 75 pounds per cubic foot. The approximate densities of expanded perlite may range from 3 to 4 pounds per cubic foot, for use as lightweight cast insulating slabs, to 8 to 20 pounds per cubic foot or more, sized for concrete aggregate.

Expanded perlite ranges from a fluffy, highly porous material to glazed particles having almost no porosity.

For interior plaster aggregate, where light weight, good insulation, and acoustical qualities are more important than low porosity, a satisfactory particle-size range for raw ore is 100 percent through 8-mesh, with not more than 5 to 10 percent through 100-mesh and substantial proportions in the range from 30- to 60-mesh. For exterior stucco and precast masonry concrete, a suggested grading is 100 percent through 4-mesh, with 10 to 15 percent maximum through 100-mesh and the intermediate range as nearly one size as possible. This latter grading can produce a concrete with 1,000 to 2,000 pounds per square inch compression strength after 28 days with 6 to 12 pounds of water absorbed per cubic foot of concrete and a weight of 40 to 70 pounds per cubic foot for the concrete when air dried.

The suitability of expanded perlite aggregates is usually determined by trial. Standard test specimens of perlite concrete and plaster are prepared and tested for compressive strength and other physical properties.

The Perlite Institute, Inc., New York, N.Y., has published tables showing typical mix designs for perlite insulating concretes and plaster with the corresponding physical properties of these products (*7*).

TECHNOLOGY

Geology

Petrographically, perlite and other volcanic glass may be essentially free of crystalline material, although most natural glass contains microscopic crystallites and large phenocrysts; the latter range from 1 percent by volume to 50 percent or more in rocks known as vitrophyres. If crystallization progresses, the glass may become crowded with minute grains throughout the mass, or with stratifications almost microscopic in thickness. Silicification or opalization of the glass can also occur. The presence of crystals and devitrification products in any appreciable quantities in volcanic glass often produces a noncommercial perlite.

Factors that affect the physical and chemical characteristics of volcanic glasses include water content, rate of cooling, and age. Volcanic glass often becomes devitrified by the effects of steam from fumaroles or hot springs. It also devitrifies in time under normal conditions, as witnessed by the changes of manufactured glass objects found in prehistoric Egyptian tombs. Hence very few occurrences of undevitrified glass older than Cretaceous are known.

The color of volcanic glass ranges from black, through shades of red, green, and brown, to nearly white. While some glasses break with a conchoidal fracture, others have the well-known, closely spaced concentric fracture patterns, or "onion" structure. Some glasses have a columnar or prismatic jointing that may yield a needle structure, while others contain vesicles and show strong flow structure, approaching pumice.

Some deposits of perlite and pitchstone are intrusive, occurring as dikes, sills, and quickly cooled zones in the margin of other intrusive bodies. The most important current production, near Tres Piedras, N. Mex., comes from an extensive flow, almost 1,000 feet thick, which has been eroded into several individual island remnants. The hardness is between 5.5 and 7; specific gravity ranges from 2.2 to 2.4, and weight ranges from 139 to 150 pounds per cubic foot. Volcanic glasses are a product of igneous processes within the earth's crust, and the combined water is evidently from the original magma.

As domestically occurring undevitrified siliceous volcanic rocks are found only in the West, all known deposits of perlite occur there. Although rare occurrences of volcanic glass are known in volcanic strata as old as Cretaceous, most glasses are found in beds of Tertiary or Quaternary age. Rocks of similar composition that were formerly true glasses, but from older series, are now thoroughly devitrified and thus have lost their expansion qualities. (*3–5*, *9*).

Mining

The perlite deposits are massive lava flows, sometimes several hundred feet thick and extending over hundreds of acres. Because of the

areal extent, pits are usually kept shallow to maintain low mining costs.

All perlite mining is done from open pits, and the first step is the removal of overburden when present. Although blasting is occasionally employed, mining more frequently consists of loosening the rock with bulldozers equipped with rippers and excavating with carryalls, power shovels, or bulldozers moving ore to loading chutes. To insure uniformity in the quality of perlite ore, the open face operation mines in a lateral section, in contrast to conventional open pit mining. Because of the low unit value of crude perlite, only those deposits that can be mined cheaply are operated.

Processing

Ore from the mines is trucked to the mill where it is dumped on a grizzly and usually falls to a jaw crusher. The ore in a typical plant is then raised by bucket elevator to a storage bin, from which it goes by apron feeders to a direct-fired cylindrical rotary dryer. Drying improves efficiency of screening and air classification.

From the dryer a bucket elevator raises the ore to enclosed vibrating screens, the oversize going to a secondary crusher. Undersize drops to mechanical-air classifiers for removal of the excessively fine fractions, which are detrimental to the final product. After dust removal, the products go to bins where different-size shipping products are stored.

Perlite ore is usually processed dry because water is scarce in many perlite mining areas; also drying a wet-processed product costs more.

Perlites, which crush to particles approaching a cubic shape, expand to a more uniform size range. However, shape cannot be closely controlled, because perlite tends to break along preexisting fractures.

The expansion of crude perlite is influenced by (1) the amount of originally combined water present, (2) the amount of this combined water retained when the softening point is reached, (3) the rate of heat application, (4) the maximum temperature reached, (5) the structure of the perlite including fractures, (6) the size distribution of the crude ore particles furnaced and (7) the softening point of the crude perlite.

In expansion the temperature at which the glass is just soft enough to be plastically deformed by the expanding steam ranges from 1,400° F for some perlite to 2,000° F for others. A high frequency of parting planes increases the formation of fines. Some perlites explode on heating because of weaknesses in the rock.

The unexpanded particles are dropped through the fast-moving flame of the gas- or fuel oil-fired furnace. Optimum conditions are difficult to attain, especially when the feed is coarse. As the softening point is reached, the release of part of the combined water raises the eutectic temperature and causes resolidification unless the heat is correspondingly increased. If not adequately increased, larger particles may be ejected from the furnace before the heat has penetrated to their centers (*10*).

Two types of furnaces are now used for expanding perlites.

The horizontal rotary furnace usually has three metal shells. A hot flame inside the inner shell chamber gives sufficient heat to preheat the ore as it travels between either of the two outer shells. Preheat temperature ranges from 400° to 600° F. A scoop attached to the revolving furnace picks up the raw ore, and helical flights move the ore through the preheater and then into the inner chamber of the furnace, where it meets the flame and where the direction of ore travel is then reversed. The flights in the inner furnace chamber repeatedly lift the ore and drop it through the flame area, and as the ore particles are lightened by expansion the air pressure from the burner vent blows them out of the furnace.

The discharged expanded perlite is raised in the hot gases by a suction fan to a collection cyclone and one or more smaller auxiliary cyclones. This collection system separates the fine and coarse products and permits a relatively clean air discharge to the atmosphere.

The vertical furnace is essentially a vertical tube with maximum dimensions of about 1.5 feet in diameter by 18 feet high. An inner shell of high-temperature alloy steel surrounds the expansion chamber, insulated by refractory brick or an air space.

As the product of the expanding furnace enters a collection cyclone, 10 to 30 percent of the expanded fine perlite is carried over with the hot gases to one or more smaller, high-efficiency cyclones that allow clean air and hot gases to discharge. Material not carried from the collection cyclone by the gases drops to a pipe where it is met by a stream of cold air. This cools the product and also transports it through the plant.

The fine material collected in cyclones is either recombined with the cooled product and sent to the bagging plant or sent to waste if this product is too fine to be salable. Some plants are equipped with a baghouse to collect dust escaping the cyclones. The abrasion of dust

particles rapidly deteriorates screens, bearings, and other moving parts.

Gas and air should be well mixed if gas burners are used, and when using fuel oil, a finely atomized oil-air dispersion is required. Many ordinary burners are not suitable because the perlite feed tends to extinguish the flame. Use of a burner collar, just in front of the burner nozzle, to radiate heat onto the flame, helps to maintain combustion.

USES

About 60 percent of the expanded perlite produced in the United States in 1963 was used for construction purposes. The 1963 use of expanded perlite, computed from a Bureau of Mines canvass, follows:

	Percent
Building plaster aggregate	39
Filter aids	15
Concrete aggregate	12
Oil well cement	4
Insulation (loose fill)	4
Miscellaneous uses	26

Owing to its lightweight and heat-insulating advantages, perlite has become a major aggregate in gypsum plaster. When mixed with gypsum and water in lieu of sand, perlite creates a plaster that can be troweled or sprayed on lath to form a resilient wall or ceiling that can withstand stresses and thermal changes. Mill mixing of perlite plaster has become a major feature of the industry in recent years.

Because of its low specific gravity, perlite has advantages as a raw material for the manufacture of filter aids. Perlite is particularly adapted for situations where high flow rate is more important than clarity of the filtrate. Perlite filter aids are now being used to filter various food products, beverages, chemicals, resins, pharmaceuticals, and other liquids.

Perlite lends itself to the preparation of lightweight aggregate insulating concrete. The most common use is in roof deck construction where the structural deck and insulation can be combined in one lightweight slab that needs no further insulation. Perlite concrete also is being used as a floor fill in multistory buildings, in insulating concrete blocks and tilt-up panels, and as exterior insulating walls sprayed as a backup for metal panel facings.

Oil well cementing and grouting present a growing market for expanded perlite. It prevents lost circulation of drilling lubrication fluids by bridging openings in the wellhole walls.

Substantial quantities of expanded perlite are used annually in soil conditioning, as a plant growing medium, as packing material for shipment of nursery stock, and as a carrier or diluent for herbicides and insecticides.

Expanded perlite with bulk densities below 4 pounds per cubic foot is used as insulation in the form of loose fill. Poured in the hollow centers of concrete block or between wall studs, it is a very effective insulator. In this loose form, it is used for imbedding hot steel ingots during transportation, for packing containers of liquid air, and as foundry sand to prevent rapid cooling in the mold. Packed in batts or jackets, it is placed around steam and refrigeration pipes. It is also used in lining refrigerators, refrigertor cars, cold storage space, and frozen-food shipping boxes.

Perlite has been used successfully as a porous support for catalysts and reagents in various chemical reactions. It also has some application as an abrasive and as a refractory in the medium temperature range.

The uses for perlite fines include fillers or extenders in rubber, paints, enamel, glazes, plastics, paper, textiles, resins, cleansing compounds, and tile.

Within the past few years perlite powders have become widely used in cryogenics. Perlite has proved a most effective insulator at temperatures below −150° C and is now used extensively for insulating tanks containing liquid gases such as oxygen and hydrogen (*2*).

ALTERNATE MATERIALS

Perlite encounters several long-established competitive commodities in all its fields of use. As plaster aggregate it must compete with silica sand, exfoliated vermiculite, and pumice. Competitive concrete aggregates are the heavy materials, such as sand, gravel, crushed stone, and slag, and lightweight aggregates, which include expanded clay, shale and slag, exfoliated vermiculite, cinders, pumice, sawdust, organic fibers, and diatomaceous earth. Air entraining agents, which lighten concretes, can also be considered a lightweight aggregate substitute. Mineral wool, exfoliated vermiculite, pumice, and diatomite compete in the loose-fill category.

In oil well cementing, vermiculite and clays, including bentonite, are competitive materials.

There are many fillers and extenders with which perlite must share the market. Some of these are feldspar, gypsum, pumice, mica, talc, limestone, kaolin, silica sand, diatomite, exfoliated vermiculite, barite, and synthetic calcium silicates. Most of these require fine grinding when used as fillers.

In filtration diatomite is the principal competitive material, while silica sand is used in

large-scale filtering of coarse sludges, for which perlite is only seldom used.

RESERVES

Few data have been published on the reserves of perlite in the United States. However, estimated figures published by a few companies indicate reserves amounting to more than 150 million tons (*5*). Extensive resources occur in Arizona, California, Colorado, Idaho, Nevada, and New Mexico, and to a lesser extent in other Western States. Perlite occurrences in Alaska also have been described (*11*). The total reserves of usable perlite are adequate for any foreseeable requirements. Foreign perlite deposits occur in New Zealand, western Canadian Provinces, Sardinia, Northern Ireland, Mexico, Japan, Greece, Iceland, Australia, Italy, France, Turkey, and the U.S.S.R.

SOURCES OF STATISTICAL INFORMATION

The available commercial statistics on perlite are essentially limited to domestic figures. There are scant records of foreign trade or foreign production of perlite. The Bureau of Mines canvasses producers of both crude and expanded domestic perlite annually, and the Census of Mineral Industries provides industrial data on perlite for a single year intermittently.

PRODUCTION, CONSUMPTION, AND TRADE

Disregarding change in stocks, there was a difference of 33 percent between the weight of total crude perlite produced and expanded perlite output in 1963. This difference is partially due to fines formed in the somewhat explosive expanding process and also to fused and unexpanded particles removed from the furnace. Statistics on stocks are not collected by the Bureau of Mines or the Perlite Institute, but accumulations of currently unmarketable fines are large.

Nevada was the first State to record production of crude perlite, but New Mexico has been the leading producer since 1951.

In 1963 California, with 14 expanding plants, had the largest number of processing operations, followed by Pennsylvania and Texas with 6 each, Illinois and New York with 5 each, and Colorado, Florida, Indiana, Iowa, and New Jersey, each with 3 plants.

Table 1 shows statistics for crude and expanded perlite produced and sold or used during 1954–63.

TABLE 1.—*Crude and expanded perlite produced and sold or used by producers in the United States*

[Thousand short tons and thousand dollars]

Year	Crude perlite						Expanded perlite		
	Quantity mined	Sold		Used at own plant to make expanded material		Total quantity sold and used	Quantity produced	Sold	
		Quantity	Value	Quantity	Value			Quantity	Value
1954–58 (average)	348	190	$1,690	92	$634	282	239	238	$12,174
1959	443	221	1,846	104	891	325	276	273	14,187
1960	385	214	1,847	98	818	312	248	244	13,046
1961	374	196	1,665	114	998	310	240	235	12,605
1962	408	198	1,611	122	1,052	320	238	234	12,536
1963	404	203	1,631	122	1,096	325	272	270	14,497

In 1953 the Bureau commenced canvassing the industry to determine the relative consumption of expanded perlite for various uses. From 1953 to 1958 consumption in building-plaster aggregate increased from 141,000 tons to 155,000 tons; it dropped to 105,000 tons in 1963. Aggregate construction concrete increased from 18,000 tons in 1953 to 38,000 tons in 1958 and decreased to 32,000 tons in 1963. Filter aid consumption was 4,500 tons in 1953 and increased to 26,000 tons in 1958, with a further increase to 42,000 tons in 1963.

There are no published government records of specific imports of perlite. Crude perlite is exported to Canada, but no record of shipments is available.

Crude perlite may be imported duty free, and expanded perlite is dutiable at 15 percent ad valorem.

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in perlite. All 1963 production of crude came from seven Western States; other Western States have un-

developed occurrences. Imports of crude to eastern seaboard areas seem likely in the future because ocean freight from some foreign sources may be less than rail freight from western domestic mines.

PRICES

The average unit value of crude perlite sold by miners to expanders in 1963 was $8.05 per ton, crude used for expanding by prime producers had an average unit value at crushing plants of $8.94 per ton. The average price of expanded perlite in 1963 was $53.69 per ton, and the 1959–63 average was $53.36.

TAXES

No special taxes are imposed on the perlite industry. Crude perlite producers are allowed a depletion allowance of 10 percent on domestic and foreign production.

TRANSPORTATION

Crude perlite is produced in seven Western States, the easternmost being Colorado. Transportation therefore plays a major role in the distribution of costs. In 1963 carlot shipments of crude perlite from Antonito, Colorado, to the eastern seaboard were: Washington, D.C., $12.99; Boston, Mass., $14.49; Trenton, N.J., $13.39; and Jacksonville, Fla., $13.57. Ore freight rates, in these costs represent over 60 percent of the total delivered cost to expanders.

RESEARCH

The Perlite Institute has sponsored research on physical, thermal conductivity, acoustical, and fire properties of perlite. Fire tests sponsored by the Institute have resulted in a wide variety of fire ratings for lightweight concrete and plaster constructions. Investigations have been sponsored at universities and independent laboratories which have developed data on perlite for use as insulation at low and high temperatures, as a plastics extender and fertilizer carrier (*7*).

Some research was done by the Bureau of Mines on the composition and physical properties of perlite and thermal data and energy required in expansion. Details were reported in three publications (*1*, *6*, *8*).

OUTLOOK

Perlite consumption will depend to a great extent on the increase of residential and industrial construction. Trends in the production of expanded perlite indicate a slight increase in the rate of growth. In 1958, 292,000 short tons of crude perlite was sold or used by producers compared with 325,000 in 1963. Expanded perlite production increased 13 percent during 1958–63. Such a rate of increase indicates the continuing growth of the perlite industry.

Trends in the use of expanded perlite as a replacement of sand in building plaster indicate a reversal in the rate of growth. Use as a filter aid is expected to increase. It is expected that perlite will continue to take over a portion of the filter aid market now held by the diatomite industry. Although the greatest usage of perlite today is in the construction industry, it has a large market as a filtration medium, additive, thermal insulator, soil conditioner, and carrier for insecticides and weed killers. Over the short terms period (5 to 10 years) consumption of expanded perlite is expected to increase 3 to 5 percent per year.

Building code authorities have recognized the official fire ratings on perlite insulating concrete. This will permit a broader use of lightweight aggregate and will encourage the use of perlite. There is a growing trend to use silicone-treated perlite for loose fill insulation.

Many deposits of perlite have been discovered, but estimates of total reserves are not available. The many millions of tons of usable perlite presently known, however, indicate that supplies are adequate for any foreseeable demand. Because perlite is found only where recent volcanic activity has occurred, discovery of perlite deposits in the Eastern United States seems unlikely. Foreign sources may in the future supply some eastern areas, because of the high cost of rail freight from the Western United States.

Growing use in cryogenics is expected. Perlite has proved an effective insulator at temperatures below −150° C.

PROBLEMS

One of the principal problems of the perlite industry is to hold and to expand its share of the filter aid market.

More information is needed on the technology of perlite processing. Many advances have been made but they have not been adequately documented in available literature.

The perlite industry needs to utilize the fines produced during the various perlite processing steps. These fines might be used in place of finely ground limestone for white pigmentation. Specially graded perlite now is purchased by many companies to produce fines for use in pigments.

High transportation costs of crude perlite to expanders in eastern and northern sections of the United States invites competition, to some extent, from alternate materials. Substantial savings have been realized, however, on 100 ton shipments.

The mining and processing of perlite creates a dust hazard. The advent of air pollution controls in many cities has resulted in the installation of dust collection systems in most perlite plants.

The majority of companies engaged in the production of expanded perlite are relatively small and marketing and distribution over a large geographic area presents a problem.

The low value of crude perlite restricts mining to deposits amenable to low-cost open-pit exploitation. Cost limitations also eliminate many deposits in which variations in quality necessitate highly selective mining.

PETROLEUM AND NATURAL GAS

By R. F. Zaffarano [1] and J. D. Lankford [2]

A LITTLE over a century ago in 1859, when Edwin L. Drake discovered petroleum in the first commercial well at Titusville, Pa., he unleashed the potential of one of Nature's versatile commodities. The industry has grown to the point where petroleum and natural gas and their hydrocarbon derivatives now supply three-fourths of all the U.S. fuel energy needs. World consumption of petroleum continued to increase in 1963; in the United States the increase was about 6 percent annually, and in the rest of the free world the increase was about 10 percent. The estimated proved reserve of recoverable liquid hydrocarbons in 1963 in the United States included 30.9 billion barrels [3] of crude petroleum and 7.7 billion barrels of natural gas liquids. The worldwide reserve increased to a record high of 326 billion barrels. Five-eighths of the world reserve is in the Middle East, where the 1963 output was 6.8 million barrels daily.

The importance of Middle East oil reserves is clearly shown by the announcement that increased on-site facilities in the world's largest known oilfield, Ghawar in Saudi Arabia, will enable that field to increase its daily production to 800,000 barrels. This production approximates the combined daily crude-oil production of Oklahoma and Kansas. Such prolific production in view of the continued increased growth rate of foreign petroleum consumption (approximately 60 percent greater than the U.S. demand) has influenced many U.S. companies to divert their exploratory efforts abroad. Thirty-two leading U.S. companies derived $39.2 billion in revenue from their worldwide operations in 1963—an increase of 7 percent over that of 1962.

In the United States the demand for natural gas has shown a phenomenal growth in the past 20 years, with an average increase of 5.8 percent per year for the last decade. Natural gas and natural gas liquids provided 34.2 percent of the total energy utilized in the United States in 1963. Marketed production of natural gas reached 14.7 trillion cubic feet in 1963.

Natural gas proved reserves in the United States at the end of 1963 amounted to 276 trillion cubic feet. World reserves of natural gas are considered indeterminate at present.

Natural gas consumption outside this country has been limited because of poor access to markets. This is being remedied to some extent in the newly developed gasfields in North Africa where liquefied methane is shipped to Western European markets in special insulated and refrigerated tankers. Huge new offshore gas reserves in the Netherlands are slowly being developed for European energy markets, formerly the sole domain of solid and liquid fuels.

The international petroleum industry is experiencing a supply-demand race for world markets. Middle East fields alone in 1963 almost equaled the combined production of the United States for the first time in history. They are expected to accomplish this task in 1964. The continued advantage of foreign sources, because of the lower costs for finding and developing crude oil compared to domestic costs, has provided the necessary incentive to U.S. producers to invest and participate increasingly in foreign operations. Companies are willing to forego high initial costs to pioneer foreign area markets because of the strong and growing world demand. The advantage is about $1 per barrel in finding-producing cost below that in the United States.

The domestic petroleum industry has been working diligently to improve its economy. Research efforts are under study on technical problems covering the entire range of oil and gas activities. Improvement in the recovery from oil and gasfields is a major study area. On the average, only 30 to 35 percent of the oil discovered is recovered before the economic limit is reached. Likewise, numerous petroleum resources are submarginal economically and cannot be produced with present technology.

[2] Chemical engineer, Division of Petroleum.
[3] Barrels as used in this chapter refer to a 42-gallon barrel.

As new field and laboratory research data become available, a better understanding of the mechanisms, applications, and limitations of techniques will be developed. When performance of new processes can be predicted as accurately as that of present conventional methods, commercial application may be feasible. One effect may be that additional oil is recovered thereby at lower cost than by exploration for new reserves. Among the new innovations for oil recovery receiving attention are several methods to supplement waterflooding, which now is the predominant method used in secondary recovery.

One main reason that real drilling costs have been increasing is the greater depth of productive wells. Individual segments of drilling costs have increased only slightly; but as wells go deeper, their cost is greater. The industry is confronted with larger exploration expenditures, which in part have contributed to the long upward trend in real costs of finding domestic crude oil; but the major consideration in these costs is that most of the new discoveries are small oil and gas accumulations, and consequently the industry is paying more to discover less.

The economics of finding, developing, and producing oil that will provide domestic petroleum availability is of prime importance in the dynamic mix between consumer preference and the technologies of processing, use, and production so that the Nation may be certain that its ever-changing fuel needs will be met.

BACKGROUND

Petroleum, natural gas, and related bituminous materials have been used by mankind since antiquity. In the ancient world, pitch or native asphalt was used as a binder for pavements, for waterproofing cisterns, calking ships and grain silos, and for mummification. It is believed that the fires of the ancient oracles probably were burning natural gas seeps. North American Indians used petroleum obtained from springs for a variety of medicinal unguents, salves, and hair pomades, and for other purposes such as softening and waterproofing leather. In colonial times "rock oil" was a high priced and valued patent medicine about which great claims were made for a variety of medicinal purposes.

The first recorded production of natural gas in the United States was in western New York in 1821 when a gas seep on the banks of Canadaway Creek was ignited accidentally, demonstrating that natural gas was an excellent fuel. As a result, a well was drilled to a depth of 27 feet, and the gas was used for lighting. The delay in developing natural gas was due to economic conditions and limited technology, not neglect. Natural gas usually was found at locations remote from cities and therefore it was cheaper to serve city markets with gas manufactured locally from coal.

The modern petroleum industry dates from E. L. Drake's well which was drilled near Titusville, Pa., specifically in search for oil. Oil was found at a depth of less than 70 feet on August 27, 1859. At that time, there was a demand for a better and cheaper lamp oil. Whale oil was expensive, in limited supply, and unsatisfactory in other ways. Kerosine—as the name was coined originally—from coal and oil shale and generally called "coal oil," was made in about three dozen refineries in the United States at the time of Drake's well, but this product, too, was expensive and of poor quality as a lamp fuel. Some illuminating oil was being distilled from petroleum obtained from oil springs and seeps. In addition to lamp oils, there also was a strong demand for better quality lubricants.

The oil search spread to other States and countries. Ohio had very little production in 1860, but by 1876 had sustained output. West Virginia, Tennessee, Kentucky, Colorado, and California were producing small amounts of oil in 1865, and before 1900 were joined by Indiana, Illinois, and Texas. By them, oil was being produced in Rumania, Canada, Russia, Poland, Italy, Germany, Japan, Indonesia, Burma, India, Pakistan, and Peru. During this same period, Pennsylvania was the leading gas-producing State, and natural gas had been discovered in 17 States.

The first production in Mexico was in 1901. The great Middle East oilfields were slow to develop; the first oil was produced in Iran in 1913; 14 years later oil was discovered in Iraq. About two decades later the immense Bahrain and Saudi Arabian fields were discovered, followed by discoveries in Kuwait in 1946. The African Sahara's great potential was not proved until large new discoveries were made there in 1958, and important discoveries continue there even now. Venezuelan oil possibilities were first shown in 1917, and for many years it has ranked second to the United States in production in the Western Hemisphere. The United States, long an exporter of both crude oil and products, became a net importer in 1948, and imports of Venezuelan and other foreign oils and residual stocks gradually have increased. In 1963, 20 percent of the U.S. crude-oil supply

was imported. The Middle East now supplies the principal part of the rapidly expanding European market as well as the markets of several countries in the Eastern Hemisphere.

The first oil pipeline to transport crude petroleum satisfactorily in the United States was completed by Samuel Van Syckle of Titusville, Pa., in 1865. The line connected Miller's farm to Pithole City, about 5 miles away. Sections of 2-inch pipe were joined by fitted screw sockets. The line had 2 pump stations and carried about 80 barrels of oil per day. In 1872, the first iron pipeline was constructed to transport waste gas from nearby oil wells to Titusville, Pa. The 2-inch line was 5½ miles long and capable of delivering 4 million cubic feet of gas per day to 250 domestic and industrial customers.

A rapid buildup of large-diameter, long-distance pipelines for natural gas distribution began in the late 1920's when pipe-welding methods were perfected. Since World War II, many product pipelines for finished products, LPG, and petrochemicals also have been built, and the trend is continuing.

The first oil tanker was the SS *Charles* of Antwerp, Belgium, which sailed between the United States and Europe from 1869 to 1872. The ship had 59 iron tanks in its hold with a total capacity of 714 tons (about 5,000 barrels). In 1879, the first tank steamer was constructed by Nobel Bros., the pioneering petroleum refiners in Russia.

The internal-combustion engine, using both the diesel and Otto cycles, came into use in large numbers after 1900. This engine changed the oil industry because of the large gasoline market that developed to supply fuel for automobiles, trucks, and buses.

The first plant for extracting natural gasoline from natural gas by the compression and cooling method was constructed at Titusville, Pa., in 1904. At present, natural gasoline extraction is a large industry, and most gasolines contain some of this product which is used as an ingredient to adjust vapor pressure, boiling range, volatility, and octane-number rating.

For 50 years gasoline has been the major petroleum product. The spreading use of electric lighting had only a slight effect on the oil industry, because the increased demand for gasoline and other products offset the decreased usage of kerosine lamps, fuel for which formerly had been the major oil product market.

After World War I, the development and use of automatic burners for homes and industrial buildings resulted in increased consumption of oil fuels. In the past 20 years railroads have converted almost completely from steam to diesel locomotives because of greatly reduced costs for fuel, operation, and maintenance.

About 1930, the natural gas industry emerged as an essential dynamic industry because of the following factors: (1) the development of steel pipe at reasonable costs that was capable of withstanding great pressure for the transportation of gas over long distances; (2) development of more modern technology for exploratory work; (3) the rapid increase in demand for natural gas service because of its advantages as a clean, flexible, relatively low-cost fuel.

Continuous-distillation units were installed in refineries about 1900, but the conversion from batch to continuous stills was gradual. Large numbers of automobiles and trucks soon upset the refinery-product balances, because straight-run gasoline comprised only about 15 to 20 percent of the crude oil, and markets for the other products grew but slowly; consequently the non-gasoline fractions were in excess supply. Introduction in 1912 of the Burton thermal cracking process, which cracked gas oils, helped to solve this problem by increasing gasoline recoveries to 35 percent of the crude oil processed. Beginning in 1923, tetraethyl lead was used as a gasoline additive to increase the octane rating of gasoline and was a big factor in solving the "knock" problem in high-compression engines. It permitted greater use of lower quality gasolines and more efficient and higher performance engines.

Special aviation gasoline was necessary in World War I, and its composition, manufacture, and testing were greatly advanced in the 1920's and 1930's. A method to produce better quality gasolines was catalytic cracking which came into use in the late 1930's. Equally important was the development of several alkylation, polymerization, and related processes for transforming gaseous and liquid hydrocarbons into gasoline having high antiknock ratings. More recently new catalytic re-forming and hydrogenation processes have been developed, based on the use of platinum and other noble metals and various minerals as the active catalytic agent. This technology has made great transformations in the industry, both in gasoline manufacture and in production of a whole gamut of petrochemical, raw, intermediate, and fininshed products.

Soon after World War II, secondary-recovery methods came into use, and from 1930 to 1945 production obtained by using secondary methods, chiefly waterflooding, remained stable at about 20 million barrels of oil per year. After 1945, production from waterflooding increased at a very rapid rate. In 1963, production from secondary methods exceeded 800 million barrels.

Natural gasoline plants and refineries extract the volatile hydrocarbons, propane and butane, which are associated with petroleum and gas. These can be used in motor fuel only in small quantities because of their volatility, so until fairly recently they were not commonly used except as on-site boiler, furnace, or stationary engine fuel. Propane and butane are excellent heating fuels in the gaseous state, but they must be recovered, stored, transported, and utilized under pressure. Because of this volatility, the development of a substantial LPG industry awaited techniques, procedures, and equipment for extraction and utilization that were efficient, safe, and low in cost. Within the past 30 years the industry has grown phenomenally, chiefly because LPG components are major raw materials used for the manufacture of petrochemicals.

SIZE AND ORGANIZATION OF THE INDUSTRY

Petroleum

Petroleum products are readily available in every locality in the United States and in most countries throughout the world. In 1963, world crude-oil production was 9.5 billion barrels, of which the United States produced 29 percent, or 2.8 billion barrels. Domestic crude oil production, 7.5 million barrels per day, was 70 percent of the U.S. supply of which natural gas liquids supplied 10 percent. The remainder, consisting of crude oil and products, was imported.

The petroleum industry by its nature functions roughly in the following four groups: (1) exploration, drilling, and production; (2) transportation; (3) refining and processing; and (4) distributing and marketing raw, finished, or intermediate products.

In the United States and Canada the industry differs from that in the rest of the world largely because the free enterprise system allows individuals, small companies, and large companies to compete in all phases of the industry. There also is a large measure of cooperation between the various companies, some large, some small. State ownership of land and minerals is generally the case in most of the world outside the United States. This precludes any but the larger companies engaging in foreign operation in most segments of the industry. Many domestic companies (predominantly large corporations) have oil interests in other countries of the free world in production, transportation, refining, and marketing.

More than 18,000 operators are engaged in oil and gas exploration, drilling, and production operations in the United States. These include all legal entities, such as individuals, partnerships, corporations, subsidiary companies of integrated large corporations, and contract services (*4*).[4] Petroleum employment in the producing, recovery, and refining sections of the industry in 1963 was over 480,000 employees (*6*). Refinery capacities of the domestic units ranged from 1,000 barrels to 250,000 barrels daily, with a total daily throughput of almost 10 million barrels. Combined world crude oil refining capacity in 1963 was 250 million barrels daily in 627 operating refineries.

Natural Gas

Natural gas is the most rapidly growing of all the fuel energy resources in the United States and represents the sixth largest industry in the Nation in terms of investment. The 14.7 trillion cubic feet of marketed production in 1963 was a record output which increased 6 percent over the previous year and per capita gas consumption reached a record high of 78 million Btu, a gain of 33 percent in the past decade (*1*). Within the next 4-year period, 1964–67, the gas industry is expected to spend $7.2 billion on construction. During 1960–63 the gas industry spent $6.7 billion on construction, and $273 million for underground gas storage.

The natural gas industry comprises three interdependent branches: (1) producers, (2) pipeline companies, and (3) distribution companies. Some parts of the industry are regulated by National, State, and local governments to maintain an equitable relationship for consumers, industry, and investor.

The term "natural gas producer" includes the following functions: Exploration for finding, developing, producing, gathering, processing, and selling natural gas in the field. Most of the Nation's natural gas is produced by companies that do not combine producing with normal pipeline and distribution operations.

The main purpose of gas pipeline companies is to provide the essential linking of transportation from the producer to the distributor. A pipeline company must obtain a steady and reliable supply of gas and then deliver and sell it to distributors or directly to consumers, often under differing situations. Usually numerous producers are involved, and a variety of conditions prevail concerning price, location, and volume. Therefore, coordination of supply to match demand and to maintain an overall eco-

[4] Italicized number in parentheses refer to the items in the list of references at the end of this chapter.

nomic balance is essential to the gas pipeline company. Gas imports from Canada now have reached about 1 billion cubic feet per day and imports from Mexico about 135 million cubic feet daily. Exports to Canada are approximately 19 million cubic feet per day and those to Mexico, 27 million.

The gas distribution company usually is the only branch of the gas industry that deals directly with the consuming public, but some pipeline companies as well as some gas producers sell gas directly to large industrial consumers. The typical user of gas, whether residential, commercial, or industrial, normally depends on a distribution company as his supplier of gas service. In 1963, large volumes of gas were shipped from gasfields in 33 States through 710,000 miles of transmission and distribution lines to consumers in 47 States, leaving only Maine, Hawaii, and Vermont without gas service.

Interrelations Between Petroleum and Natural-Gas Industries

In most producing areas petroleum and natural gas companies engage in the same activities because oil and gas occur together in petroleum reservoirs. Elsewhere, these industries compete vigorously for the same fuel markets, in domestic and commercial heating, power generation, and industrial fuels.

An oil company often produces natural gas in quantity along with crude petroleum, and oil operators sometimes own "dry" gas wells (produce gas and no oil). Natural-gas companies buy gas from both sources. Conversely, natural-gas producers may own oil wells and sell their production to oil companies.

Most natural-gasoline plants are operated by the producing departments of oil companies, but some are operated by the producing or pipeline departments of gas companies. Others belong to companies that specialize in natural gasoline.

Interstate oil pipelines by law are common carriers and, therefore, are subject to Interstate Commerce Commission regulations. Natural-gas pipelines engaged in interstate business are subject to regulation by the Federal Power Commission. Gas pipeline companies contract to supply certain volumes of gas to their customers, including the local distribution utilities. Some contractual commitments are required before the Federal Power Commission will issue a certificate of necessity to build a gas pipeline. These commitments prevent the gas pipelines from being considered as common carriers as are railroads and oil pipelines.

Geographic Distribution of the Industry

In the past the natural-gas industry was forced to operate on a strictly local basis, but today the enormous and rapidly growing needs for energy outside North America suggest that gas will take its place alongside oil and be of comparable importance in major energy markets. In 1960, the accessibility of gas to European consumers was advanced by the discovery in the Netherlands of what has since proved to be the second largest natural gas field in the world. The Groningen discoveries in the Netherlands, within 375 miles of Paris and 125 miles of the Ruhr, have helped decrease the high transportation costs that have plagued the natural gas industry and have given gas substantially lower flexibility than oil in European markets. At the same time, the Groningen discoveries have been made more significant by the demonstration that marine shipment of natural gas, at atmospheric pressure but liquefied by lowering the temperature below −258° F, is technically feasible. This has made it practical for gas to supply markets too remote to justify the laying of a pipeline. Shipments of liquefied methane in specially constructed tankers from North Africa to France have already begun.

U.S. companies have a dominant interest in oil production in other areas of the free world, as well as in transporation, refining, and marketing. United States is the leading consumer and producer of oil. Within the past decade the United States has had a decreasing proportion of world production and use; however, in many other countries during this period, supply and demand for oil have had a higher growth rate.

The six largest oil-producing States are Texas, Louisiana, California, Oklahoma, Wyoming, and New Mexico. Each produced over 100 million barrels in 1963; the largest producer was Texas with 973 million barrels. For total natural gas withdraw output, the order was the same except that Oklahoma ranked third and California fourth. Principal gas-consuming States are, according to rank, Texas, California, Louisiana, Ohio, Illinois, Pennsylvania, and New York.

The preferred location for refineries combines several features, such as being on or near seaboards and producing areas, or both, and close to large markets and ocean transport. Good examples are the refining centers in the East on the Delaware River close to Philadelphia and New York; those on the gulf coast near Houston, Beaumont, and Port Arthur; those on the west coast near Los Angeles, San Francisco, and on Puget Sound, Wash. Inland,

780-887 O—65——43

the largest refineries are in the Chicago and St. Louis areas.

The same pattern of location was followed in the great postwar refinery construction in Western Europe, the Middle East, and Venezuela. In the Caribbean, Aruba and Trinidad are the major refining centers. In the Middle East the principal refineries are in Kuwait, Bahrain, Ras Tanura, Saudi Arabia, Abadan, and Iraq, all of which are on the Persian Gulf.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The petroleum industry's primary raw material—crude oil—has widely varying properties. Historically, crude oil has been sold on the basis of gravity. The higher API gravity oils contain more of the more valuable products, gasoline and light distillates, than heavier oils, so that lighter crudes sell at higher prices. Another criterion has been the amount of sulfur present. Many sulfur compounds have disagreeable odors, are toxic, and corrosive; oils containing them (sour oils) are more expensive to handle and refine, so they are penalized in the market. Other factors that reduce quality are salt and substances that poison cracking and reforming catalysts (in addition to sulfur), such as nitrogen compounds, arsenic, vanadium, and other minerals, and metals. Elaborate price scales for crude oils, which take into account both quality and location, have been established all over the world.

For natural gas the quality problem is simplified because its composition is less complex. The final product reaching the consumer is rather uniform in composition and heating value which usually is between 900 and 1,000 Btu per cubic foot. There is an increasing trend toward the sale of natural gas on a heating-value basis (therm, 100,000 Btu) rather than on a volume basis.

In the United States the major petroleum products are motor and aviation gasoline, and domestic and industrial fuels. Motor gasolines are sold in two principal standard grades by most refiners, three by others, and by a few companies in a series of grades blended at the service station pumps on an octane-number basis. There are five grades of aviation gasolines and three grades of jet-propulsion fuels. There are three standard diesel fuels and five standard grades of fuel oil. Lubricating oils, greases, and related specialty products have appropriate standards, and these products are produced in great number and variety to suit thousands of different needs.

Natural gasoline and LPG are petroleum products, but in the pactice of industry they are treated more as natural gas rather than petroleum materials. They, likewise, are sold in a number of grades for many purposes. Volatility is important in gasoline, and these volatile natural gasolines are blended into gasolines to give them the proper temperature-boiling range-vapor pressure properties to suit the type and location of use. Volatility of motor gasolines, for example, is varied in this manner as may be required by the season as well as the latitude and altitude.

The term "natural gas" is applied to all varieties of gases produced from underground rocks in which the paraffin series of hydrocarbons predominates. Normally the gaseous hydrocarbons in commercial natural gas are predominately methane (CH_4) with significant quantities of ethane (C_2H_6), with other hydrocarbons in small amounts. Natural gases, as produced, usually have small amounts of moisture, nitrogen, carbon dioxide, and hydrogen sulfide, and there also may be small percentages of helium and traces of oxygen, argon, and hydrogen. In a few locations, gas with a high carbon dioxide content is processed to manufacture dry ice or liquid CO_2. Sulfur compounds in natural gas-hydrogen sulfide and mercaptans are odoriferous, corrosive, and/or toxic impurities that must be reduced, altered, or removed for the gas to be suitable for domestic or commercial use. Gas companies in recent years have placed a minimum limitation of 20 grains of total sulfur and 1 grain of hydrogen sulfide per 1,000 cubic feet (Mcf) on gas for it to be acceptable for transmission.

TECHNOLOGY

The modern petroleum and natural-gas industry grew from a realization of the value of both crude oil and natural gas. The utility of natural gas was known and commercially exploited in the United States long before Colonel Drake "drilled the first oil well" in 1859. Drake's well was drilled directly as a result of Professor Silliman's scientific examination of a crude oil sample and his detailed report of the many useful and needed products that could be obtained from petroleum in quantity. Then little technologic skill was needed except the elementary skills of the brine-well drillers borrowed from the salt industry and those of the refiners borrowed from the coal-oil plants, which were striving to supply the illuminating-oil deficiencies caused by declining catches of sperm whales. Creekology and surface seeps were the methods used by the oil finder when Drake spotted his well location on an oil seep. The application of geology to finding oil began 25 years later when several fields were discovered,

based on the theory that oil accumulates underground in the crest of rock-layer folds, called anticlines.

The first drillers sought oil in places where oil escaped to the surface, and because seepages were found along streambeds and in low spots, wells were drilled in valleys. As the more venturesome drillers, the first wildcatters, found oil by drilling on hilltops away from oil seepages, and learned that oil existed thus without surface indication, it was realized that underground rock formations were more important than seeps when exploring for petroleum.

In 1848, before the Drake well, Sir William Logan, Director of the Geological Survey of Canada, visited the oil seeps of the Gaspé Peninsula and reported that they were on anticlines. This theory was not accepted in Pennsylvania for the simple reason that it did not apply in that State, which for over 50 years was the foremost oil-producing area in the world. Even in southwestern Pennsylvania and West Virginia, where large closed anticlines are found, oil occurs in lenticular sands and is as likely to be located off an anticline as upon it. The age of seepage drilling (that is, the location of wells near seeps) persisted far into the 20th century. The 1912 discovery of the Cushing field, Oklahoma, was the first attributed to the Federal Geological Survey. The period from 1912 to 1925, during which most of the principal anticlines in the United States were discovered, is therefore known as the "anticlinal" period. The end of this period is said to mark the initiation of modern scientific exploration.

Exploration

Early oil exploration was mainly a search for surface features which might indicate subsurface structures containing oil and gas. Few engineers or geologists were present in the early years of the oil industry, and it was only after they had been employed in numbers for a substantial period that knowledge was gained and used by the industry. Gradually conditions such as favorable source beds, marine environments during sedimentation, porus reservoir rocks, and tight gas-capped rocks were determined to be important for location of oil reservoirs. Driller's logs or other data on the underground rocks were put to use by the geologist for subsurface studies.

Today, petroleum engineers and geologists are constantly searching for new tools for interpretation of subsurface conditions. Some of the developments are electrical logging (resistivity and self-potential measurements of formations adjacent to well bores), microcaliper logging of holes and subsurface dip instruments, sidewall coring of boreholes, and electrically fired, explosive-propelled corebarrels. In recent years various types of radioactive well logging have been developed in the form of gamma ray and neutron instrumentation.

Perhaps the most useful instrument for geophysical oil prospecting employs shock waves and is known as reflection seismography. Seismographs have long been used to measure and record earthquakes. The instrument is so sensitive it can measure the footfall of an ant, and it is used to detect and record shock or sound waves reflected from subterranean rock strata. The shock wave is created by exploding dynamite or by generating seismic waves by dropping heavy weights on the surface (the "vibroseis" technique). When using explosives, a hole is drilled some 50 feet deep into the area to be explored and 5 to 50 pounds of dynamite are tamped into the hole. Shock waves are sent into the earth from the explosion or heavy impacts of waves just above or below the surface. The waves return to the surface either by reflection from subsurface interfaces or by refraction along them. These methods are expensive and are used only for detail work in favorable areas and sometimes where overall indications appear good for regional reconnaissance.

The trend toward higher cost of seismic operations will continue. Recently introduced refinements, such as magnetic-tape recording, transistor electronics, and high-speed automatic computers, combined with application of data-processing techniques, have improved the effectiveness of seismic operations; however, these refinements have also increased costs.

The gravity meter is used to explore underground structures by measuring the earth's gravity. It is essentially a sensitive spring balance which measures differences in the pull of gravity at different locations. A dense rock buried in lighter rocks will be indicated on the gravity meter by an increase in the value of the earth's gravity at points above the rock. The gravity meter is particularly useful in locating salt domes and salt beds because of the difference between the density of the salt and the other surrounding rock. Gravity meter surveys have located many salt domes in the Gulf of Mexico and adjacent gulf coast area, as well as a number of salt beds in Canada.

Geophysical prospecting also is done with a magnetometer, an instrument that measures the earth's magnetic field. Magnetometers are used chiefly in hard rock or in nonsedimentary areas to prospect for minerals. Like the gravity meter, they can be used to plot the contours of hard rocks underlying sedimentary rocks.

Essentially the instrument is a vertically mounted magnetic needle which measures the downward pull of the earth's magnet field. Rocks have varying degrees of magnetic attraction due to their orientation relative to the earth's magnetic field and their nearness to the earth's surface. Variation in readings of the magnetometer obtained over an area may be interpreted as indicative of the presence or absence of oil traps.

Gravimetric and particularly seismic methods have received added significance with the increasing interest shown since the late 1940's in those sections of the Continental Shelf which are submerged parts of potential oil basins. Special techniques have been developed to enable surveys to be conducted in the shallow seas covering such regions. Gravimetric instruments are lowered to the sea bottom on a cable, and the instruments are carefully leveled and adjusted by remote control before readings are taken. Several seismology methods have been developed which allow progress at sea much faster than on land. Marine geophysical activity has been most intense in the gulf coast area of Louisiana and Texas where the discovery of several oil-bearing or gas-bearing structures has amply proved the value of geophysical methods.

Neither geophysical nor geological surveys indicate the actual presence of oil. At the very most they can suggest the existence of an underground structure which may be favorable to oil accumulation. Only the drill can prove the presence of oil.

The soil-gas method is the best known geochemical technique for petroleum exploration in the United States. In using this technique, samples of the soil are gathered at intervals over the study area in a grid or profile pattern in search for hydrocarbon anomalies. The resulting data are plotted on a map which, if positive, reveal a characteristic "halo" effect. These anomalies do not give the nature (oil or gas) or the depth of the hydrocarbon source formation because the haloes are essentially static phenomena representing hydrocarbons locked in the soil from source oil or gas deposits. These hydrocarbons may or may not have migrated elsewhere.

Claims for the effectiveness of soil gas analysis are difficult to evaluate. Although such techniques have not proved successful in this country, the Soviets document numerous successes, the validity of which remains in doubt.

Drilling

Well drilling is a combination of art and science. In recent years the trend is toward more science and technology. The art of well drilling is very old and was practiced by the Chinese in drilling brine wells as early as 221 B.C. Their equipment was of the percussion type, although wells were drilled as deep as 3,500 feet in search of petroleum. Wells were drilled with a heavy tool called a bit, which hung from a rope and was jerked up and down by relays of men bouncing on a springboard. The weight of the periodically rising and falling bit drove it deeper and deeper into the ground.

In cable-tool drilling (sometimes referred to as percussion or churn drilling), the formation is pounded by a heavy bit on the end of a cable which is raised and dropped by machinery to produce a regular eccentric motion similar to the hand drill of the stonemason. The cable tool assembly is about 40 feet long and has four parts made of steel: The bit (about 6 feet in length), a long drill stem (a 25-foot cylindrical bar to add weight), jars (massive telescoping links to accentuate the motion), and a socket for attaching the cable. Weight on the end of a flexible cable (steel, formerly manila) causes the bit to strike the bottom of the hole with great force and break the rock.

Drilling is done with water in the hole so that the broken material becomes a slurry which periodically is removed from the bottom of the hole by pulling out the drilling tools and lowering and withdrawing a bailer on another cable. Cable-tool rigs are driven by steam engines, internal combustion engines, or electric motors. Steel pipe (casing) usually is screwed together as it is lowered into the well to line the hole. It prevents caving and is used to control ingress or egress of fluids (oil, gas, mud, and water) to or from the well in the various formations penetrated. The term "rig" includes a derrick or mast with the necessary hoisting equipment for spooling the various cables and a walking beam to raise and drop the drilling string.

At the turn of the century a radically different drilling system, the rotary method, was introduced successfully when drilling the discovery well of the famous Spindletop field, in the gulf coast region of Texas. No reciprocating movement is employed. A column composed of joints of pipe screwed together (termed a drilling string) is suspended by hoisting gear in a derrick. This string is turned by an engine which drives the rotary table and the hoisting equipment. The bit is screwed to the bottom of the column of pipe. Lowering of the drilling string is controlled so as to allow the desired amount of weight to rest on the revolving bit, causing it to penetrate the formation as it turns. The rotary bit bores a hole in the earth by slicing, crunching, or abrading the rock at the bottom of the hole. A stream of liquid, generally colloidal mud, is pumped through the drill

pipe, the function of which is to wash away the formation cuttings and bring them to the surface. The mud passes through nozzles or eyes in the bit and returns to the surface in the annular space outside the drill string. Holes can be made much faster by rotary drilling than by cable tool drilling, especially in the softer formations. Even so, a long time elapsed before rotary drilling obtained its present prominent place. Rotary rigs are relatively more expensive and require more men to operate. Cable tool footage is, as a rule, higher than rotary rig footage, but daily operating costs are lower, an important factor to small operators. The rotary system basically has remained unchanged since the Spindletop days. However, there is little resemblance between the rig of 1900 with its wooden derrick and a primitive hoist driven by a small steam engine and a modern rotary rig equipped with a steel derrick, pneumatic and hydraulic controls, and a group of gas or diesel engines to supply power having an output of 3,000 horsepower or more.

Water-base muds are employed extensively in drilling wells as the natural result of availability, low cost, and generally satisfactory performance. Oil-base muds and water-oil emulsion muds are often used, where damage may be done by contact of water with reservoir beds containing reactive clays. Aerated muds, oil, or air and natural gas alone may be used as the circulating fluid for relatively low-pressure exposure of producing formations when damage by excessive pressures might otherwise be incurred in these formations.

Advanced engineering has produced highly integrated units which can be speedily moved and erected. Drilling techniques, drilling fluids, and methods of identifying and evaluating the formations penetrated have been and still are being greatly improved. Rotary drilling is more costly per day than cable tool drilling, but it is about 10 times faster and more economical, particularly for deep drilling. Economy is an important consideration since most wells drilled today are over 5,000 feet deep, many are 10,000 feet, and a few have reached 20,000 feet. The deepest well to date is 25,515 feet. Since rotary drilling is the only method of reaching these great depths, almost 90 percent of drilled footage today is by rotary.

Marine Drilling

Before World War II, little effort had been given to drilling for oil in the underwater regions of the oil basins. In 1880, shallow wells were drilled from piers off the coast of Southern California near Ricon. In the 1920's, development of portions of the famous Lake Maracaibo, Venezuela oil field, and the offshore area of the Huntington Beach-California field, were drilled by means of directional wells drilled from beach locations. Drilling in the Caspian Sea near Baku was still a later development.

After World War II, intensified search for oil and favorable prospects in the Gulf of Mexico soon led to the drilling of the first offshore well. Since then, the technique of offshore drilling has developed rapidly, and many types of drilling platforms suitable for operations far from shore have been constructed. These are now designed for drilling in waters of varying depths up to several hundred feet, and wells are being drilled offshore in the Gulf of Mexico along the coast of Louisiana, Texas, and California.

Offshore work outside the United States is being done in scattered locations from the Persian Gulf to British Isles and from the Far East to the Caribbean area. The industry has not standardized on any particular style of rig for particular types of jobs, and rigs now putting to sea for the first time resemble each other as little as did the previous rigs.

Offshore drilling platforms are classed in three general categories. One of these fixed-derrick platforms are units large enough to carry derrick, drawworks, and engines erected on piles driven into the seabed. A seaworthy drilling tender is moored to the platform and contains the circulation pumps (connected to the platform by hoses), storage tanks for mud, drill pipe racks, casing, cement and cementing equipment, crew living quarters, and generally, a helicopter landing platform. The tender platform is a relatively deep-water tool, designed for operations in waters of 300 feet or deeper.

Self-contained platforms are best suited for development of a proved area. Such a platform does not require a tender and is particularly suitable for drilling a number of directional-deviated development wells. After completion of wells, the platform provides an area for the installation of production equipment such as oil tanks and pumps for transferring oil production into barges or, via a submarine pipeline, to a shore installation. A self-contained platform is designed for development operations in water to a depth of 110 feet.

Floating-mobile platforms are used for drilling exploratory wells because their mobility allows quick and comparatively inexpensive moves from well sites. Producers use this method to move in, evaluate a lease with test drilling, and move out rapidly at minimum expense. The mobile unit includes space for drilling equipment, a helicopter port, mud tanks, pipe racks, crew quarters, communications,

cooking and recreation facilities, auxiliary power, and other miscellaneous equipment. Such built-in flexibility enables a company to drill vertical holes which are 50 percent cheaper than deviated holes from a fixed platform. The ability to move to different locations diminishes the danger of a blowout destroying a cluster of wells, as is the case on multiple well permanent platforms. Since all equipment is on the platform, downtime (time when drilling operations ceases) resulting from wave action is reduced. The water depth limitation for floating mobile units is now about 125 feet.

Many oil prospects in soft, marshy soil on the gulf coast of Louisiana and Texas are readily reached by shallow-dredged canals. Here a drilling unit is mounted on a large flat-bottomed barge which is divided into compartments. The barge has a narrow longitudinal slit in the hull from one end to the center under the derrick. The drilling barge is towed to the drilling site and is settled on the bottom by flooding the tanks. After a well has been completed, the barge is raised by pumping out the tanks and is floated off the well site. In general, such barges are capable of work in water depths to 80 feet. Barges of the submersible and self-elevating types continue to be popular for work within their depth ranges, and their depth capacity continues to increase.

Between 75 and 80 offshore units are now working in the waters of Louisiana. This includes 30 mobiles, 30 tenders, and the rest self-contained units.

Formation Evaluation

Drill stem testing, first developed over 35 years ago, is a method of evaluating the producing potential of a given horizon. The tests involve removing the hydrostatic pressure of the drilling fluid column from the formation and allowing formation fluids present to flow into the empty drill pipe. Data obtained include quantity and quality of produced fluids during a measured time interval. Such testing is the most reliable method known for evaluating a potential reservoir short of completing the well. Economics of the method are gained because the method eliminates the necessity of completing the well to test potentially productive formations.

Coring is a process of obtaining formation samples from the hole by special apparatus, or as drill cuttings returned from the formation face by the circulating drilling mud. Cores taken over the total depth interval of the prospective productive interval have the advantage of representing the reservoir as it occurs in the subsurface strata. Core data provide essential information concerning bed contacts, dip, grain size distribution, grain orientation, porosity and and permeability values.

Well logging may in some instances replace continuous coring, but it is generally used to supplement core data. At best, both methods can only infer the presence of oil or gas. Of the many existing logging tools, electric, gamma ray, neutron, and sonic logs are the most widely applied. Comparisons of the different logs enable determinations and estimations of geologic and reservoir data required for the ultimate technology in well completion practices and overall recovery of hydrocarbons.

Well Completion

Wells drilled for production of hydrocarbon fluids normally are walled or cased with one or several strings of tubular casing to protect fresh-water formations, to support the walls of the hole to prevent caving of the incompetent formation beds, and to protect produced hydrocarbons from contamination. A conventional well completion may involve the installation of two, three, or more strings of casing, "telescoping" within each other, with each string extending to a depth dictated by local formation conditions. Before casing is placed into the hole, the borehole may be reamed and scraped or acid treated to remove mud accumulations to improve cement bonding.

Oil-well cementing is the process of displacing cement slurry down the casing, tubing, or drill pipe to a predetermined point in the well. Cement is forced into the annular space between the casing and the wall of the hole and allowed to set and form a permanent barrier to the movement of fluids. More than half of the cement pumped in wells within the last two or three decades contained some type of additive. Over 30 special additives are available to change oil-well cements for specific applications.

Several choices of perforating equipment are available to provide the most useful path for flow of fluids into or from a cased borehole. Detonation of explosives in open hole opposite low-permeability sandstone formation is probably the earliest method of perforation used. The explosion creates fracture and fissure systems in the surrounding pay, and extends the wellbore. In conventional completions the formations are exposed by shooting holes at preselected intervals and densities over the length of the selected sections. Using a gun perforator, the holes through the casing and cement sheath are created by jet charges, or bullets. Following this exposure on a potential flowing well, tubing (usually of 2-inch internal diameter for single zone completion) is installed in

the well and attached to the casinghead. An assembly of valves and variable chokes are placed above a master valve on the tubing head, referred to as the "Christmas Tree." This assembly is arranged to direct the fluid flow from the well to lease facilities.

Acidization is frequently applied to acid-soluble carbonate reservoir rocks, such as limestone and dolomite, to open up or enlarge flow channels to the wellbore by dissolving barriers and restrictions in the formation. Hydrochloric acid is basically the main constituent because it is the most efficient and economical acid available for permeability improvement. Acids are modified in advance to suit the formation.

One of the most outstanding well stimulation methods for increasing well productivity is hydraulic fracturing. Many fields are in existence today because of these fracturing techniques for, without them, many producing horizons would very probably have been bypassed in the past 15 years as either barren or commercially nonproductive. Hydraulic fracturing of formations is produced by the application of sufficient hydraulic pressure to the face of the exposed subsurface productive formation to induce fractures in the formation. The technique is a means of increasing the effective permeability and is particularly applicable to formations with naturally low permeability. In thick producing sections, parts of the sections are isolated and fractured separately to insure maximum effectiveness.

The most common fracturing fluid used is lease oil. Although oil is not always the most satisfactory, it can be used more universally than other fluids. Fracturing fluids are classified into the following general groups: (1) fluids, (2) gels, and (3) emulsions. Fluids used are oils, fresh water, salt water or oilfield brines, and acids. Gels used are composed of oil, water, or acid with a proper chemical added to the base fluid to increase its viscosity. Emulsions are comprised of two fluid phases: (1) oil and (2) water or acid. They are formed by mixing the two phases together in correct proportions in the presence of an emulsifying agent to form either oil-in-water or water-in-oil emulsions.

In addition to fluids, the fracturing medium contains a propping agent to hold the fracture open to increase effective flow of formation fluids to the wellbore. Sand has been used almost universally for this purpose. Recently, glass pellets, aluminum pellets, nutshells, or plastics have been introduced as propping agents.

A permanent completion involves placing the lower end of the well tubing above one or more potential producing intervals and subsequently performing all completion and recompletion work with small tools that pass through the tubing. After the well casing has been set and cemented, this type completion can be used with any common size casing and tubing, provided the well is properly equipped.

Multiple completion is a technique which permits two or more reservoirs to be produced simultaneously, but separately through the same wellbore. Most multiple completions are used only for production. Many wells of this type serve as multiple injection wells for pressure maintenance or secondary recovery projects. Others are used for the injection of fluid into one or more reservoirs while maintaining production from others.

Recovery of Petroleum

Oil and gas accumulates underground in reservoirs of porous rock masses which have impermeable rock boundaries. In such a reservoir generally, free gas, if present, will occupy the space above the oil, and water, if present will occupy the space below the oil.

In any system fluids flow from regions of higher to lower pressure, and within a reservoir the flow is toward the producing wells. This movement is the result of: (1) propulsive action of gas either free or in solution in the oil which expands by lowered pressure to force the oil and gas through the pore spaces in the reservoir rocks; (2) displacement action of water from adjoining parts of the sand; and (3) gravity drainage. The space vacated by the removal of oil is filled by expansion and movement of the remaining oil, gas, and water. The general reservoir types are classed according to the major recovery mechanism.

(1) Gas-drive fields are reservoirs where oil accumulations are overlain by a gas cap. Movement of the oil results primarily from pressure of gas within the gas cap, supplemented by expanding gas liberated from solution in the oil. In this mechanism, the pressure reduction accompanying oil production allows the compressed gas in the gas cap to expand, to invade the oil zone downstructure, and to drive oil toward regions of reduced pressures at the producing wells. Under efficient operations a gas cap drive is capable of yielding approximately 20 to 60 percent of the original oil in place, depending on the size of the gas cap.

(2) Water-drive fields are reservoirs in which the space voided by the oil produced is refilled entirely or in part by water from the adjoining parts of the sand. No "free" gas is present in the reservoir as long as formation pressures are maintained above the saturation point; that

is, above the pressure at which gas comes out of solution from the oil. A small fraction of the space voided by the produced oil is taken up by the expansion of the oil plus dissolved gas still present in the reservoir. Water-drive fields are typified by slight or no declines in reservoir pressure with approximate recoveries between 30 to 80 percent of the original oil in place.

(3) Depletion reservoirs are those from which the oil is produced by gas liberated from solution in the oil, and aided by gravitational forces. Ultimately the available energy becomes inadequate to move oil, and some means of secondary recovery must be initiated. Oil recovery by depletion drive is basically and inherently inefficient, with the average recovery from about 10 to 25 percent of the oil in place in the reservoir.

Seldom do reservoirs produce by a single drive mechanism, but instead produce from several of the drives at sometime throughout the life of the field. For simplicity, a reservoir is classed by the dominant mechanism, although other drives may have some effects.

When reservoir pressures are high enough, wells will flow; that is, the oil and gas are produced because of natural energy latent within the fluids as they exist within the reservoir rock. In flowing wells this energy is utilized not only to expel the oil from the reservoir rocks into the well bore but also to lift it to the surface. Oil and gas may be allowed to flow to the surface through the casing, but usually the oil flow is confined within a smaller auxiliary column of pipe (tubing) suspended within the casing.

After natural flow stops, it is necessary to install additional equipment to lift the oil to the surface. Lifting methods fall into two general classes: (1) gas-lift methods and (2) mechanical pumping.

The "gas lift" method of producing oil (and water) involves the injection of natural gas from the surface through the space between the casing and tubing with resultant production of the gas and oil through the tubing.

The mechanical devices for lifting liquid in wells include the various types of oil-well pumps, of which rod-actuated plunger-displacement pumps and centrifugal pumps are the most common.

In the past, waterflooding has been applied on a large scale only in shallow oil sands but now is being applied in deeper reservoirs. A typical waterflood has an initial fillup period of several months before there is any marked pick-up in oil production. This initial period is usually followed by rapid increase in oil recovery, and combined fluid output continues thereafter with a gradual decrease of oil, and a corresponding water increase until the project reaches its economic limit.

After primary methods of extracting oil from reservoir rocks no longer recover oil at economical rates, many fields still are capable of yielding large quantities of oil economically by stimulative or secondary methods.

Hydrocrabon recovery can be increased by applying energy to maintain pressure or to move oil, gas, and related hydrocarbons through a reservoir by the injection of liquids or gases into the reservoir. Injection of gas and water into reservoirs has been practiced for the past 90 years to increase recovery.

Secondary recovery in early years was started when a reservoir was near its economic production limits. The growth in use and in the understanding of the technology and the economics of secondary recovery operations has led to the starting of more projects early in the productive life of the reservoir, and increased recoveries have been obtained. The majority of oilfields now are operated to obtain a maximum recovery of oil by maintaining a minimum change in reservoir pressure.

A number of experimental recovery methods are in various stages of tests in the laboratory and in the field. Miscible phase displacement has been thoroughly studied in the laboratory and has undergone field testing. The method consists of injection of alternate slugs of dry gas and water, or simultaneous injection of either dry gas and water, or enriched gas and water. The purpose of these types of drives is to improve the sweep efficiency in heterogeneous formations by the use of solvents that are miscible with the reservoir oil. Up to now, these methods have been promising, but not outstanding. Two other approaches being tried are based on methods for introducing heat into the reservoir. These are fireflooding, or in-situ combustion, and steam injection. Steam injection is the most popular new method because of its simplicity and fast payout. Both methods are directed to obtain additional recovery from deposits of heavy crude, previously considered uneconomic. Before these methods can be used with confidence, additional technology must be developed, for both have been used on a limited basis.

The high-pressure gas injection process has proved successful in reservoirs containing crude oils of 35° API gravity or higher. In this process natural gas is injected at pressures near 4,000 pounds per square inch to oil formations, which results in vaporization of the crude. Pressure maintenance or cycling operations are usually undertaken on gas-condensate reservoirs where insufficient water drive is available to

maintain the pressure in the producing interval at or above the dew or bubble point of the fluid.

Natural Gas and Natural Gas Liquids

Natural gas is produced by methods similar to those used in producing crude petroleum. The only differences result from the physical characteristics of the two commodities. Three types of reservoirs—dry gas, condensate, and oil—produce natural gas. Gas from dry-gas reservoirs is accompanied by only relatively small amounts of liquid hydrocarbons when it is reduced to atmospheric pressure and temperature. Gas from condensate reservoirs is accompanied by larger amounts of liquid hydrocarbons which may be in the gaseous state under reservoir conditions, but liquefied in the production and processing operation. Gas produced from oil reservoirs may be either "gas cap" gas from the crest of the reservoir or solution gas liberated from the oil as pressure and temperature are reduced in the production process. In the primary phase of producing a petroleum reservoir, the reservoir pressure gradually is reduced by producing the reservoir fluids (oil, water, and gas). The production rate normally exceeds the influx of water even in the most effective natural water drives, with the result that the reservoir pressure under these conditions also will decline unless the natural drive is supplemented by the injection of water or gas from the surface. As the reservoir pressure declines, a larger portion of the gas in the oil comes out of solution, thus resulting in higher produced gas-oil ratios. However, when the reservoir pressure is maintained, or permitted to decline only to a predetermined point through injection of water or gas, the produced gas-oil ratio will not exceed the solution gas-oil ratio until a breakthrough of injected gas or gas from a gas cap occurs.

In a gas-condensate reservoir the hydrocarbons originally are considered to be in a single gaseous phase at reservoir pressure and temperature. On reduction of pressure, condensation of some of the hydrocarbons will result. The liquid so obtained is termed "condensate." Condensation of the gas to form a liquid when pressure is reduced is a phenomenon directly opposite to common concepts. Normally when a substance is near the dewpoint, an increase in pressure results in condensation and a reduction in pressure causes evaporation. Gas-condensate reservoirs contain, in addition to the condensate, natural gasoline and lighter hydrocarbons similar to those found in gas associated with oil. The extractable constituents fall into the broad classification of natural-gas liquids; the amount ranges from 10 to 75 barrels per million cubic feet of gas. In the cycling process of producing gas-condensate reservoirs, the dry residue gas is returned to the reservoir, thus retarding condensation with resultant loss of liquids and preserving the dry residue gas for later marketing.

Extraction Processes

Methods of extracting hydrocarbon liquids from natural gas are the results of three stages of development. In the early years of the industry, extraction was accomplished by compression and cooling. The crude natural gasoline recovered by this method contained a substantial amount of butane and propane which made the gasoline unstable at atmospheric pressure and temperature. As the more volatile constituents vaporized, some of the desirable heavier components were carried with them. Because of the inefficiency of this method, the number of compression plants has declined, and they have been replaced by larger and more efficient absorption units.

The absorption process involves passing the produced gas through an absorber countercurrent to the absorption oil from which the liquefiable hydrocarbons are removed by distillation. The process gives high extraction efficiency and is capable of close operational control.

Petroleum Refining

The petroleum refining industry has blazed an impressive trail since the mid-19th century. Out of the small hand-tended batch stills and batch treaters of years ago have evolved the complex and highly automated refineries of today.

Today's refining plants are made up of multiple integrated processing units designed and operated for manufacturing with precision a multitude of finished or semifinished products from crude petroleum. Although the refineries are highly specialized in one sense, they are at the same time flexible enough to be adaptable to changing demands in quantity and quality of products. Such flexibility may on occasion be achieved by varying the type of crude oil that is charged. In other cases, changes in equipment or in process variables may be required. The petroleum refining industry, through continuous development, has continued to meet changing demands by the evolution of new processes involving steady progress in application of science, technology, and engineering.

Crude petroleum has few uses in the raw, unrefined state. It contains chiefly hydrocarbons, ranging from highly volatile compounds

to viscous fluids and heavier materials that cannot be distilled.

Distillation

Atmospheric distillation—the first process that was used for refining petroleum—remains the basic operation in modern refineries, but modern equipment and techniques are employed. It makes use of differences in boiling points of the constituents of the crude oil to separate it into many fractions which are the charge stocks for subsequent processes. The primary distillation unit operates at about atmospheric pressure. One or two separate fractionating columns may be used in this unit. The oil is heated by passing it through tubes installed in a gas- or oil-fired furnace, and vapors from the heated oil are then fed to the fractionating tower containing numerous trays.

Operation of the fractionating tower is countercurrent. The tower is hottest at the bottom, and each successive tray upward is at a lower temperature. As hot oil vapors rise, those having the higher boiling points condense on the lower trays and the lower boiling materials pass upward to condense on the upper trays, or pass on in the vapor state. The condensate flows down from tray to tray and serves to scrub the rising vapors to establish a vapor-liquid equilibrium at each level in the tower. Fractions having definite boiling ranges can be withdrawn constantly from the various trays and bottom of the tower (residuum) as liquids. Vapors from the tower top (overhead) are subsequently condensed to liquids by heat exchange. Noncondensed gases pass off with the overhead fractions. The residuum may be charged to a vacuum fractionator, sometimes termed a "secondary distillation unit", for additional separations, where, because of lower pressure, more of the oil may be vaporized below decomposition temperatures (about 800° F) than is possible at atmospheric pressure.

In the atmospheric column the products in general are, top to bottom: gasoline, kerosine, light gas oil, heavy gas oil, lubricating distillates, and residuum. These are continuously removed overhead and from drawoffs at specific trays down the column and from the bottom. The highest boiling material from the bottom of the column in some cases is reheated and fed to a vacuum distillation unit to separate the heavier distillate and residual lubricating oil stocks, residual fuels, and asphalts.

Practically all straight-run products from the distillation steps must undergo further refining that may include acid, caustic and solvent treating, dewaxing, decolorizing, blending plus addition of special additives. Those fractions that are not prepared as straight-run products undergo various cracking and other conversion processes discussed later. Each product during manufacture through the various steps must meet specifications of the buyer. Generally, marketed products are prepared to American Society for Testing and Materials or Government specifications.

Thermal Cracking

Thermal cracking was the first major advance in petroleum refining for obtaining more and better gasoline from crude petroleum than could be obtained straight run. It was introduced in 1913 and was the dominant processing feature of refineries for over three decades. Thermal cracking means the decomposition of oil by heat. The oil fractions are brought to about 950° to 1000° F and usually 250 to 300 pounds per square inch, with the result that the hydrocarbon molecules break apart, or "crack," to yield lighter products such as gases, gasoline, and naphtha, and heavier products such as cracked gas oils and asphalt and in the more severe thermal cracking processes, petroleum coke. Yields of gasoline from some crudes can be increased from about 15 to 50 percent or more by thermal cracking, and production of heavy residual fuel oils can be eliminated entirely through thermal coking.

Catalytic Cracking

As the knowledge grew of petroleum composition and its reactions under various conditions, it was learned that cracking could be done better and yield more and higher quality products if the cracking is done in the presence of certain solid mineral particles. These solids are known as catalysts and their use in refining is termed "catalytic," or "cat" cracking. The first commercial catalysts were specially treated bentonitic clays, but soon synthetic ones were developed which improve yields and operations. Catalyst particles are about one-sixth inch in diameter and usually are in the form either of pellets or beads. The active components usually are silica, magnesia, zirconia, and alumina, singly or in combinations. "Cat" units of large and small sizes have been built that charge from as low as 1,500 to over 60,000 barrels per day. Enormous amounts of catalysts are circulated through these plants, and in some the rate may be as high as 70 tons per minute. Operating pressures are low—10 to 30 pounds per square inch—and reactor temperatures are from 800° to 900° F.

Alkylation

Cracking processes also yield quantities of light hydrocarbons having two to four carbon atoms that have high octane numbers, but these

hydrocarbons are too volatile for blending into gasoline. However, they may be brought into chemical combination by catalytic alkylation to form compounds (alkylates) that have higher molecular weights, higher boiling ranges, high octane numbers, and are less volatile. From this alkylate mixture blending stocks are extracted for use as components in the best aviation and motor gasolines. The supply of alkylate at times during World War II was a limiting factor in producing aviation gasoline (avgas). Currently, much alkylate goes into motor gasoline, and it provides a substantial portion of the high-octane gasolines being sold. Nearly all alkylation processes employ either concentrated sulfuric acid or hydrofluoric acid as the catalytic agent, but some phosphoric acid is used.

Catalytic Reforming

During World War II, a large demand developed for aromatic hydrocarbons, mainly benzene and toluene, but also cumene (isopropyl benzene), styrene (phenyl ethylene), and other aromatics. Their traditional source was from the coking of coal but this supply was inadequate, and the petroleum industry began to supply an increasing share of the demand. Some aromatics were obtained by the petroleum refiners from various straight-run, cracked, and reformed naphthas, usually by the use of selective solvent and distillation processes.

Catalytic re-forming is a procedure for altering the molecules of straight-run or other naphthas. This method converts some nonaromatic constituents into products containing aromatic compounds. Their amount and nature depend upon the charge stock and conditions selected.

Following World War II, and especially during the Korean war, catalytic re-forming grew in use. Not only was this a means of producing aromatic compounds, but also as a source of high-octane gasoline in greater volume than was possible by methods formerly used. Much of this was due to the development of processes using platinum and other noble metals as well as various nonnoble metals and minerals as catalysts. Re-forming plays an important role in upgrading low-octane stocks to the demand for premium gasolines, and supplying aromatics to the rapidly expanding petrochemical industry. "Cat re-forming" is important for another reason—a large amount of byproduct hydrogen results from the chemical reaction of re-forming. This low-cost hydrogen has aided the rapid development of hydrogenation and processes involving hydrogen treating which are used for upgrading products, such as diesel and other distillate fuel oils and for improving storage stability, through desulfurizing, removing nitrogen, and for improving burning characteristics. Lubricants, various straight-run and cracked light and heavy gas oils, are hydrogenated as a step in preparing feedstocks for further processing. By these methods the refiner is able to produce more and better distillate products from crude petroleum and to reduce the amount of low-value "bottom of the barrel" heavy fuel oil. In the future, hydrogenation alone and in combinations with catalytic reforming, such as hydroforming, are expected to have increased use in upgrading refinery stocks which will accentuate the continued decline of heavy fuel production per barrel of crude.

Chemical Treatment

Low boiling fractions which occur naturally in petroleum and are separated by distillation with little or no decomposition generally are called "straight run" distillates. Included are gasoline, naphthas, kerosine, and gas oils. Fractions prepared in this way are distinguished from cracked products. It also is common to designate straight-run oils as "virgin" stocks.

Straight-run distillates contain mostly nonreactive compounds and usually require little chemical treatment. Cracked distillates require treatment because they have been subjected to severe temperatures and pressures and contain unstable, reactive compounds that form undesirable materials such as gums and color bodies. They also may contain various impurities such as nitrogen and sulfur compounds. These materials are removed or altered to improve the color, odor, stability, burning qualities, response to tetraethyl lead, and other properties of the products. Some lubricating-oil fractions require solvent extraction, dewaxing, acid and alkali treating, clay decolorizing and other processing, including hydrogenation which in some modern petroleum refinery technology is classed as treatment.

In early days of the refining industry, sulfuric acid was the principal chemical reagent used in treating petroleum fractions. Caustic soda solution and sodium plumbite (doctor solution) were next in importance. Sulfuric acid removes gum-forming compounds from light distillates and caustic soda removes hydrogen sulfide. Doctor solution converts odorous mercaptans to insoluble lead sulfide and odorless, oil-soluble disulfides. Many other processes for treating light distillates have been developed involving oxidation, catalysis, hydrogenation, and distillation and solvent extraction methods. Continuous methods generally are employed, but batch treating still is being used in many plants.

Solvent Refining

Solvent refining of lubricating oils has contributed markedly to petroleum utilization. In these processes a petroleum fraction is mixed with another liquid (or a combination of them) that is not completely miscible with oil, but has a preferential solubility for some of its constituents. The mixture upon settling separates into two layers: One is rich in the petroleum fraction which has been freed of undesired constituents (raffinate) but contains a small amount of dissolved solvent; the other layer is a mixture of undesired materials (extract) and is rich in solvent. The solvent is recovered from each of the two mixtures by distillation and is reused in the process. The raffinate oil has improved characteristics, such as low rate of change of viscosity with temperature (high viscosity index), increased stability, better color and appearance (bloom) and a lower carbon residue. Lubricating oils manufactured by solvent treating Mid-continent stocks of "mixed" base have characteristics similar to lubricants made from more paraffinic crudes.

Solvent refining is not new. A liquid sulfur dioxide process was used to extract aromatic constituents from Rumanian kerosine almost 50 years ago, but large-scale use of solvent refining for lubricating oils is relatively recent. A variety of solvents and mixtures of solvents is used for the major application of refining distillate and residual lubricating oils and waxes. The first commercial units for solvent-refining lubricating oils were installed in 1927. Approximately 70 commercial units for lubricants, waxes, and other oils are in operation in the United States.

Some solvent treating also is used to improve the lighter distillates: naphthas, kerosine, diesel fuel, burner oils, and catalytic cracking feed and cycle stocks. Treating solvents that are used singly, and in combination, include liquid sulfur dioxide, liquid propane (both of which require pressure at low temperature), furfural, phenol, and cresols.

In addition to solvent treating, there is a widely used solvent dewaxing process that uses a combination of aromatic solvents and refrigeration both for removing wax from oils (usually lubricants) and to deoil waxes. Waxes that are obtained are a valuable coproduct of lubricating oil manufacture. The solvent dewaxing process uses various mixtures of benzene and toluene with methyl-ethyl-ketone and/or acetone (di-methyl ketone). A common dewaxing solvent mixture is one part each of benzene, toluene, and ketone.

USES OF PETROLEUM, NATURAL GAS, AND PRODUCTS

The principal uses of petroleum are to produce heat and power. There is a diversity of fuels and heating equipment in most American cities. Natural gas and LPG are both burned for all forms of heating and compete with distillate fuels oils for space heating, especially for homes and small buildings. The larger oil-burning heating units in apartments, industrial and commercial plants, and electric utility stations that usually are fired with residual fuels or solid fuels frequently have natural gas as a standby fuel. Petroleum coke is burned in a few large utility furnaces and some is sold as briquets, but it is not a large volume fuel. Two other formerly important heating fuels are gasoline and kerosine, but heating units to burn them now are used only to a very limited extent.

Power for almost every kind of transportation on land, sea, or air is or can be supplied by burning petroleum fuels. Gasoline is available any place in the United States, nearby or within a few miles, as are light and heavy fuel oils. Railroads, buses, and trucks consume large amounts of diesel fuels. The volatile LPG fuels are used chiefly for space heating, but to an increasing extent they also are being burned for many types of transportation, including passenger cas, buses, and trucks. Most ships burn residual or diesel fuels and virtually every piece of machinery is lubricated with petroleum oils and greases.

The petroleum industry is organized for and depends on large-volume operations to be economically successful. Although there are over 5,000 petroleum products, about 90 percent of them are gasolines and fuel oils; the remainder includes such products as lubricants, solvents, wax, asphalt, coke, chemicals, petrochemicals, and a wide variety of specialty products. Substantial portions of the total supply of many important chemicals and commodities are oil based. Noteworthy are benzene and phenol which are two of the most important aromatic chemicals that formerly were obtained from coal tar, but the major supply of which now is petroleum based. Table 1 shows the 1963 refinery production of the major products which amounted to over 3,360 million barrels of products.

Gasoline

The largest use of gasoline is for spark-ignition engines in passenger cars, trucks, and aircraft. A large part of the total gasoline production contains natural gasoline as one of the ingredients blended with other stocks to produce

finished motor fuel. Chief among the components are straight run, thermally cracked, catalytically cracked naphthas, natural gas liquids (NGL), and various products from the more sophisticated catalytic processes such as polymerization, hydrogen treating, re-forming, and isomerization. To the blends also are added other agents such as antiknock compounds, deicers, antifouling additives, and dyes.

TABLE 1.—*Output of petroleum products at refineries in the United States in 1963*

Product:	Production, thousand barrels
Gasoline	1,603,304
Kerosine	164,705
Military-grade jet fuel	98,745
Distillate fuel oil	764,483
Lubricants	63,086
Wax	5,126
Residual fuel	276,766
Asphalt and road oil	118,740
Coke	80,628
Petrochemical feedstock	91,356
Miscellaneous	93,936
Total	3,360,875

Kerosine

In 1963, about 44 percent of the kerosine was consumed as commercial jet aircraft fuel. The remainder was consumed for illumination, heating and cooking, tractor fuel, and other minor uses.

Jet Fuel (Military Grade)

Most of the jet fuel listed in table 1 was used by the military. Military-grade JP–4 jet fuel is a wide-cut gasoline (approximately 65 percent gasoline and 35 percent kerosine materials) and the JP–5 grade is a high flashpoint kerosine. The components of blended jet fuels are low-volatile gasoline, naphthas, kerosine, and a small amount of other distillate fuels.

Distillate Fuel Oil

Refineries in the Texas Gulf Coast and East Coast Districts produced over 43 percent of the total 764.5 million barrels of distillate fuel oil in the United States in 1963. Total U.S. consumption of distillate fuel reached 748 million barrels in 1963 for a 2.6-percent increase over that of 1962. Heating oils, diesel fuel, and railroad fuels (includes diesel fuels) accounted for 70, 14, and 12 percent, respectively, of the distillate fuel oil consumption.

Lubricants and Wax

The 63 million barrels of lubricants produced in 1963 was less than 2 percent of refinery output, but this small proportion of the crude going to lubricants reflects several trends: Improved quality of all types of lubricating oils and greases that enables them to withstand harder and longer use; changes in engine and other equipment design that have reduced consumption; and a decline in exports caused by increased foreign lubricant manufacture. Lubricating oils usually contain different types of additives which are specially prepared to meet service conditions. It is not unusual, for example, for the additives in a lubricant to cost more than the petroleum oil present in it.

The demand for petroleum wax in 1963 was 5,264,000 barrels, a 2.4-percent decline. Domestic demand continued to decline, but exports were slightly higher than they were in 1962.

Residual Fuel Oil

The U.S. refinery output of residual declined 52,000 barrels daily in 1963, and represented 8.6 percent of the crude charge to stills which was a decline from 11.2 percent in 1960. The reduction of domestic residual oils output is indicative of the increased trend by refiners to coke low-value residual oils and to use of various hydrogenation and related processes to upgrade resulting cracked distillates. Thereby a larger proportion of the crude product yield is higher valued distillates. Imports of residual fuel, which are subject to quota regulations of the Oil Import Administration, amounted to an average daily total of 567,000 barrels in 1963.

Coke, Asphalt, and Road Oil

Asphalt and road oil have maintained an almost constant percentage yield position for the past 10 years at about 3.5 percent of crude oil processed. These products are playing an important role as paving and waterproofing materials in the Nation's road building and construction industries. The most important and growing nonfuel uses of petroleum coke are for metallurgical electrodes used in the aluminum industry and for electric motor brushes.

Petrochemicals

Petrochemicals are chemicals derived from petroleum and its products, LPG or natural gas. This definition is broad and there are no clear-cut lines of distinction between petrochemicals and organic chemicals from other sources. For example, synthetic fibers are considered to be petrochemicals in some cases, while in others they are considered to be chemicals.

The discovery by Carlton Ellis, in 1916, of a method to make isopropyl alcohol from propylene derived from petroleum sometimes is

called the beginning of the petrochemical industry. In the early part of the 20th century, coal tar, wood, and certain fermentation processes were the major sources of organic chemicals. Since then, petroleum has become increasingly important as a source of chemicals. The growth of the organic chemical industry can be attributed largely to the development of various treating, cracking, and re-forming processes, more efficient methods of fractional distillation in refining, and chemical synthesis. Most of these have been strongly influenced by the use of catalysts. Byproducts of many refining processes formerly used as refinery fuel or included where possible in marketed products now provide the raw materials used in the synthesis of organic chemicals.

The chemical industry is composed of many small and distinct industries which manufacture more than 10,000 commercial products. These range from simple basic raw materials, such as sulfuric acid, to complex hydrocarbon polymers and plastics that may be further processed to form films and fibers. Production of petrochemicals currently is approximately 30 million tons per year, double the 1955 production.

The oil industry's interest in petrochemicals has provided many new entrants into the chemical manufacturing business. The oil companies in most cases have established separate petrochemical subsidiaries, or separate divisions. A factor influencing this change has been the recent low growth rate of petroleum fuels which has encouraged diversification by oil companies. Petrochemicals offer the quadruple incentive of rapid growth, attractive profit potential, ability to use captive raw materials, and a technology closely related to refining. Petrochemicals are a natural step for large, integrated oil companies that have plentiful raw materials and available process equipment. In practice, petrochemical units frequently are within oil refineries and are almost indistinguishable from the adjacent oil-refining units. Petrochemicals manufacture is largely oriented toward production of raw materials. Plants generally are placed near sources of hydrocarbons from refinery streams, although low-cost transportation by tanker and pipeline has enabled some operations to be established in areas having no local sources of hydrocarbons.

LPG, which is a byproduct of oil refining and natural gas processes, is in plentiful supply and is becoming an increasingly important petrochemical raw material. Chemically LPG, preponderantly, is a mixture of propane, butane, and isobutane, with propane being about half of the total. A mature technology has been developed on production, processing, handling, and storage of LPG and its major derivatives.

A general classification by types of petrochemical product is aliphatics, aromatics, and inorganics.

Aliphatics

The production of aliphatic petrochemicals is largely based on the use of four basic materials: Ethylene, acetylene, propylene, and butylene, all of which may be derived from LPG. The installed ethylene capacity in United States in 1963 was 9 billion pounds per year, about 7 billion pounds was consumed in that year. Growth in demand is expected to continue at about 6 percent through 1970, and the largest outlet is for the manufacture of polyethylene, followed by ethylene oxide, ethyl alcohol, and styrene monomer.

Aromatics

In the aromatics field, about 80 percent of the benzene, toluene, and xylene, which are the major basic aromatic chemical building blocks, are petrochemicals produced by oil companies or their subsidiary firms. Benzene is by far the most important of the petroleum-derived aromatics, and production from petroleum is close to 600 million gallons per year. The principal uses of benzene are for manufacturing styrene monomer, synthetic phenol, and nylon. Toluene and xylenes largely are blended into motor gasoline, but there also is a substantial solvent market, and part of the toluene is converted into benzene and explosives.

Inorganics

Ammonia, carbon black, and sulfur are the major inorganic chemicals derived from petroleum and natural gas. In a typical synthetic ammonia plant, hydrogen is obtained from natural gas by steam re-forming and then combined catalytically with atmospheric nitrogen. Ammonia production reached 6.6 million tons in 1963 and was distributed to the following markets: Fertilizers, 75 percent; industrial uses, 20 percent; and exports, 5 percent. Allied major products are nitric acid, ammonium nitrate, urea, and ammonium phosphates.

Most of the carbon black produced is made in furnace black plants from aromatic oils such as side-cut or cycle stocks from catalytic cracking, although channel blacks (the traditional gas black) and gas furnace blacks also are made in substantial but diminishing amounts. High natural gas prices have resulted in a diminishing number of natural gas channel black plants in recent years. Oil black has proved to have better reinforcing properties for rubber compounding than channel black which, however, is still the preferred material in many applica-

tions. Total carbon-black production in 1963 reached 2,100 million pounds, with over 1,600 million pounds for rubber products.

Natural Gas

In 1963, natural gas consumption was 14,640 billion cubic feet, an increase of 5 percent over that of 1962. The average value at the wellhead was 15.8 cents per Mcf and 51.2 cents per Mcf at the point of consumption. Consumption of natural gas, classified according to major uses, is shown in table 2.

TABLE 2.—*Use of natural gas in the United States, in 1963*

Use:	*Quantity, million cubic feet*
Residential	3,589,021
Commercial	1,267,783
Field (drilling, pumping, etc.)	2,081,339
Carbon-black manufacture	117,378
Other industrial and utilities	7,584,959
Total consumption	14,640,480

BYPRODUCTS AND COPRODUCT RELATIONSHIPS TO OTHER ENERGY SOURCES

Byproducts

The major petroleum products, such as gasoline, kerosine, diesel fuel, and distillate fuel oil, are made to specifications designed to suit performance requirements. Some original constituents of these major products may be removed during processing to meet specifications, and these unwanted materials often have value as byproducts. Also, there often develops a use for a particular hydrocarbon or other component of the fuel so that separation of the constituent results in more advantageous use.

From the early days of the oil industry, efforts were made to separate and recover the liquids contained in the wet gas which usually accompanied crude oil production. The simple processes of compression and cooling normally accompanying the handling and movement of the gas caused some casinghead gasoline to separate. This casinghead gasoline, also called natural gasoline, could be blended into motor gasoline in small amounts but could not be used by itself as motor fuel because its high vapor pressure caused "vapor lock" in automobile engines. After most of the propane and a large part of the butane were removed from the casinghead gasoline, the vapor pressure was reduced to levels acceptable in motor gasoline. Until improved techniques were evolved for recovering these natural gas liquids and for their utilization, they often were wasted. Markets developed gradually for them, largely propane and butane, which now supply large and important domestic, commercial, and industrial fuel; and chemical markets.

Hydrogen sulfide is a common impurity which must be removed from natural gas before it is acceptable as fuel. Processes now are widely employed that not only remove this contaminant to purify the natural gas for marketing but also recover the sulfur as a profitable byproduct in the form of either elemental sulfur or sulfuric acid. Purification of natural gas by sulfur recovery and the companion steps of carbon dioxide and water vapor removal have greatly increased the supply of natural gas of a quality suitable for fuel and petrochemical uses. Capacity for producing sulfur from natural gases in the United States is approximately 1.0 million tons annually, and in 1963, 925,000 long tons of sulfur were produced. In the United States 80 percent of the sulfur consumed is used in making sulfuric acid.

Synthetic rubber is an outstanding example of a product derived from petroleum by the application of science and technology. Prior to World War II, synthetic rubber production in the United States was limited to small quantities of specialty products. Because of the shortage of natural rubber early in World War II, the Government using privately developed technology, which was just then becoming practical, supported an emergency synthetic rubber industry to meet wartime rubber demands. Butyl and butadiene-styrene copolymer rubber feedstocks were produced from fractions derived from natural gas liquids and from petroleum refinery cracking plants.

In 1960, two new synthetic rubber products, polybutadiene and polyisoprene, were developed which are outstanding rubbers, and they are rapidly capturing rubber markets. In 1950 about 41 percent of all new rubber consumed in the United States was synthetic rubber, and by 1963 its consumption had increased to 73 percent.

The helium content of some natural gases is high enough for its extraction for commercial use. This is a substantial operation of the Helium Activity, Bureau of Mines, which operates helium-extraction plants to supply the Government and industry with this unique gas. In addition to the Bureau's plants, several companies in recent years have built helium-extraction plants to remove helium from fuel gas going to market. The crude helium product is sold to the Bureau and stored in its gas reservoirs in the Texas Panhandle for future recovery and use. This is a conservation effort which now is retrieving about 3 billion cubic

feet of helium per year, most of which otherwise would be lost in fuel gas. Detailed helium information is given in the "Helium" chapter in the bulletin.

Examples of product and byproduct development are extensive and the list continues to grow. The trend will continue because of the virtually endless potential of petroleum, the basic fuel and chemical raw material.

Relationships to Other Energy Sources

Petroleum and its products compete with other fuels for some uses and have a virtual monopoly in other fields. Gasoline has no successful competitor as a passenger-car fuel, although other methods of applying motive power, such as steam and electricity, were utilized, but discarded, over a quarter century ago. For some commercial vehicles and trucks there is competition between the three petroleum fuels: gasoline, diesel oil, and LP gases. Diesel locomotives have performed so well for American railroads that the majority of them now have converted to diesels. In aviation, gasoline remains important, but kerosine and jet fuels are gaining as the use of jet engines increases and use of piston engines declines. No fuels other than gasoline, kerosine, and jet fuel are being used in aircraft or are being contemplated as present.

Relationships to Other Fuels

In commercial and industrial heating and in the generation of steam and power, both petroleum and natural gas fuels are on a more equal basis with other fuels. In these applications, price frequently is more decisive than it is in domestic or small commercial uses where convenience and related factors outweigh the price advantages of other fuels. Petroleum and solid fuels are both undergoing experimental trials in gas-turbine-powered railroad locomotives The choice of fuel ultimately will be determined by performance and overall operating costs. Another approach in fuel-energy conversion studies is that of the fuel cell. The energy principal involved in the fuel cell is the conversion of fuel to electricity without such intermediate steps as burning to produce steam, or operating an internal combustion engine to drive an electrical generator.

The oil industry is working currently toward what is termed a total energy concept which is an effort to retain, or even to regain, that part of the market that has been converting from oil to the use of natural gas and electricity for heat. The total energy concept involves on-site generation of electricity in a commercial or industrial facility using a gas turbine or an internal combustion engine, as a prime mover to drive an electric generator. Heat, normally wasted, is recovered from the exhaust of the prime mover, and in the case of engines, from jacket cooling water, and diverted to useful work. The concept is applicable to commercial establishments, office building, schools, hospitals, motels, and apartment complexes. It is particularly attractive to industrial applications in remote areas and in situations requiring large volumes of process heat and steam. In all applications a prime consideration in this concept is the cost of fuel. Fuel selection is decisively governed by the economics of available fuel sources and in some locations economics favors natural gas over oil.

Other fossil fuels are receiving attention in the fuel-energy source picture. Among those receiving attention are oil shale, tar sands, and gilsonite. Gilsonite is used on a small scale and the huge oil shale resources of the West are under study as a source of liquid fuels to supplement petroleum. No active work is underway in the United States on tar sands, but active commercial operations have been undertaken in Canada. Currently, the Bureau of Mines Oil Shale Research Center near Rifle, Colo., has been reactivated by lease to industry. The facility is leased to the Colorado School of Mines Research Foundation which is operating it experimentally for six oil companies to investigate on a pilot-plant scale, economic methods of extracting oil from shale (for additional information, refer to "Oil Shale" chapter).

RESERVES

Attempts to estimate the magnitude of oil and gas reserves in the early years of the petroleum industry appear to have been prompted primarily by scientific curiosity. Most of the early appraisals were made by comparing declining productivity with that of fields which already had neared depletion. Later, reserve estimates were required for business and tax purposes, such as the Revenue Act of 1918 which required oil and gas producers to determine their recoverable reserves for oil and gas on owned or leased acreage. In fact, because of the income tax law, one of the early comprehensive publications on oil reserves was published in 1919 by the U.S. Treasury Department assisted by the Bureau of Mines and Geological Survey. Many of the concepts now in use, especially on decline in natural-gas production, were presented in this report. In 1936, the American Petroleum Institute created a Committee on Petroleum Reserves. Subsequently, each year this committee has computed the reserves of crude oil

in the United States which are recoverable under existing economic and operating conditions. In 1945, and annually thereafter, the Committee on Natural Gas Reserves of the American Gas Association has published its authoritative study of proved natural gas reserves.

Proved reserve figures are no more than a working inventory of oil and gas already discovered and recoverable under existing conditions. This inventory does not represent the total amount of oil or gas in existence at any given time, but merely the amount of oil and gas the industry has already proved by drilling. Under this system of estimating petroleum reserves, large amounts of oil are not reported which undoubtedly will be produced later after improved production techniques are applied. These incremental amounts in most cases are not included in proved reserve statistics until their recovery is virtually a demonstrated certainty. Hence, reserve estimates are subject to future revision, although the established proved reserves estimates are as accurate as possible on their issue date.

The quantity of liquid or gaseous hydrocarbons in a reservoir that can be classed as proved reserve involves knowledge of the physical characteristics of the reservoir rock and the oil or gas contained therein.

Some of the factors required for estimating reserves are: areal extent of the productive reservoir, production history, geologic structural features of the reservoir, and the characteristics of the reservoir rocks and fluids. Included in these characteristics are chemical and physical properties, porosity, permeability, and amount of oil and water in the pore spaces of the rock. Other important determinations are the type of driving mechanism that provides the natural reservoir energy, such as fluid expansion, free (external) gas cap, solution (internal) gas and water or gravity drive.

Many basic data used in preparing reserve estimates are obtained by the industry while carrying our normal exploratory and development programs. To operate and maintain a successful position in this highly competitive business, oil companies assemble data on the availability of their reserves. The aggregate of these individual company estimates obtained from the technical staffs of the companies, and published by trade organizations and technical journals, provides the most comprehensive overall estimates that are now available as published information. Much petroleum research is carried on in the industry and by private industrial laboratories and universities to develop additional information and data.

780-887 O—65——44

World

The international petroleum industry is growing vigorously. At the end of 1963, worldwide crude oil reserves were estimated at 326 billion barrels as shown in figure 1, table 3 (*9*). This is a record volume which has increased 20 percent since 1958. It reflects in part the present strong interest and development of offshore areas which only a few years ago were considered remote possibilities. Worldwide importance of offshore oil is increasing because of the vast reserve potential of good reservoir structures on the continental shelves in comparison with the comparatively fewer favorable prospects on shore. Many petroleum firms are more willing to risk capital in offshore ventures and pay the higher development costs because of better success ratios there, which in some cases are aided by lower sea transportation costs to markets. Recent progress in resolving the legal problems associated with offshore concessions has provided a strong inducement to offshore exploration. This is especially true in offshore areas in the United States and Europe, in the North Sea areas adjacent to Germany, the Netherlands, and the United Kingdom.

TABLE 3.—*Estimated world proved reserves of crude petroleum in 1963*

[Million barrels of 42 U.S. gallons]

Area	Dec. 31, 1958	Dec. 31, 1963	Percent increase	Ratio of reserves to 1963 production
North and Central America	36,736	38,455	4.7	12.3–[1] 11.3
South America and Caribbean	19,643	22,885	16.5	15.8–8.7
Western Europe	1,402	1,686	20.3	14.5
Eastern Europe (including U.S.S.R.)	27,170	33,441	23.1	20.9
Middle East	173,951	204,821	17.7	82.4
Africa	4,119	15,015	264.5	[2] 35.8–[3] 23.4
South Asia, Far East, and Oceania	10,146	10,322	1.7	[4] 24.0–[5] 46.7

Venezuela's recent reserve additions are in offshore areas in Lake Maracaibo. In the Middle East, where five-eighths of the known oil reserve of the world has been found, important proved reserves recently have been added, especially in the Persian Gulf area. The Middle East now has an 82.4 to 1 reserve to production ration. Shown in table 3 are these ratios and proved reserves for other areas of the world.

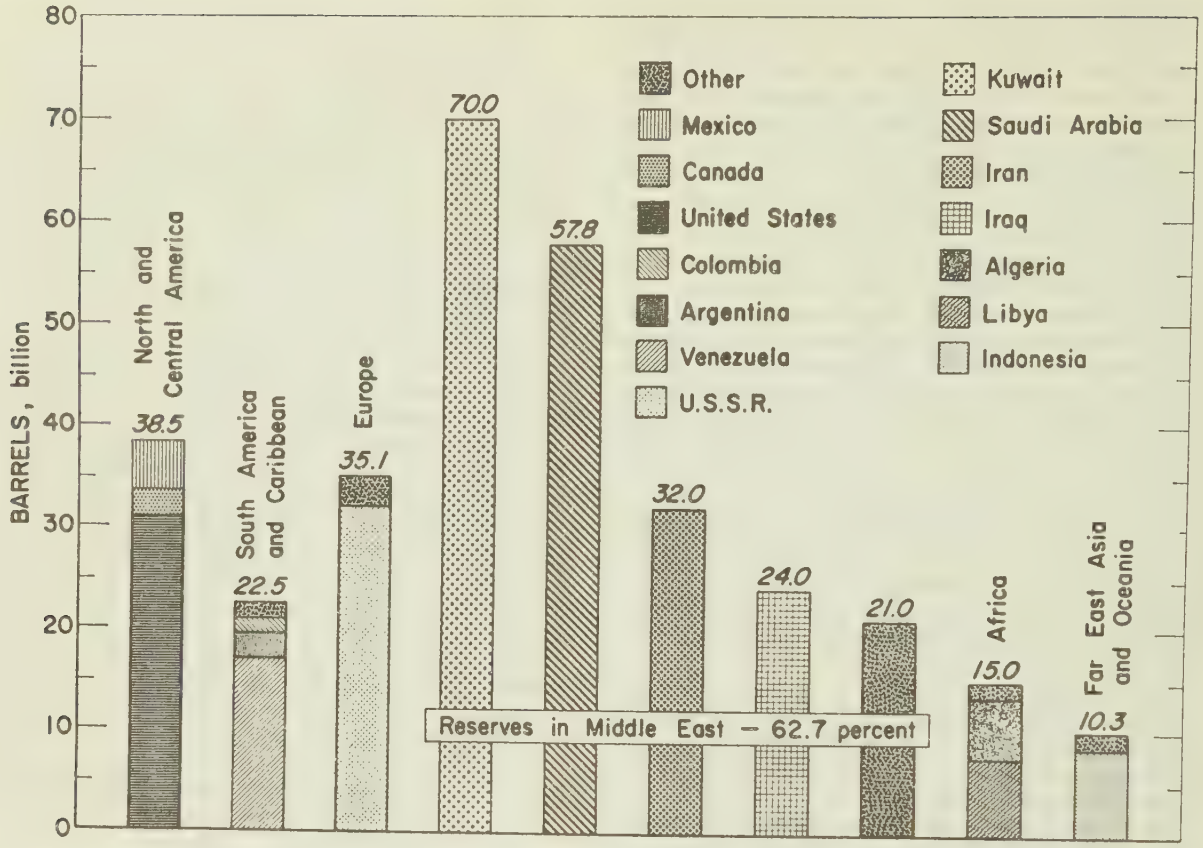

FIGURE 1.—Estimated 1963 Proved Crude Oil Reserves in the World.

United States

Exploration and the consequent discovery of new oil reserves by the industry is interrelated with supply and demand for crude oil and its products at prices that will compensate for the cost of exploration. For example, the flood of oil that became available after the discovery of the East Texas field in 1930 and the decrease in both demand and crude oil prices during the depression years of the early 1930's were reflected by fewer discoveries of new reserves for several years in the early and midthirties. Similarly, the flush production from the large reserves discovered in the Illinois basin in 1937 and in subsequent years affected the annual rate of discovery for several years.

During World War II the shortage of manpower, machinery, and low priorities for exploration resulted in a lower-than-normal amount of reserves discovered during that period. Within the past decade a large excess of petroleum-producing capacity has been built up in the United States, and allowable rates of production per well have been curtailed. Some results of this are a lessened initiative to explore and a decline in both the annual number of exploratory wells drilled and number of discoveries.

The estimated proved reserves of liquid hydrocarbons by States, prepared by American Petroleum Institute and the American Gas Association as of December 31, 1963, are shown in table 4. The total reserve of 38.6 billion barrels consists of 30.9 billion barrels of crude petroleum and 7.7 billion barrels of natural-gas liquids (*2*).

The estimated proved reserves of natural gas in the United States, prepared by the American Gas Association as of December 31, 1963, amount of 276.2 trillion cubic feet; which data are summarized in table 5 (*1*).

CONSERVATION

Petroleum conservation by common usage and statutory definition is prevention of reasonably avoidable waste of oil or gas aboveground and underground in drilling, production, and storage operations. Conservation is brought about by technology in the finding, development, production, and utilization of oil and gas. Such is

the use of sound engineering practice which combines in application both economic and scientific principles.

TABLE 4.—*Estimated proved reserves of liquid hydrocarbons, December 31, 1963*

[Thousand 42-gallon barrels]

State	Crude oil	Natural gas liquids	Liquid hydrocarbons
Alabama	45,069		45,069

The petroleum industry has been the leader in supplying the Nation's expanding economy demands for fuel energy in the past several decades. The rapid industrial and agricultural output of the United States and continued improvement of living standards have been aided to a substantial extent by an abundant supply of low-cost fuels for heat, light, power and transportation.

Oil and gas have been a primary source of such low-cost fuels and presently supply approximately three-fourths of the total U.S. fuel energy requirements. In addition, oil and gas are raw materials for a vast number of essential products that are of common daily use. Continued progress in technology, operating practices, and conservation practices will be imperative if anticipated requirements are to be met.

Conservation implies more than simply saving resources to meet possible future needs or hoarding. All minerals are wasting (in the sense of diminishing) resources and, therefore, are irreplaceable. Oil and natural gas are not known to be replaced by natural geologic processes at a rate sufficient to maintain a commercial supply.

In 1963, U.S. oil production amounted to 2.8 billion barrels. This output was made possible mainly through the continuous, orderly development and expansion of the industry. A major factor in the present output and productive capacity has been the growing use of conservation practices that each year result in the recovery of larger shares of the oil in place than was obtained formerly.

The future supply of petroleum is determined both by past discoveries and current and future discoveries. Reserves at any time fix merely the possible portion withdrawable at that time. Continuity of supply is dependent on exploration and development drilling, both of which are financed by the industry's current profits and venture capital. Therefore, the future petroleum supply is dependent upon the industrial and financial health and vigor of the oil industry.

Many of the problems of oil and gas conservation arise from the nature of petroleum, the conditions under which it exists underground, and the methods by which it is recovered. Proper consideration and understanding of these factors require detailed knowledge of the physical characteristics of the reservoir and the effect on recovery and ownership rights of various development and production methods that may be utilized. Engineering research studies and operating experience have proved that reservoirs may be produced to the point of depletion efficiently with a small number of properly located wells. The size of a plot of land for a drilling unit assigned to a well should be

the maximum area that can be drained efficiently and economically. Inadequate natural energy forces should be supplemented as early as economically justified by injection of fluids to achieve greater ultimate recovery.

Since 1910 the Bureau has pioneered in oil and gas research and studies of the Nation's petroleum resources to provide a sound technologic basis for oil and gas conservation through prevention of waste, greater recovery, and efficient utilization. The Federal Geological Survey has conducted programs relating to reserves, mapping, and geology. Both Federal agencies in cooperation with industry and State regulatory groups have recommended and supported oil and gas conservation.

The laws and regulations of the various States should encourage utilization of improved technology, such as the methods stated to assure maximum economic recovery of oil and gas. Revisions of statutes and regulations are needed as time passes to accompany improvements in technology.

Federal laws authorizing the Interstate Oil Compact Commission and the Connally Hot Oil Act have supplemented State conservation efforts and have aided enforcement of State laws.

SOURCES OF STATISTICAL INFORMATION

The principal source of petroleum and natural gas information presented herein is the Bureau of Mines, Minerals Yearbook, volume II, and Bureau of Mines, Mineral Industry Surveys. Other Government sources are the Federal Power Commission, Bureau of the Census, Maritime Administration, Bureau of Labor Statistics, Bureau of Public Roads, and Business and Defense Services Administration. Oil industry organizations providing statistical data include: American Petroleum Institute, American Gas Association, Independent Petroleum Association of America, American Association of Petroleum Geologists, Interstate Oil Compact Commission, American Association of Oil Well Drilling Contractors, and the National Petroleum Council.

Secondary sources include State agencies, petroleum and natural gas periodicals, technical journals, trade publications, individual companies, as well as numerous publications of foreign governments.

PRODUCTION, CONSUMPTION, AND TRADE

In 1963 world crude-oil production was 9.5 billion barrels, of which the United States produced 29 percent, or 2.8 billion barrels, as shown in table 6.

The demand for natural gas has increased about 6 percent per year for the last decade. Marketed production of natural gas reached 14.7 trillion cubic feet in 1963, as shown in table 7.

World consumption of petroleum continued to increase in 1963. The U.S. increase was about 6 percent and the rest of the free world the increase was about 10 percent.

Average cents per Mcf	12.9	14.0	15.1	15.5	15.8

[1] Comprises gas sold or consumed by producers, including losses in transmission, amounts added to storage, and increases in gas in pipelines.

Imports of all oils in 1963 increased 17.8 million barrels to a total of 777.6 million barrels. Residual fuel oil imports accounted for 56 percent of the increase and military jet fuel, 30 percent. The additional imports of residual fuel oil were needed to meet the demand requirements of east coast consumers, because of the decline in the supply available from domestic sources.

Exceptionally cold weather during the first part of 1963 in Europe which required large shipments of fuel oils to relieve the fuel shortage there was responsible for reversing the downward trend in exports for the past several years. In 1963 exports of petroleum increased from 61.4 million barrels in 1962 to 75.9 million barrels.

Under the Tariff Schedules of the United States, effective August 31, 1963, imports of crude petroleum are dutiable at the rate of 5¼ cents per barrel if under 25° API, or at 10½ cents per barrel if above 25° API. Rates on petroleum products are 1¼ cents per gallon for gasoline and other motor fuel (including diesel oil intended for use in diesel engines), 2 cents per gallon for lubricating oil, ¼ cent per gallon for other liquid derivatives of petroleum (including liquid petroleum asphalt) except medicinal-grade mineral oil, and ½ cent per pound of paraffin wax and other petroleum wax products. These rates apply only to imports from non-Communist countries; rates for Communist countries are somewhat higher.

GOVERNMENT PROGRAMS

Responsibility for petroleum and natural gas conservation rests chiefly with the States through powers derived from the Constitution, although the Federal Government exerts influence, both direct and indirect, on State conservation programs.

Conservation of petroleum (and other resources as well) is practiced by the Federal Government by regulation of those who operate on lands of the public domain and on those submerged lands of the Continental Shelf which are owned by it; the Government serves also as steward of Indian lands. In these capacities the Federal control and sponsorship of conservation is important to a substantial part of the Nation's petroleum reserves.

In both World War II and the Korean war, the Government encouraged and provided financial incentive to industry for enlarging producing and refining capacities in excess of peacetime requirements. Some of this excess remains, and it has sharpened the need to practice conservation. Rigid production control by the States and by the industry has maintained a capacity adequate for peacetime needs and provided sufficient additional capacity to meet emergencies, as was demonstrated during the Suez crisis.

In furtherance of policy set forth by the Congress to meet the "urgent need" for offshore exploration and development, the Government has offered lands for oil and gas leasing whenever the industry has indicated it is ready to bid for leases. This policy has resulted in widely spaced big lease sales rather than uniformly spaced small sales. Caution has been exercised to discourage a disproportionate commitment of industry capital to offshore exploration and development at the expense of onshore areas. Outer Continental Shelf leases have been sold with a minimum bonus requirement of $15 per acre, with rentals or minimum royalty at $3 per acre per year.

The Federal Government has always included conservation requirements in lease terms and conditions and has cooperated with the States in application and enforcement of spacing and production restrictions. Since 1930 the Government has been a foremost proponent of the development of the Nation's oil and gas resources under unit plans of operation.

Petroleum conservation programs of the States are supported indirectly by the Federal Government. These programs are aided by the Bureau of Mines' Monthly Petroleum Forecast and the Forecast of Market Demand for Crude Oil.

The Bureau does not allocate crude production quotas to any State or area. Information derived principally from the industry is analyzed and used to determine the month-to-month need for crude oil and products. This, and similar information from many other sources, is used by the States in their production-proration programs. The Bureau's forecast of demand does not consider price. The consensus is that demand for petroleum and its products is inelastic for short periods so that the effects of monthly price variations on the demand forecasts are negligible.

The Interstate Oil Compact Commission was authorized by law in 1935. It serves as a forum for interstate problems, and indirectly and to a lesser degree for intrastate problems. The activities of the Compact have a direct strong influence on petroleum conservation. Through this Commission's activities, State laws and policies in matters of oil and gas production tend more toward uniformity and are coordinated to the benefit of the entire Nation.

The Federal Government, in recent years, has used its authority under the 1958 extension of the Trade Agreements Act which provides for limiting commodity imports that threaten the economy and national security. Currently, the Department of the Interior establishes oil-import quotas under this act that have an influence on U.S. oil production. Licenses are issued to authorized importers which permit them to import crude oil or petroleum products into specified refinery districts in which the importers qualify. All licensors are required to process the crude oil they import in their own refineries, unless they exchange their foreign oil for domestic oil. In that event, they must process this domestic oil in their plants. Authorized importers are not allowed to sell, transfer, or reassign their allocations or licenses to any other person.

The Federal Power Commission under the authority of the Natural Gas Act of 1938 (and as amended) regulates interstate commerce in natural gas.

The Department of Justice and the Federal judiciary also affect conservation of petroleum and natural gas. In circumstances where operations are practiced to control markets and prices, the Department of Justice takes restrictive legal action. The Justice Department reports annually concerning the Interstate Oil Compact Commission. These reports cover the entire spectrum of the oil industry and are not confined merely to conservation and Compact matters.

Petroleum is unquestionably a necessity to both peacetime and wartime economies. In war, suddenly expanded military requirements are added to necessary civilian requirements that must be satisfied at a level to insure an efficient homefront. In both World War II and the Korean war, it proved practical to have Government petroleum matters centralized as much as possible in one agency. During World War II, this agency was the Petroleum Administration for War (PAW) and during the Korean war, the agency was the Petroleum Administration for Defense (PAD). These agencies were responsible for determining the amount and location of available supplies of petroleum and how they could best be used to meet the needs of the United States and its allies.

Petroleum is found in many countries with which the United States has collective security-treaty relationships. Hence, the national security of the Nation is closely alined with that of its treaty allies. An expanding domestic oil industry, plus a healthy oil industry in friendly countries, constitute important elements in an industrial strength which contributes to strong national defense. In this, both domestic production and imports are essential.

Oil has a vital role in national security and is one of the major essential items in military needs. Petroleum cannot be economically stockpiled; the quantities required are too great. An oil stockpile actually is measured in refining capabilities, pipeline throughput, capacities of storage terminals, and producibility and deliverability of proved reserves of crude oil in the ground.

The continuing mechanization of military equipment and greater mobility of troops portend a steady increase in petroleum requirements. It appears that with few exceptions military equipment will continue to derive energy from liquid petroleum and its products. Some naval ships now have nuclear power, but it is not likely that there will soon be any appreciable decrease in the Navy's petroleum-fuel requirements.

PRICES AND COSTS

The costs of finding and bringing a particular oil or gas field into production have no direct relation to the value that will be received for the output of that field. The costs of finding petroleum (exploratory costs) depend upon the following factors: (1) Area that must be surveyed before a favorable structure is found; (2) complexity of the geologic formations studied in deciding on a favorable location; (3) accessibility of the selected site to men and equipment; and (4) terms agreed upon with the landowner for his mineral rights. Drilling costs will vary with the geographical location of the well, the type of formations penetrated, the depth of the producing formation, and the character of the oil-producing formation. There is no certainty that oil in producible quantities will be found by the first well drilled or by any well drilled—in which case the total expenditure is a loss. And moreover, if oil or gas is found, the financial success of the venture still depends on the extent and quality of the reserves as well as the price obtained for the output.

Data on costs and trends of drilling and completing oil and gas wells are of interest to many in business and industry as well as officials in Government who formulate and administer national energy resource policies (*8*). Cost data is held in confidence by most oil and gas companies. A widely quoted source of such data is the Joint Association Survey. This study is undertaken by the Cost Study Committee of the Independent Petroleum Association of America in cooperation with the American Petroleum Institute, and the Mid-Continent Oil & Gas Association. A survey was published in 1964; previous surveys were conducted and published in 1953, 1955–56, 1959, and 1962. These surveys present statistical information of the cost of drilling and equipping wells and expenditures incurred by oil and gas operators during a year incident to the finding, developing, and producing of oil and gas.

In 1954, the Supreme Court decreed that the Federal Power Commission should regulate the price of gas sold by producers in interstate commerce. As a result of this decision, the FPC obtained and published many records and statistics in its effort to develop a cost-of-service approach to the regulation of gas prices.

A lack of reliable data has made it difficult to appraise the economic factors and costs in the exploration and production of oil. The cost categories most used are as follows: (1) finding or exploration, (2) development, and (3) production or lifting. Finding or exploratory costs include: leasing; geological and geophysical operations; drilling of exploratory wells, which includes completing successful wells; and installing wellhead connections.

Development costs encompass all items necessary to develop an oil pool following discovery. These include outlays to equip the discovery wells beyond the wellhead for production; for drilling additional wells to define pool limits; and later, expenditures for pressure maintenance and secondary recovery.

Production cost is a straightforward accounting of costs for pumping or lifting, field maintenance, other operating expenses, and continuing expenditures on land use operations.

The potential profits of oil producing are indicated by analyses of replacement costs which are the sum of finding, developing, and operating, usually expressed on a per-barrel basis. This apparently simple relationship actually is difficult to compute because finding costs incurred at present must be related to costs and returns obtainable at some future time when oil is produced, and this production may be spaced over many years. Current development costs likewise must be referred to those pertaining to some future quantity of oil that will have been made recoverable, overtime, by the outlays. When a calculation is made of finding costs for a given year in relation to development costs, the reference may not be exact because such costs may or may not have been incurred in the same year or spaced closely enough in time to be economically or technologically comparable.

The general trend in oil prices over the past 5 years is shown in the Independent Petroleum Association of America's price index. The crude-petroleum index is the weighted-average well price for eight principal areas and closely approximates the average price of all crude oil in the United States. The refined-products index also is a weighted-average refinery price of gasoline, kerosine, and light and heavy fuel oils for nine principal areas, calculated from low quotations reported weekly by the National Petroleum News. From 1958 to 1963 the crude-petroleum index ranged from $3.12 to $2.98 per barrel and the refined products index, from $3.89 to $3.79 per barrel. At present the value added by refining is 77 to 81 cents per barrel, or less than 2 cents per gallon. The index shows the narrow margin and the competitive nature of the petroleum industry.

The Joint Association Survey of drilling costs in the United States for 1962 shows that the total petroleum industry expenditures for drilling and equipping wells amounted to $2.6 billion, or an increase of 7.5 percent over 1961 (*5*).

The costs reported in the survey include both tangible and intangible costs for drilling and

completing wells up to and including the "Christmas Tree," but exclude surface equipment such as pumping units, and tanks, as well as exploration, development, and production costs which will be reported in part 2 of the survey at a later date.

In 1962, the average productive well was 4,326 feet deep and cost $63,435 (see fig. 2 and table 8). These represent an increase in depth of 2.6 percent and an increase of 5 percent in costs over that of the preceding year.

The trends of averages in depths and cost per foot of productive wells and dry holes for 1955–62 are shown in table 8 and figure 2. Average depth of productive wells increased 315 feet from 4,011 to 4,326 feet, and the average cost per foot rose by $1.72 per foot from $12.94 to $14.66 from 1955–62.

Since 1955, the average depth of dry holes has risen from 4,051 to 4,533 feet, costs per well have increased from $37,300 to $50,800, and the average cost per foot of dry hole has risen from $9.21 to $11.20.

A comparison of the averages of depth per well and cost per foot of gas and oil wells in 1962 is shown in figure 3, table 9, indicating a higher cost and a greater depth for gas wells. On an average, gas wells are more expensive to drill and complete than oil wells because of greater depth and completion charges. These higher completion charges result because the average gas well has a thicker producing formation and requires more perforations, cementing, fracturing, logging, and related services than the average oil well.

Some 700 wells were drilled offshore in 1963. Approximately 90 to 95 percent of these wells were in Louisiana offshore, and the remainder were drilled offshore from California, Texas, and Florida.

The average offshore gas well completed in 1962 cost 42.5 percent more than an offshore oil well ($495,792 versus $348,011) (*5*). Offshore gas well depth averaged 10,961 feet in 1963, 1,236 feet deeper than in 1962.

Average refining operating costs during 1958–63 have been relatively stabilized and actually slightly reduced from $1.26 per barrel of crude in 1958 to $1.23 per barrel, crude in 1963 (*7*).

Chemicals, catalysts, and gasoline anti-knock-improver costs decreased from $0.21 per barrel of crude in 1958 to $0.19 per barrel of crude in 1963, primarily through more efficient catalyst utilization. These savings were offset to a major extent by increases in costs of purchased fuel and power, insurance, taxes, royalties, and research.

TAXES

The taxes paid by or through the petroleum industry are multiple and varied. In addition to the income and property taxes to which all companies are subject, most oil-producing States impose a tax on each barrel of crude withdrawn from the ground, many States collect inspection fees on petroleum products, and finally, there are Federal, State, and some city taxes on gasoline, on diesel fuel used in highway transportation, and on lubricating oil. It is reported from a Chase Manhattan Bank study of 33 selected oil companies that in 1962 they paid $2.3 billion as indirect taxes to domestic and foreign governments, 9 percent above the amount of 1961. These companies collected $5.5 billion from the public in excise and sales taxes and paid a total to governments of $7.8 billion, which was more than double the companies net earnings that year. During 1959–61 the oil industry paid 4.9 percent of its gross income as direct taxes, com-

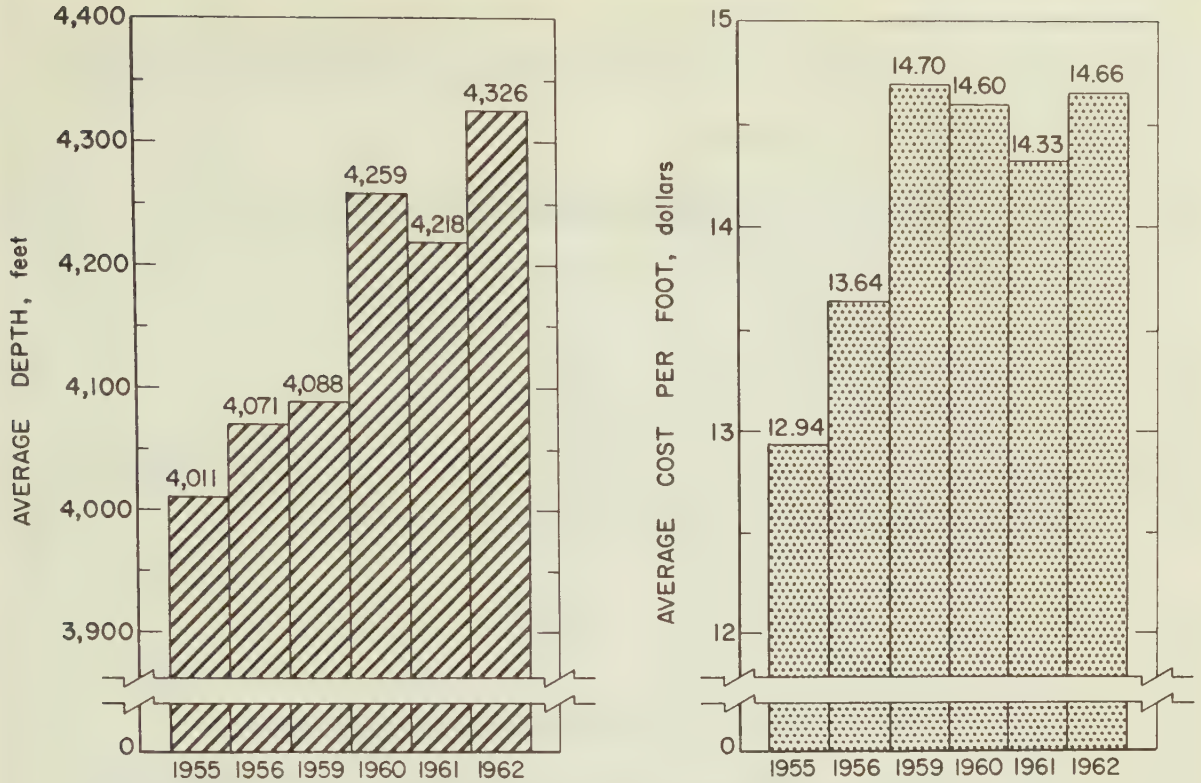

FIGURE 2.—Average Depth per Well and Costs per Foot of Productive (Oil and Gas) Wells in the United States.

pared with 5.1 percent for all manufacturing and mining, and 4.5 percent for all business. The Chase Manhattan study shows that a typical oil well in the United States generates direct tax payments to local State and Federal Governments of about 63 cents per barrel of crude oil. The indirect taxes on the products from a single barrel of crude are about $1.60.

Three tax provisions contained in the Federal income tax law are pecularily relevant to the oil industry. These are the intangible writeoff, depletion allowance, and foreign tax credit. Intangible writeoff provisions permit the option to deduct as expense, intangible drilling and development costs, or to capitalize such costs and recover them through the depreciation deduction. Intangible expenses have not been clearly defined, but they are generally understood within the industry to be expenditures for items not having salvage value. Many expenses are indeterminate within the provision, particularly in offshore operations where many of the expenses incurred are controversial. The intangible writeoff is available for all operations, whether a small independent operator or large integrated oil company. The deduction serves a useful purpose to the oil industry by permitting early recovery of capital to be available for other purposes.

Producers of oil and gas are allowed to deduct an allowance for depletion. The principle of depletion allowance in its present form, as far as the oil industry is concerned, began in 1926. Depletion may be calculated in the oil industry upon one of two bases. One formula provides for cost depletion which assures tax-free return of the original capital investment in property by amortizing part of that cost each year in proportion to the year's production, relative to the estimated total production ultimately recoverable. Producers may take as a deduction for each property the lesser of: (1) 27.5 percent of its gross income; or (2) 50 percent of the net income from the property computed without any allowance for depletion.

Transportation and Storage

Pipelines and tankers provide the primary transportation for petroleum, although tank trucks play an important part in short-haul transportation, and railroad tank cars for transportation of specialty products.

In 1963, pipelines delivered 75 percent of the crude oil to U.S. refineries, tankers and

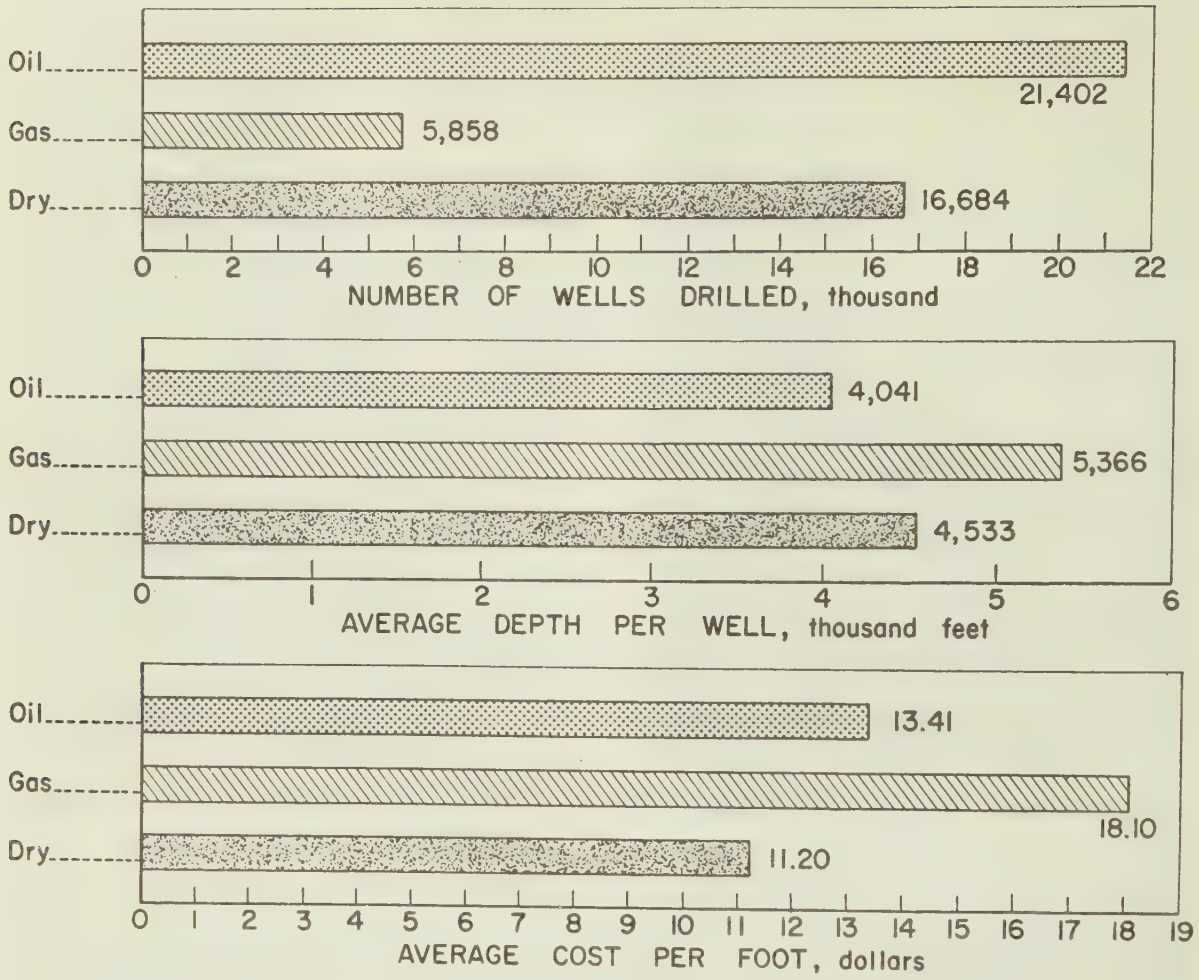

FIGURE 3.—Summary of Drilling in the United States in 1962.

barges 24 percent, and railroads and trucks about 1 percent. Of the crude oil delivered to refineries by tanker, the sources were 58 percent domestic and 42 percent foreign. Pipelines moved 45 percent of the bulk refinery products; tankers 25 percent; and barges, railroads, and tank trucks the remainder. Final delivery of nearly all finished petroleum products was made by truck, but delivery to large users, such as air terminals, is being made increasingly by product pipelines.

A comparison of the range of costs for various types of petroleum transporation based on a long-haul basis is given in table 10. In general, the high prices apply to very small types of equipment or, in the case of trucks, to densely populated areas. Conversely, the lower costs reflect longer hauls and the use of newer, large equipment. In all forms of petroleum transportation, cost reductions have been sought through increase in size, by greater use of automation, and by better design and quality of materials.

TABLE 10—*Representative cost of petroleum transportation*

Type of transportation	*Mills per ton mile*
Tankers	0.5– 2.0
Barges	1.5– 3.0
Pipeline	1.5– 6.0
Tank truck	30 –50
Railroad tank car	30 –70

There were more than 200,000 miles of petroleum pipelines in the United States in 1962. There are 77,000 miles of pipe in crude gathering systems in oilfields. These are generally from 2 to 6 inches in diameter. Another 70,000 miles of pipe are in crude oil trunk pipelines ranging from 6 to 30 inches. There are 53,000 miles of petroleum products pipelines

which extend from refineries to distribution terminals serving most U.S. cities.

The gas utility industry operated over 710,000 miles of pipelines at the end of 1963, which was a gain of approximately 27,000 miles over the pipeline mileage in 1962. Transmission mains totaled over 200,000 miles, distribution mains over 448,000 miles, and field and gathering lines approximately 61,000 miles (*1*).

Prior to the mid–1930's crude pipelines were generally regarded as plant facilities of their refinery owners. Pipelines were of small diameter with a limited capacity. After World War II, the Nation's petroleum demand expanded, and demand continued to increase at an accelerated rate. During this time, pipeline building proceeded rapidly, and improvements in the quality of pipe and in construction methods helped contribute to the development of large-diameter pipeline systems. The capacity of a pipeline increases approximately as the square of the diameter; however, investment and operating costs do not increase nearly so rapidly as the increase in capacity. Large-diameter pipelines were justified by the large volume of crude oil to be moved and by the savings that could be gained. During the past 20 years many of the networks of crude oil lines have been interconnected. The result has been the development of a common carrier pipeline system that allows refiners flexibility in seeking supplies of crude oil from an almost unlimited number of oilfields in many States, and it permits refiners to move products from one area to another.

Water carriers rank second only to pipelines in the volume of petroleum transported. In 1962, the total crude petroleum and products moved in the United States by water carriers was slightly in excess of 2 billion barrels, or 29 percent of the total transported.

In early 1963, the world tankship fleet capacity for oceangoing vessels of 2,000 gross tons and over was 4,543 T–2 equivalent (*4*). The term "T–2" is used as a unit of measure of carrying capacity of tankers and represents a World War II tanker of 16,725 deadweight tons (dwt).

The continued growth in number and size of world tankers in the past decade is related to favorable economic advancements in moving petroleum from the Middle East producing areas to Western Europe and Japan to meet rapid growth in consumption and new energy needs.

The cost of operating a 45,000-dwt tanker is about one third less than that for a T–2 tanker, and the operating cost for an 80,000-ton tanker is about half. Surplus capacity and intense competition have characterized the tanker business. The downward trend in tanker transportation costs is the result of the following: (1) marked decline in tanker construction costs from the high level of the Suez crises; (2) increases in speed which represent time savings of as much as 5 days on some long hauls; (3) substantial improvements in port facilities which reduce time for loading and discharge; (4) reduction in fuel costs (bunker oil prices have declined 20 percent since 1956); and (5) most recently, the application of automatic machinery and centralized control systems by ships under foreign flags.

From World War II to 1956, the United States had the largest tanker fleet in the world. In 1956, the United States had 19 percent of the world total carrying capacity. However, by 1963, the United States ranked fourth (12 percent) because of aggressive and fierce competition from foreign-flag owners. In 1963, Liberia ranked first (17 percent), the United Kingdom second (15 percent), and Norway third (14 percent), respectively.

According to the U.S. Department of Commerce Maritime Administration, effective June 30, 1964, the privately owned fleet of U.S.-flag tankers, and oceangoing steam and motor ships of 1,000 gross tons and over contained 103 tankers. Of these, 87 are medium tankers, 25,000 to 45,000 dwt; 15 are large tankers, 45,000 to 70,000 dwt; and 1 is in the supertanker class, over 100,000 dwt. The largest U.S.-flag tanker is the SS *Manhattan*, a 108,590-dwt tanker with a carrying capacity of about 910,000 barrels of heating oil. This tanker is longer than 3 football fields and as high as a 10-story building.

The most economical forms of bulk petroleum transportation—pipeline and tanker—can obviously be used only where hughe batches of fluids can be placed in storage at destination.

Faster loading facilities and reduction in the evaporation loss during loading have aided tank-truck shipments. The major improvement in tank-car and tank-truck transportation has been that of increase in carrying capacity.

Natural gas is the only fuel transported by pipeline in the gaseous state from source to consumer. Within the past 2 years, experiments in transportation of liquefied methane by refrigerated ships have proved successful, but markets are located that have access to ocean transport. Shipments of liquefied methane are not permitted on inland waterways in the United States for reasons of safety. Liquefied methane carriers are not competitive with pipeline transportation. Hence, seaports on the east coast of this country are served more cheaply by gas pipeline than is possible by seagoing vessels.

Most of the storage of crude oil and petroleum products is in aboveground steel tanks. The principal improvements in oil storage have been

larger size tanks to decrease the cost per unit of volume and increased use and better floating roofs to reduce evaporation losses.

The storage of natural gas at or near major consuming centers to meet peak demands (peak shaving) of short duration has long been practiced by gas utilities. Aboveground low-pressure holders have been in common use by the manufactured-gas industry for many years.

Within the past 20 years underground storage has been developed for LPG. Caverns mined from impervious rock, or washed from salt beds, are used for this purpose and have proved most economical. Natural gas storage near large distribution areas provides a means by which the varying load requirements can be satisfied while providing a more desirable high load factor for pipelines. Reservoirs generally used for natural gas storage are: (1) depleted gas fields; (2) depleted oilfields; and (3) aquifers (porous rock formations similar to oil and gas formations but containing water). Of these, depleted gas and oilfields are the most desirable reservoirs, but they are not available in all areas of the continental United States. Consequently, the search has turned to locating suitable aquifers for prospective storage use, and some of these projects have been used successfully for natural gas storage.

A part of the phenomenal growth of the natural gas industry following World War II has been the great expansion of underground storage of natural gas. The quantity of natural gas in storage reservoirs has more than doubled over the last 9 years, reaching a total of 2,745 billion cubic feet at the end of 1963; an average annual growth of about 9 percent. Most of the natural gas stored in 1963 was in Pennsylvania, Michigan, Ohio, and West Virginia with storage volumes of 491 billion, 471 billion, 376 billion, and 320 billion cubic feet, respectively.

RESEARCH

Industry research covers the entire range of petroleum operations. Efforts are directed to new and improved instruments and techniques for finding new oil-bearing reservoirs and oil deposits, better equipment for drilling wells and better fluids for drilling, better methods for completing wells, and more efficient methods for producing the oil from the oil reservoir. Research is concerned with corrosion problems associated with producing, refining, and storing petroleum and natural gas. Research applied to transportation has achieved significant results, and oil and gas move more economically than almost any other commodity.

The United States now is freed from dependence on imported rubber, and the synthetic rubbers now are far better for major uses than the natural. Military aviation supremacy in World War II was based on the high-octane aviation gasoline developed through research. Research developed processes for increasing the amount of gasoline obtainable from a barrel of crude oil from about 20 percent to over 75 percent, even though gasoline demand does not require over 50 percent. Increased octane number of motor gasoline enables 2 gallons of present fuel to do the work of 3 old lower octane gallons.

High-speed, high-output, internal-combustion engines are the result of research efforts in metals, engine design, and fuels and lubricants. Lubricants have received much attention from petroleum research staffs and have kept pace with engine requirements.

Another outstanding industry development achieved largely from research is the creation and continuing great expansion of the petrochemical industry. Currently, one-half of the total dollar value of organic chemicals produced in the United States is from petrochemicals or derivatives of them.

The cost of petroleum research and development is high. In 1963, the industries and Government in the United States spent $312 million on fundamental research.

During the past 3 years about 20 percent of the petroleum industry's research effort has been devoted to exploration and production, 23 percent on refinery processing methods, 20 percent on petroleum product development, 24 percent on petrochemicals, and 13 percent on other types of research.

The diversity and magnitude of the research effort supported by the petroleum industry is evidenced by the technical manpower employed—about 9,000 professional engineers and scientists, supported by 6,000 technicians, with a total of more than 20,000 persons employed in research and development.

The industry now allocates about 16 percent of its total research expenditures for basic research. The National Science Foundation defines basic research as original investigation for the advancement of scientific knowledge that does not have specific commercial objectives, although it may be in fields of present or potential interest to the suporting company.

The Bureau of Mines has had an active and productive petroleum and natural gas research program for over 50 years. This program has been supported financially in part by State governments, industry and industry associations, and other Federal Government agenices for most of these years. The research of the Bureau and the Department is broad and has a nationwide, and in many ways even a worldwide, view which includes both long- and short-

range activities; its aim is to benefit the Nation by solving petroleum problems relating to its own functions as well as those of other Government agencies and in serving as technical consultant to them on petroleum matters. Many of the problems are such that industry will not or cannot undertake them because of their broad industrywide significance, which would not be attractive to an individual company. Other problems are related to broad technologic areas that are commercially marginal and have only future importance.

The early Bureau of Mines program investigated oil-well cementing, drilling mud, physical properties of hydrocarbons, and detailed petroleum-engineering field studies. Later cooperative research efforts were of great value in understanding and operating oil and gas reservoirs, in high-pressure separation of oil and gas, and in natural-gasoline productions (*3*). Fundamental studies of the properties and composition of oil, gas, and associated fluids and rocks have been a continuing part of the program.

The current research program of the Bureau contains studies involving determination of metallic materials in crude oils to provide efficient processing of crude oil fractions, storage stability of finished products, research on combustion of hydrocarbon fuels in engines and burners, investigations of products of combustion relative to air pollution, studies of new and improved ways to store natural gas, development of computer programs for fluid flow problems in petroleum reservoirs, research on the use of explosives (conventional and nuclear) for stimulating oil and gas production, studies of the use of radioactive tracer application to fluid flow in underground reservoirs, and research on methods to increase ultimate petroleum and natural gas production.

OUTLOOK

Rapid growth in energy demand resulting from an increasing population and expanding economy accompanied by a greater per capita energy consumption indicates that in the next few decades oil and gas will be providing a greater volume as well as a larger share of the world's fuel supply. Free world consumption during this period is forecast to double. In the mid-1960's world consumption of petroleum increased 6 to 7 percent annually, with a 10-percent increase outside the United States and a 3-percent increase in the United States. The present rate of consumption in the United States is 10.5 million barrels per day; within the next two decades consumption is expected to reach 15.6 million barrels per day. The lower rate of growth of oil consumption in the United States is a reflection of a mature economy where the use of oil for fuel is established and widespread. Another major factor for the low growth rate of oil has been a substantial and continuing shift by the consumer from oil fuels to natural gas.

Over five-eighths of the world's proved crude oil reserve is in the Middle East, mainly in the Persian Gulf region. Recent increases in the proved petroleum reserve there have been simultaneous with unusual increases in demand resulting from the expanding economies of many of the previously undeveloped nations. Should present trends in world oil supply continue, petroleum and natural gas will be derived increasingly in the future from offshore oil reservoirs; by liquefaction of natural gas and transporting it as a refrigerated liquid from remote areas to energy markets; and by the production of supplemental fuels obtained from oil shale and bituminous sands when these resources, which are now economically marginal, become more competitive with oil and gas. Exactly what proportions of the oil supply will be produced eventually from these marginal resources, and the timing of such events are at present indeterminate. A substantial part of the technology needed on extraction of oil from oil shale and bituminous sands has been developed, and research and development is still in progress. Success in this work will enable future economic utilization of these vast unused hydrocarbon resources which far exceed known petroleum reserves.

Petrochemical production in the United States will continue to rise and can be expected to be the area of the petroleum industry having the greatest increase in profits. For example, during 1963 the market for polyethylene resins increased 11 percent over the previous year. Approximately 30 million pounds of ethylene-propylene rubber and straight-chain alcohols derived from ethylene were produced in 1963, and a demand growth of about 100 million pounds is forecast within the next 10 to 15 years. By the end of this decade estimates of ethylene-propylene rubber requirements place the increase in ethylene annual demand at 300 million pounds. Although sometimes not considered a petrochemical in the strictest sense, ammonia, one of the fastest growing chemical products, now is predominantly derived from petroleum hydrocarbons.

For the next few decades the petroleum and natural gas industries may expect a continuation of keen competition from other energy sources. Oil, having its inherent advantage in supplying energy for transportation, is almost certain to retain its present superior position. Gas can be expected to win a larger share of the U.S. market in space heating and industrial fuels. The same trends for both oil and gas are expected in Europe, where newly discovered gas supplies are being made available, as both fuels demonstrate their convenience and low cost and establish a record of dependability in price and supply. The short-term outlook for the U.S. oil and gas industries is more favorable than it has been for several years, but the oil industry's present capacity to produce 2.5 million barrels of oil per day in excess of demand will continue to exist for several years.

Natural gas accounts for 98 percent of all gas consumed in the United States and has displaced manufactured gas, which formerly was distributed in most cities. Within the past 20 years, natural gas has exhibited a consistently high growth rate. The average increase has been 5.8 percent per year for the past decade, and future growth to the end of the century is estimated at about 3 to 4 percent per year.

Yearly crude oil demand in 1963 increased 3.3 percent over the demand in 1962. Competition for markets continued to be intense, but the supply of crude oil and products remained at about the consumption level. Crude-oil prices have remained stable in the United States for the last 5 years; this probably will continue because of excess productive capacity. Product prices, especially for gasoline, in general were down to the 1961 level.

Prices of natural gas at the wellhead have increased by about half in the past 7 years, and the average consumer price has increased over 25 percent. Gas prices are expected to remain stabilized because of competition from new energy sources being developed.

Asphalt production and consumption have continued to grow in recent years and are expected to reach recordbreaking marketing years in the immediate future because of the use of asphalt paving in the new Interstate Highway System and the related primary, secondary, and urban highways.

Production of natural-gas liquids (NGL), a coproduct of oil and gas, in recent years has had record gains. Combined with natural gasoline, NGL currently constitute about 10 percent of total new petroleum production. This has resulted from increased oil and natural gas production, especially from deep, high-pressure reservoirs having greater proportions of natural gas and NGL. Both NGL and natural gasoline have been establishing record yearly production totals.

Natural gas has increased its share of the U.S. energy market from 18 percent to about 30 percent in the last 10 to 12 years. In 1963, natural gas provided 42 percent of the industrial fuel consumed. With a sustained exploratory effort the growth in domestic natural-gas production is expected to be adequate to meet anticipated demands in the foreseeable future.

Of prime importance is the development of technology that will enable drilling exploratory wells to greater depths and to produce from them at economic costs; and the solution of problems in offshore operations which will result in extension of these operations farther into the deeper seas on the continental shelves.

PROBLEMS

The U.S. petroluem industry continued its efforts in 1963 to cope with a variety of conditions confronting it in a transition period. Domestic demand for oil, gas, and products has not grown sufficiently to utilize fully the present capacity of producing and refining, both of which are in excess of present market needs. The industry is adjusting its operations to remedy economic ills and achieve a supply-and-demand balance.

The matter of efficiency in operations, although improving constantly, has been achieved only through extensive effort. There has been a large program in all segments of the industry to achieve greater efficiency, and numerous moves to diversify are planned or are underway that involve new industrial, financial, and technological undertakings. New concepts of investment and a vigorous attack on waste are being employed, and more streamlined methods and stringent economies are being exercised.

There are several causes for the current domestic surplus of oil, among which was the decline in the rate of increase in U.S. oil demand following the expanded programs to supply crude petroleum and products for the Korean war effort and the Suez crisis. The rate of increase in demand has declined from 6 percent per year to about 3 percent. Adjustment to this change in trend has been slow because of the necessary leadtime required to change supply program plans that had already been put into operation.

Another important problem facing the industry is financial incentive; that is, the industry's ability to generate capital from oil and gas pro-

duction and then to reinvest it in exploration and development of new reserves. If, for national welfare and security, the 1963 ratio of reserves to annual crude-oil production (11.3:1) is to be maintained, the petroleum industry in the next decade will be faced with the necessity of having to reinvest as much as 65 percent of the capital generated from production on exploration and development. This high level of expenditures exceeds past requirements and is due largely to the continuing increases in the costs of finding and developing new reserves. In view of this, many companies have been diverting capital to operations abroad, where a more favorable economic climate exists for the development-cost to crude-price ratio.

As a consequence, the amount of participation in international petroleum operations by U.S. oil companies has changed substantially during 1955–63. There now are many more American companies in world oil operations than formerly. These companies have been willing to absorb the high initial cost of foreign operations in order to share in the profits of supplying the rapidly growing markets in the free world. These have grown at an annual rate of 6 to 7 percent, as compared with 3 percent for the United States.

There are specific and recognized needs for additional research in practically all segments of the industry.

Basic research should be continued on the origin of oil and its early migration in prehistoric times to provide the information that is needed for the development of new and improved techniques for finding oil and for delineating oilfields after they are discovered. The present cost of exploration activity by the industry clearly is an incentive for research and development. There is a continuing need for more information about the interrelationships of oil, gas, water, and rock in reservoirs. Efforts to improve finding instruments and techniques certainly should be continued. There is a real need for the full assessment of the potentialities of proposed new methods for finding oil and gas without well drilling.

The problem of recovering the maximum amount of oil from a discovered oilfield is as old as the industry itself and has received major attention in the past. The tremendous opportunity in this area demands a continuing and increased effort. Advances are needed to increase production efficiencies in order that the economic time for abandonment of oilfields will be extended and recoveries will be increased.

Some of the largest gains in technology have been in the development of more efficient and economical processing systems and operations. The huge volume of refinery throughputs offer a most attractive target for research and present effort in such activity should continue.

The end result of the total petroleum industry effort is and has been to provide new and better products to the industry's customers, including the development of new products for new customers. The development of aircraft that can fly some two to four times faster than the speed of sound is an example of a need for better and more stable fuels and lubricants that simply were not available in the past. Research that has produced a wide variety of useful petrochemicals has been financially rewarding in the past two decades, and such research in the future will be attractive to researchers and to management. The unique characteristics of hydrocarbon materials offer tremendous possibilities for the development of many more new and better products.

If petroleum and natural gas are to retain their competitive positions in future energy markets, further improvements in geological and geophysical methods will be needed to improve discovery methods. The production segment of the petroleum industry is seeking solutions to its problems through research programs directed toward increased yields from oil and gas reservoirs by the development, improvement, and application of new techniques to drill, complete, and produce oil and gas wells; the perfection of new and improved methods of reservoir stimulation; the application of better techniques for secondary and tertiary recovery; and by making more universal applications of these techniques to producing areas to increase the efficiency of oil recovery. It is necessary that new and more effective low-cost methods be devised to recover the oil that remains in oilfields nearing the economic limit of production by primary means. Petroleum being left underground usually amounts to more than half of the oil originally in the reservoir and sometimes is as high as three-fourths.

Storage of natural gas and natural-gas liquids underground to meet peak demands (peak shaving) has become extensive in the United States, but still is beset by economic and technical problems which restrict its broader use. In gas storage, difficulties exist in selecting underground formations for storage reservoirs which are in suitable geologic strata; are not unduly deep; have favorable permeability, porosity, and other rock properties; and yet lie beneath impermeable strata to prevent leakage. They also should be suitably located with reference to pipelines and markets.

In natural-gas liquefaction there are a number of problems that require solution in both liquefaction-plant practices and liquid-methane carriers. Improvements may be expected to be

forthcoming in the near future from substantial research and development efforts of the industry, here and abroad, and from the experience now being acquired in several actual commercial operations.

Among the most troublesome problems in pipeline transportation are corrosion of steel in pipelines and the high cost of installation, operation, and maintenance. These are continuing problems even though they are being alleviated somewhat in natural-gas distribution by the use of plastic pipe for service to widely scattered customers in small communities. In oil and gas production, plastic pipe and pipe liners are being utilized to an increasing extent for gathering lines, saltwater disposal, and various waterflood applications.

Some cost reductions have been achieved that help, but are only partial solutions of industry problems in oil and gas lines. These include work on the development of improved pipelaying methods, such as better trenching machinery, improved pipe-welding techniques, and the use of high-strength, thin-walled steel pipe and anticorrosion coverings and pipe. Many of the problems remain and much still remains to be done to improve gathering, transmission, and distribution systems through better techniques and materials which will reduce costs.

The drilling segment of the petroleum industry is confronted with problems of portability because of the advancing trend in depth of drilling required, both on land and offshore. To enable these operations to continue at economic levels in this highly competitive business, continued emphasis must be placed on weight reduction and on improved equipment and drilling techniques. Transportation, well-completion costs, and reduced rigging-up time are some problem areas of major concern which offer opportunities for cutting costs.

Refining problems center on cost reduction through improved technology. Basically they involve the need to upgrade raw and intermediate stocks and obtain greater throughput, thereby increasing product quality and yields. The refiner must minimize downtime, off-specification runs, develop new and improved processes, and obtain improved catalysts and rejuvenation methods to achieve more efficient plant and raw-material utilization. In marketing there is a need constantly to develop new products and outlets.

Petroleum hydrocarbons in the last decade have become a widely recognized major source of chemicals, as well as a substantial contributor to the growth of the process industries. However, petrochemicals might be termed "microproducts" in comparison with the usual products from petroleum and natural gas which in this context might be termed macroproducts. The relative output figures are in the ratio of 30 million to 470 million tons per year, respectively. In most instances petrochemicals are coproducts of petroleum refining. They are continuing to attract the interest of oil, gas, and chemical companies, but the petrochemical industry is considered by many to be near the threshold of maturity. This maturity phase is characterized by product-price declines, which have emphasized the need for greater efficiency, better processes, and lower costs. Price declines have focused attention on global economic conditions and markets and the importance of scale of operations on the economics of the industry. The nature of petrochemical production requires a high investment per pound of product, which restricts participants to those having ample financing and marketing outlets.

PHOSPHATE ROCK

By Richard W. Lewis [1]

DEPOSITS of phosphate rock occur in many countries throughout the world, but the largest known occurrences and those now of greatest economic importance are in North America, Europe, and North Africa.

Phosphate rock is mined chiefly by open pit methods, although eventually more underground mining will be required in the Western field. Most of the Florida and Tennessee rock requires beneficiation before it is utilized by industry. Although beneficiation has not been extensively used in the Western area, it is becoming more important and in 1963 two flotation plants and several washing plants were in operation.

Three fundamental methods are in use for decomposing phosphate rock to obtain products suitable for fertilizer and industrial purposes: (1) Acid treatment; (2) thermal reduction; and (3) thermal treatment without reduction.

The United States, with its huge inferred reserve, has more than enough phosphate rock for its needs. Production capacity is more than adequate for domestic requirements and about 20 percent of production is exported.

Phosphate rock is manufactured into many products for agricultural and industrial uses (*27*). The quantity used domestically for agricultural purposes (about 60 percent of total sales in 1963) has always exceeded that used for all other purposes. Thus, the consumption of phosphate rock largely follows that of fertilizers for which demand increases annually. A continuation of this trend is expected. However, production capacity is continually expanding and it is believed that it will meet any expected increased demand, which may reach 10 million long tons, P_2O_5 content, by 1980.

Phosphate rock is not on the Government list of strategic and critical materials, but elemental phosphorus is an important war material, and phosphatic fertilizers are essential to maintain and expand the agricultural output of the Nation.

Nearly 30 percent of the known reserves of phosphate rock in the world are in the United States. This supply is adequate not only for domestic requirements but also for substantial export. The phosphate-rock industry is concerned with problems of effective utilization of this resource.

BACKGROUND

The phosphate-rock industry in the United States began in 1867 in South Carolina with a production of about 2 long tons of P_2O_5 content. Total U.S. output expanded to about 450,000 tons in 1900, and to nearly 5 million tons in 1958. During the past 5 years production has continued to increase and in 1963, P_2O_5 content of marketable rock produced amounted to more than 6 million tons. From 1867 to 1894, South Carolina was the largest phosphate-rock-producing State. Florida began producing in 1888, Tennessee in 1894, and the Western States in 1906. In Kentucky a small mine began producing in 1919 and operated until 1926. A little over 93,000 tons was mined during its 7 years of operation. Phosphate beds in Independence County, Ark., were mined, starting about 1900 and ending in 1912, but total output amounted to less than 33,000 tons. Interest in Arkansas phosphate was renewed in 1963 and production and sales were reported by one company operating in central Arkansas. Exploitation of an apatite deposit in the Piney River area of Virginia was undertaken in 1937. The ore concentrates were processed into phosphoric acid and monocalcium phosphate until 1943. Defluorinated phosphate rock was produced from 1943 to 1948 when both mine and plant were shut down. Crude phosphate rock was first produced

[1] Commodity specialist.

780-887 O—65——45

in the Western States in 1906 from deposits in southeastern Idaho. Limited production from Wyoming and Utah followed in 1907 and from western Montana in 1923. The industry expanded steadily and in 1963 a production of about 3 million long tons was reported. In 1961 several companies began to explore the development possibilities of the large phosphate deposits in Beaufort County, N.C. One firm, Texas Gulf Sulphur Co., completed test mining and construction of a pilot plant in 1963. Development of the deposit continued in 1964 and the company planned production of 3 million tons annually by 1966.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In the United States phosphate-rock deposits have been reported in 23 States. A total of 24 companies and the Tennessee Valley Authority (TVA) were producing phosphate rock in Arkansas, Florida, Tennessee, and the Western States—Idaho, Montana, Utah, and Wyoming in 1963. Deposits in North Carolina are being developed and are expected to gain commercial importance in 1965. In the past, phosphate rock has been produced in commercial quantities also in Alabama, Georgia, Kentucky, New Jersey, New York, North Carolina, Pennsylvania, South Carolina, and Virginia.

Most of the present producers beneficiate the ore to a marketable product in washer plants adjacent to the mines. In addition, many producers operate flotation plants for further recovery and upgrading. A few, however, sell the ore to other producers or processors. Also, some ore is sold for direct application to the soil. Most of the major producers manufacture phosphatic fertilizers or elemental phosphorus, usually in plants near the mining operations.

Elemental phosphorus is produced by 6 companies and TVA in 11 plants in 6 States—Alabama, Florida, Idaho, Montana, Tennessee, and South Carolina. There are about 1,400 fertilizer mixing plants dispersed throughout the United States.

Florida has been the leading producing State for many years and is currently furnishing over 70 percent of domestic production, 98 percent of which comes from the land-pebble field. This percentage is expected to drop during the next 10 years with substantial production beginning in North Carolina and increased production in the Western States. The following producing companies are listed in decreasing order of current output: International Minerals & Chemical Corp. (IMC); the American Agricultural Chemical Co. (AAC); V–C Chemical Co., Division of Socony Mobil Oil Co. (V–C); American Cyanamid Co.; Davidson Chemical Division, W. R. Grace & Co.; Swift & Co.; Armour Agricultural Chemical Co.; Smith-Douglass Co., Inc.; and New Concept Co. All of these firms except New Concept Co. manufacture phosphoric acid and superphosphates in plants, most of which are adjacent to their beneficiation facilities. Elemental phosphorus is produced in Florida by AAC, Victor Chemical Works, and V–C. Florida hard-rock is mined, washed, and dried by Kibler-Camp Phosphate Enterprise. The remainder of Florida's output comes from the soft-rock field, where four companies mine, dry, and sell soft-rock for direct application, fertilizer filler, and stock and poultry feed.

In Tennessee the following companies, which also produce in Florida, mine, beneficiate, and dry phosphate rock, and either manufacture fertilizer locally or ship the rock to their fertilizer plants in other areas: Armour Agricultural Chemical Co., IMC, and V–C. Monsanto Chemical Co., Victor Chemical Works, and Hooker Chemical Corp. produce beneficiated phosphate rock as a raw material for their elemental phosphorus plants in Tennessee. TVA mines phosphate rock in Tennessee for use in its phosphorus furnaces at Wilson Dam, Ala. TVA also purchases land pebble and other phosphate rock at various intervals for its experimental work. In addition, several smaller concerns have mined and sold phosphate rock in Tennessee periodically. M. C. Boyle Phosphate Co. was the only small firm operating in 1963.

In 1963, Central Farmers Fertilizer Co., Monsanto Chemical Co., and J. R. Simplot Co. were producing in Idaho. Montana Phosphate Products Co., George Relyea, and Victor Chemical works were mining in Montana, and San Francisco Chemical Co. mined and beneficiated phosphate rock in Utah and Wyoming. Elemental phosphorus is produced in the Western field by Monsanto Chemical Co. at Soda Springs, Idaho, FMC Corp. at Pocatello, Idaho, and Victor Chemical Works at Silver Bow, Mont. J. R. Simplot Co., a producer of phosphatic fertilizers in Idaho, supplies the phosphate rock to FMC for its furnace operation. Central Farmers Fertilizers Co. produced elemental phosphorus at its Georgetown, Idaho plant for several years but the furnace was shut down in 1963. The entire output of Montana Phosphate Products Co., a subsidiary of Consolidated Mining & Smelting Co., of Canada, Ltd., was exported to Canada where it was processed into fertilizer and the bulk shipped back into the United States for consumption.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

"Phosphate rock" is a commercial term for a rock containing one or more phosphate minerals, usually calcium phosphate, of sufficient grade and suitable composition to permit its use, either directly or after concentration, in manufacturing commercial products. The term "phosphate rock" includes phosphatized limestones, sandstones, shales, and igneous rocks.

Chemical analyses usually are reported as percent P_2O_5 or tricalcium phosphate ($Ca_3(PO_4)_2$) also known as B.P.L. (bone phosphate of lime) (1.0 percent tricalcium phosphate (B.P.L.) = 0.458 percent P_2O_5).

Ordinary superphosphate is the product made by mixing phosphate rock with sulfuric acid. Triple superphosphate, sometimes called treble superphosphate, is the product made by mixing phosphate rock with phosphoric acid.

TECHNOLOGY

Geology and Occurrence of Domestic Deposits

Phosphate rock does not have a definite chemical composition. The major phosphorus minerals of most phosphate rock are in the apatite group and can be represented by the formula $Ca_5(PO_4)_3(F,Cl,OH)$. The PO_4 radical can be partly replaced by small quantities of VO_4, AsO_4, SiO_4, SO_4, and CO_3. The (F, Cl,OH) radical may be all fluorine, chlorine, or hydroxyl ion or any combination thereof. Also, small quantities of calcium may be replaced by many elements, such as magnesium, manganese, strontium, lead, sodium, uranium, cerium, and yttrium. The major impurities include iron as limonite, clay, aluminum phosphates, fluorine, and silica as quartz sand (*17*).[2] Phosphate rock occurs as nodular phosphates, residual weathered phosphatic limestones, vein phosphates, and consolidated and unconsolidated phosphatic sediments.

Florida.—(*2*, *3*, *5*) Hard-rock phosphate occurs in localized deposits from a few inches up to 100 feet thick, overlain by 10 to 50 feet of overburden and irregularly distributed in an ore composed of sand, clay, and soft phosphate. The deposits range from areas of less than 1,000 square feet to several acres; high-grade masses contain less than 1 ton to several tons. In the workable deposits the hard-rock phosphate forms 25 to 30 percent of the material. The hard rock is usually lightcolored and dense and has a phosphate content up to about 38 percent P_2O_5.

The main body of commercial land-pebble phosphate rock occurs as an unconsolidated phosphate-rock ore, and in the operating fields averages 30 feet in thickness, with an overburden 5 to 20 feet thick. The grade of ore is not uniform but averages 15 percent P_2O_5. The phosphate rock recovered ranges from plus 14-mesh pebbles to particles as fine as 200-mesh. Most of the phosphate rock contains 30 to 32 percent P_2O_5 after beneficiation.

In addition, soft phosphate rock, a tan or gray colloidal phosphatic clay containing variable quantities of P_2O_5, commonly is associated with both the land-pebble and hard-rock phosphate deposits.

Tennessee.—Three types of phosphate rock—brown, blue, and white—occur in Tennessee. Almost all the Tennessee production has been brown-rock phosphate.

The brown rock is the product of weathering and leaching of phosphatic limestones and overlies the parent phosphatic limestones. In some places the brown-rock deposits are exposed; elsewhere they are covered by clay and soil, usually less than 20 feet thick. Brown rock occurs as bedded deposits, some of which contain substantial quantities of plate and lump rock, but much of that mined since 1945 has consisted of loose, rounded grains of calcium phosphate intermixed with siliceous material. Although designated as brown rock, the color may range from white to dark brown. The brown-rock beds average 22 percent P_2O_5 and do not exceed 32 percent; workable low-grade material ranges between 16 and 24 percent P_2O_5. Much of the rock is beneficiated by washing and screening, but substantial quantities of run-of-mine material are utilized by blending with higher grades.

The blue rock is an unaltered phosphatic shale or sandstone from a few inches to 4 feet thick and averaging 29 percent P_2O_5. Because of its limited quantity and mode of occurrence blue-rock phosphate does not have commercial importance.

White-rock phosphate is of secondary origin; it results from chemical replacement and occurs in scattered pockets with varying P_2O_5 content.

Western States.—The Western phosphate field includes the deposits in Idaho, Montana, Utah, and Wyoming (*8*, *23*). In this region the phosphate rock lies in beds at two geological horizons, the Permian and the Mississippian. Thus far most of the production has come from the Permian deposits. The region has been intensely folded and faulted and then eroded, exposing the higher grade, phosphate-bearing

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

strata in narrow bands along the flanks of folds or along the borders of the faulted areas. The beds dip from horizontal to vertical (*15, 23*).

The currently economic Permian phosphate-bearing formation is of marine origin. The phosphate beds are contained in the phosphate shale member of the Phosphoria formation, which is 75 to 180 feet thick and consists of yellowish to brown phosphatic shales, brown to black limestone beds, and one to three economically valuable beds of gray, brown, or black oöitic phosphate rock. The fertilizer grade phosphate-rock beds are 3 to more than 7 feet thick, and the P_2O_5 content is 26 to over 36 percent. Furnace-grade rock, 20 to 26 percent P_2O_5, occurs in beds 10 to 50 feet thick.

Mining

Phosphate rock is mined by open pit methods in all three producing fields—Florida, Tennessee, and the Western States. Underground mining is limited to the Western States.

In the Florida land-pebble deposits the overburden is stripped and the ore mined by large, electric, dragline excavators equipped with buckets, ranging in capacity from 8½ to 34 cubic yards. The ore is slurried and pumped to the washing plant, in some instances several miles from the mines. In the other Florida deposits, the Tennessee field, and the open pit mines in the Western field, the ore is mined by smaller dragline excavators or shovels and trucked to the plants.

Top slicing, sublevel stoping, and open stoping methods used in the Western underground mines are designed to recover the high-grade beds containing a minimum of 31 percent P_2O_5. Large tonnages of material, 20 to 31 percent P_2O_5, are not recovered.

Washing and Beneficiation

Nearly all Florida and Tennessee phosphate-rock ore must be treated before utilization. Washing is accomplished by sizing screens, log washers, various types of classifiers, and mills to disintegrate the large clay balls. The fine slime, usually minus 200-mesh, is discarded. In the Florida land-pebble field the plus 14-mesh material is dried and marketed as high-grade rock or blended with the fine granular material (minus 14, plus 200-mesh) that has been treated in flotation cells, spirals, cones, or tables.

Losses in washer and flotation operations range from 40 percent of the P_2O_5 in the Florida land-pebble field to more than 50 percent in some Tennessee areas. The discarded material, usually minus 200-mesh, contains substantial quantities of phosphate minerals and not only entails the loss of a valuable resource but its disposal constitutes an additional expense (*26*). Many hundred acres of land are occupied by old ponds, and additional pond areas are being acquired for current operations at high cost. Washer slime is discharged as a pulp, with only 4 to 6 percent solids. The pulp is discharged to slime ponds, where an initial settling occurs, and a substantial quantity of relatively clear water is returned to the mining and washing operations. Nevertheless, after settling for 2 years slimes contain only about 25 percent solids. The solids contain 15 to 17 percent P_2O_5—nearly the same as in the original ore.

A large part of the Western field phosphate-rock production is of suitable grade as it comes from the mine. Siliceous phosphate-rock ore and mixtures of phosphate rock and clay minerals are amenable to beneficiation, and in 1958 four companies in the Western field were beneficiating or planning to beneficiate part of their production. Two flotation plants and several washing plants were in operation in 1963. No economic processes have been developed to treat ores high in calcite or other carbonates.

Processing (*11, 28, 30*)

Methods.—There are three fundamental methods of decomposing phosphate rock to obtain products suitable for fertilizer and industrial purposes—acid treatment, thermal reduction and thermal treatment without reduction.

1. In the acid treatment phosphate rock is mixed with sulfuric, phosphoric, or nitric acid or a combination of the three.

Decomposing phosphate rock with sulfuric acid produces either ordinary superphosphate or phosphoric acid. When ordinary superphosphate is wanted, enough sulfuric acid is added to high-grade phosphate rock to convert the phosphate into water-soluble or available monocalcium phosphate. Calcium sulfate also is produced but is not separated from the mixture, which seldom contains over 20 percent available P_2O_5. To produce phosphoric acid, additional sulfuric acid is added, and the phosphoric acid is filtered from the insoluble calcium sulfate.

Acidulating phosphate rock with phosphoric acid produces triple superphosphate. Also, phosphoric acid may be combined with potash and/or ammonia to produce highly concentrated fertilizer salts, such as ammonium phosphates and potassium phosphates.

Nitric acid or a combination of nitric and another acid for acidulation of phosphate rock has not been used extensively in the United States. The resulting product, because of the hygroscopic calcium nitrate content, must be treated further, usually by ammoniation, to produce a suitable fertilizer product. Future

use of nitric acid processes will depend on the availability and relative cost of nitric and sulfuric acids.

2. The thermal-reduction method is based upon the smelting of phosphate rock with carbon (coke) and a siliceous flux in electric or blast furnaces. The products are elemental phosphorus, ferrophosphorus, carbon monoxide, and a calcium silicate slag. The phosphorus is volatilized, condensed, and collected under hot water as a liquid. The calcium silicate and ferrophosphorus are periodically tapped from the furnace. Carbon monoxide is utilized as a fuel, usually in preparing the furnace charge.

3. The three variations of thermal treatment without reduction are: (a) Heating phosphate rock with an alkali salt (for example, Na_2CO_3) with or without substantial defluorination; (b) heating phosphate rock with silica or a small quantity of phosphoric acid in the presence of water vapor to defluorinate the rock as completely as possible; and (c) fusion of phosphate rock mixed with magnesium silicate (serpentine or olivine). After grinding, these products do not require further treatment.

Choice of Processing Method.—The use of phosphoric acid derived from elemental phosphorus in the fertilizer industry has been retarded because of its higher cost, compared with the cost of wet-process phosphoric acid. The food, chemical, and drug industries require acid of high purity and utilize most of the electric-furnace product. Limited quantities of this acid, however, are now used in fertilizers, mainly liquid fertilizers.

Ordinary superphosphate is the simplest phosphate product to manufacture and therefore has been the most widely used. It is largely water soluble, and the phosphorus is readily available to crops when applied to acid, alkaline, or neutral soils. Ordinary superphosphate usually is manufactured close to the market and sometimes is hauled directly from factory to farm in bulk to reduce handling costs.

During the past 5 years, emphasis has changed to the use of higher analysis fertilizers and the production and sales of triple superphosphate in 1963 were equal to those of ordinary. Processes for manufacturing triple superphosphate and other derivatives of phosphoric acid, such as ammonium phosphate, are more complex than the ordinary superphosphate process and require a larger investment. The products carry a far greater proportion of plant food, which tends to offset the higher production costs (*11*, *21*).

Elemental phosphorus is more concentrated than any of the phosphorus derivatives, which results in lower freight cost per unit of P_2O_5. The thermal-reduction method requires a larger investment than the acid or wet process but has the advantage of yielding concentrated products of high-purity suitable for use in the food, chemical, and drug industries, as well as the fertilizer industry.

USES

Phosphate rock has diverse agricultural and industrial uses. The quantity used domestically for agricultural purposes (76 percent of the total sold or used, excluding exports in 1963) has always exceeded that used for all other purposes. Although a substantial quantity of finely ground phosphate rock is applied directly to the soil, particularly in Midwestern States, by far the greater part used for agricultural purposes is manufactured into superphosphate and triple superphosphate.

Elemental phosphorus and phosphoric acid are used to make inorganic and organic chemicals, which are employed as leavening agents, water-softeners, cleansing products, soaps, detergents, plasticizers, and insecticides and for many other purposes. Elemental phosphorus is used for military smokescreens and incendiary bombs, pesticides, and phosphorus alloys. Phosphoric acid also is used in producing fertilizers, animal-feed supplement, beverages, ceramics, as a catalyst and oil-refining agent, in photography, and in dental and silicate cements.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Virtually all domestic phosphate rock contains an average of over 3 percent fluorine combined as fluorapatite. An appreciable part of the fluorine is volatilized during processing creating an air pollution problem as well as a waste of a resource. Most of the fluorine is prevented from escaping into the atmosphere but only a limited quantity is currently recovered for marketing, the remainder is neutralized and discharged as waste (*9*). Owing to the very large tonnage of phosphate rock processed annually, the entire domestic market for fluorine compounds could be more than satisfied if all fluorine was recovered and processed into a salable byproduct.

Florida and Western phosphate-rock deposits contain 0.1 to 0.4 pound of uranium per ton. In 1963, nearly 500,000 pounds of uranium could have been recovered as a byproduct. Several pilot plants operating in the 1950's demonstrated that uranium could be recovered (*7*). Three commercial plants operated on a limited basis, making their final shipments in 1958.

The phosphate deposits of the Western States contain 0.07 to 0.4 percent vanadium oxide

(V_2O_3). Technically feasible processes have been developed for recovering vanadium during the manufacture of phosphoric acid by the wet-process. In the electric furnace process for the production of phosphorus, the vanadium as well as other metal impurities concentrates in the ferrophosphorus which is also a byproduct. Methods for extracting vanadium from ferrophosphorus have been developed (*1*). Two plants were operating intermittently in 1963, one at Salt Lake City, Utah, and one at Soda Springs, Idaho.

Other recoverable byproducts from the processing of phosphate rock include: Calcium sulfate from wet-processing and calcium silicate slag, ferrophosphorus, and carbon monoxide from furnace-processing.

Phosphate rock, potash, and nitrogen are considered the basic fertilizer elements. Thus, changes in the general use of fertilizers will reflect in similar changes in the demand for phosphate rock.

ALTERNATE MATERIALS

There is no substitute for phosphorus as a plant-food element. Basic slag, a byproduct of bessemer or basic open hearth steel manufacturing, however, is an important source of agricultural phosphorus in countries that do not have ample deposits of phosphate rock. Guano and bone meal are also used for their phosphorus content.

Phosphorus compounds used in products other than fertilizers, such as foods, synthetic detergents, and fire extinguisher compounds, frequently can be replaced by other materials at a sacrifice of quality or at increased cost. For example: Soda-ash, borax, soaps, and other cleaning compounds can be used in place of phosphate synthetic detergents, the largest single nonfertilizer product. Similarly, alums may be susbstituted for monocalcium phosphate monohydrate as a leavening agent in baking powder.

RESERVES

Domestic and world reserves and resources tables 1 and 2 have been revised in accordance with the most recent available data.

The reserve of 3 billion tons in the Western field has been estimated to contain one-fourth acid-grade rock (greater than 31 percent P_2O_5) and three-fourths furnace-grade rock (24 to 31 percent P_2O_5). Phosphate rock of commercial grade and minable thickness occurring below entry level is included as a potential resource. A large tonnage of lower grade phosphatic material in the Western field is not included in resources. More detail on the Western phosphate industry and resources has been published recently (*23*). The Florida and Tennessee potential resources include the low-grade minable material.

Only the more important foreign reserves and resources are listed in table 2. Many other countries have minor deposits of phosphate rock, some of which are being exploited. Reserve tonnages, however, in most instances have not been published.

TABLE 1.—*Reserves and potential resources of phosphate rock in the United States* (*14*)

[Million long tons]

Source	Total reserves		Potential resources	
	Marketable product	P_2O_5 content	Marketable product	P_2O_5 content
Arkansas			20	5
Florida	2,040	660	23,350	4,932
North Carolina	[1] 2,000	[1] 600	[2]	[2]

Egypt	200
Togo	120
Spanish Sahara	100
Islands of Pacific and Indian Oceans	40
Senegal	40
Other countries	700
Total	48,350

CONSERVATION PRACTICES IN PRODUCTION

In the Western field, when it is necessary to strip low-grade phosphate beds (10 to 18 percent P_2O_5) to recover the underlying phosphate rock, several producers segregate the low-grade material for possible future use.

The phosphatic slimes from the washing plants in the Florida land-pebble and Tennessee brown-rock fields, containing 12 to 15 percent P_2O_5, are discharged into waste ponds. The slimes can be recovered if economic processes are developed to recover the P_2O_5 content or otherwise utilize the slimes.

SOURCES OF STATISTICAL INFORMATION

Statistics for phosphate rock and related industries are collected by the U.S. Department of Agriculture, Bureau of the Census, and Bureau of Mines. Data on crude production, marketable production and value, stocks, shipments by grade, and shipments by uses are collected semiannually by the Bureau of Mines, and 12-month data are published for years ending June 30 and December 31. Data on imports and exports of crude phosphate rock and production of certain phosphate fertilizers and chemicals are collected by the Bureau of the Census. A canvass on the consumption of phosphatic fertilizers, as measured by dealers shipments, is conducted semiannually by the Department of Agriculture and published for years ending June 30.

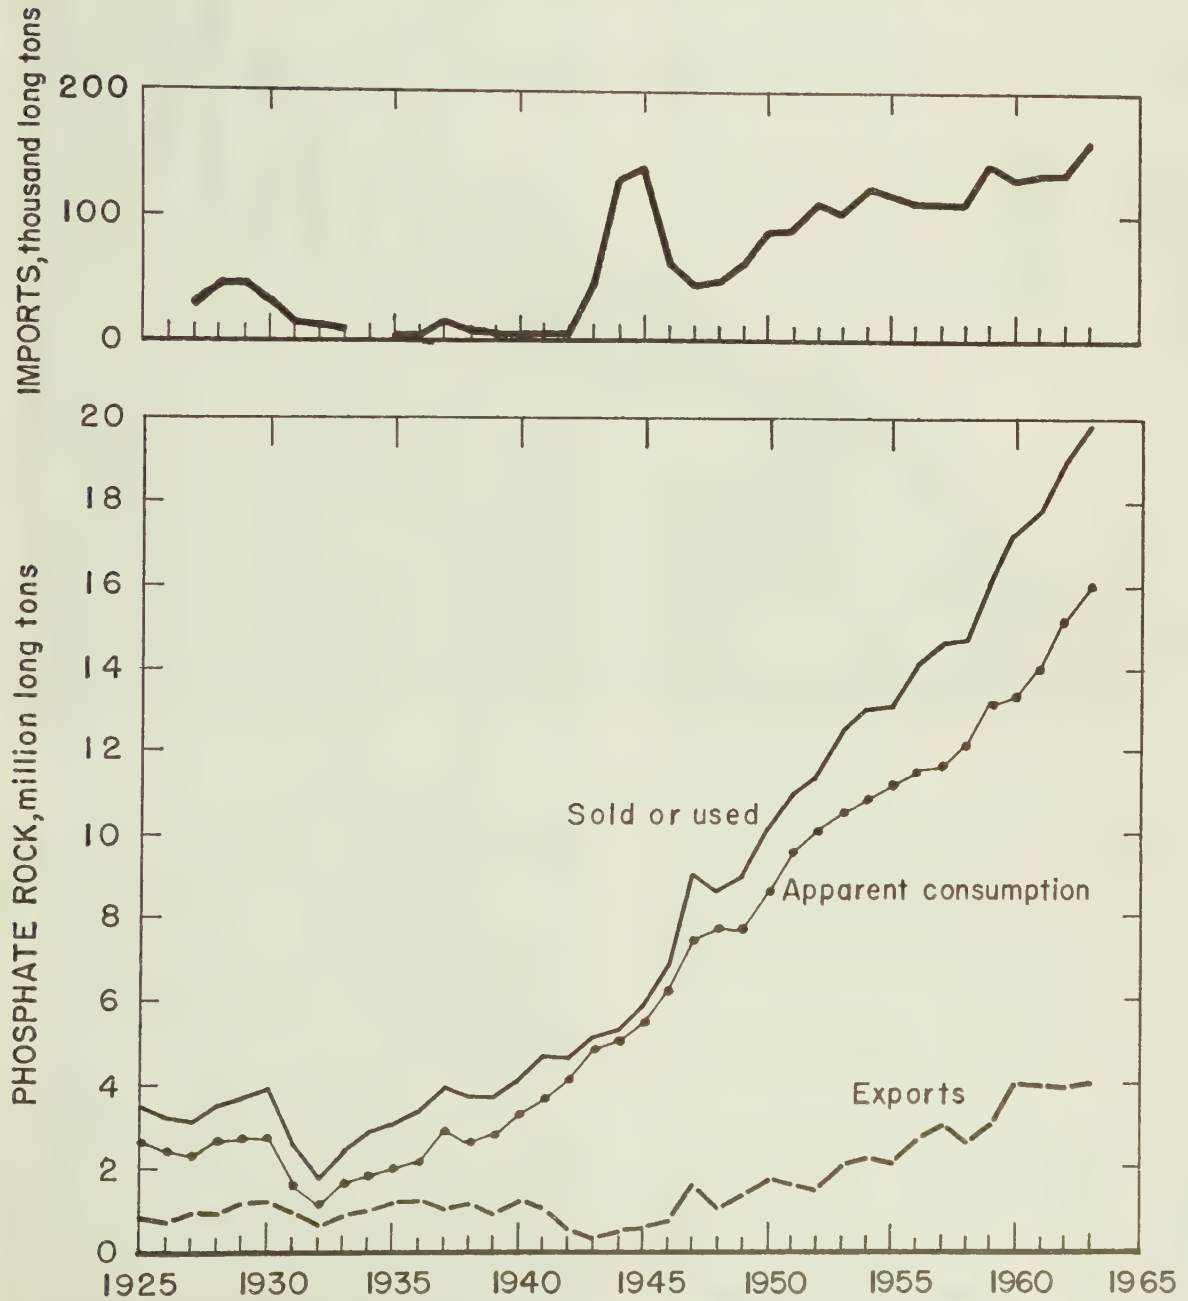

FIGURE 1.—Imports, Sold or Used, Apparent Consumption, and Exports of Phosphate Rock in the United States.

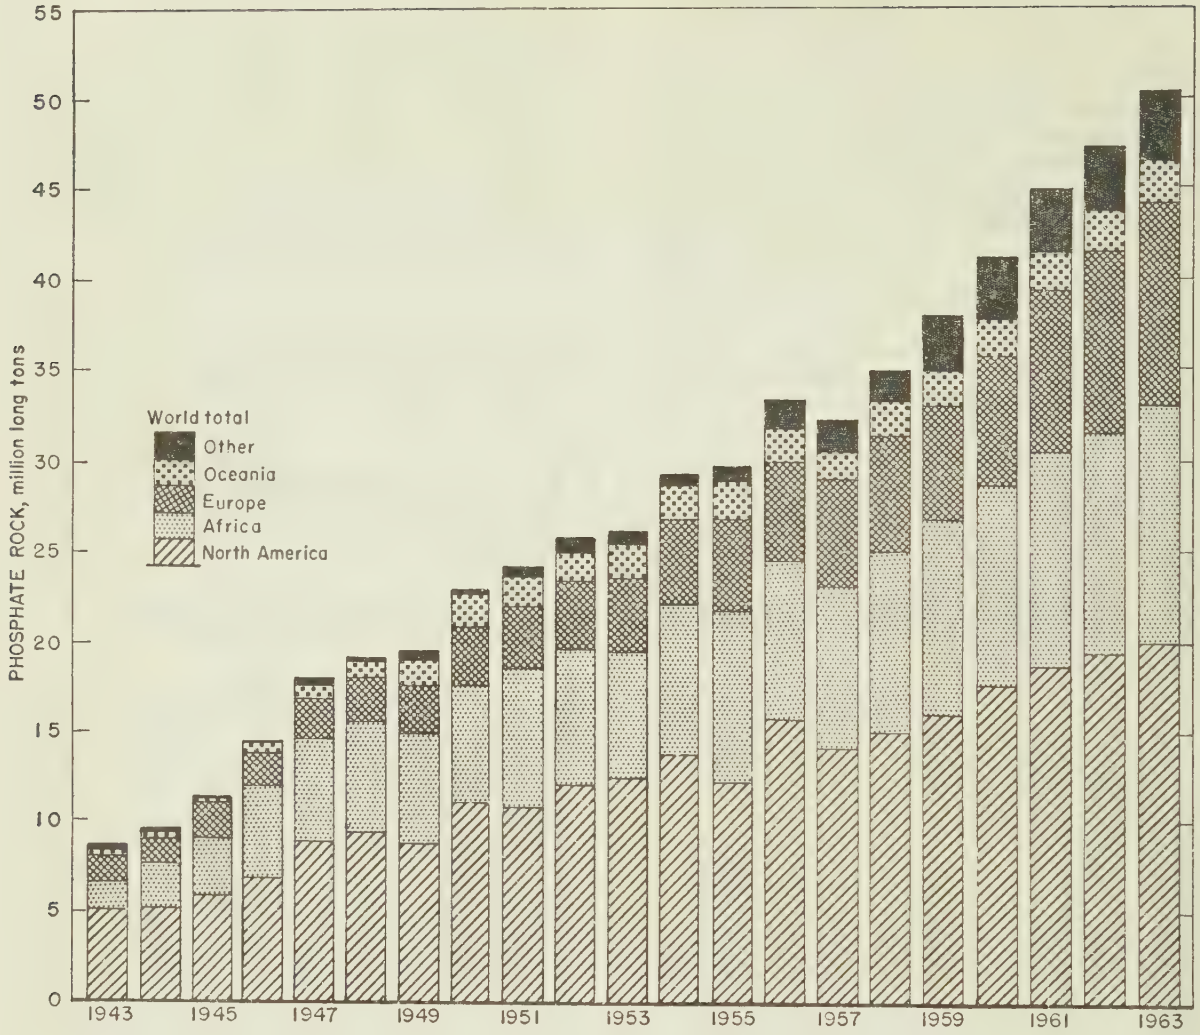

FIGURE 2.—World Production of Phosphate Rock.

PRODUCTION, CONSUMPTION, AND TRADE

U.S. imports, marketed production, apparent consumption, and exports of phosphate rock from 1925 to 1963 are shown in figure 1. World production of phosphate rock from 1943 to 1963 is shown in figure 2.

Of the 19.8 million long tons of phosphate rock produced in the United States in 1963, 74 percent came from Florida, 14 percent from the Western States, and 12 percent from Tennessee. In 1963 no phosphate rock was produced from public domain in Florida. The major part of the 1963 production from the Western States was from public domain and Indian lands.

There is no tariff on crude phosphate rock, apatite, guano, basic slag, or other phosphatic fertilizer and fertilizer materials. Phosphates for animal feed, including ground phosphate rock, have a duty of 10 percent ad valorum. Dicalcium phosphate has an import duty of 9.5 percent ad valorem. All other phosphate chemicals are subject to a tariff with varying amounts of duties.

STRATEGIC CONSIDERATIONS

The United States has ample reserves to supply the domestic requirements at a reasonable projected rate of consumption for several hundred years. The industrial production capacities are expected to keep pace with demand. The needs for low-fluorine phosphate rock, most of which at the present is imported from Curacao, can be met by increasing the plant production facilities for defluorinating domestic rock.

TABLE 3.—*Marketable production of phosphate rock in the United States, by States*

[Thousand long tons]

Year	Florida [1]		Tennessee [2]		Western States [3 4]		Total United States	
	Rock	P_2O_5 content	Rock	P_2O_5 content	Rock	P_2O_5 content	Rock	P_2O_5 content
1954–58 (average)	10,410	3,448	1,700	443	2,028	555	14,138	4,446
1959	11,564	3,794	1,755	458	2,550	687	15,869	4,939

1961	13,789	4,531	2,235	575	2,535	698	18,559	5,804
1962	13,949	4,543	2,418	638	3,015	823	19,382	6,004
1963	14,592	4,818	2,352	612	2,891	785	19,835	6,215

[1] Salable products from washers and concentrators of land pebble and hard rock, and drier production of soft rock (colloidal clay).
[2] Salable products from washers and concentrators of brown rock, brown-rock ore (matrix) used directly, blue rock, and white rock in 1954–58.
[3] Mine production of ore (rock), plus a quantity of washer and drier production.
[4] Includes Arkansas (1963), Idaho, Montana, Utah, and Wyoming.

Phosphate rock itself is not on the Government list of strategic and critical materials, but elemental phosphorus is an important war material; phosphate chemicals are essential to many vital industries; and phosphatic fertilizers are essential to maintain and expand the agricultural output of the United States. Electric furnaces for producing elemental phosphorus in the United States are meeting all demands for elemental phosphorus for military and industrial use.

GOVERNMENT PROGRAMS

In 1908, soon after phosphate-mining operations were begun in the Western States, about 7,000 square miles of phosphate-bearing public lands in that field was withdrawn from entry, pending examination and classification. In 1910 phosphate-bearing lands in Florida first were withdrawn for investigation and classification.

The Bureau of Land Management, U.S. Department of the Interior, administers leasing of phosphate public lands under Public Law 146—Act To Promote the Mining of Coal, Phosphate, Oil Shale, Gas, and Sodium on the Public Domain (Mineral Leasing Act, Feb. 25, 1920, 41 Stat., ch. 85, sec. 9, pp. 440–441).

The Federal Geological Survey is responsible for mapping the phosphate lands, for certifying to the Bureau of Land Management parcels of land known to contain economic phosphate deposits, and for supervising mining practices to prevent waste and to conserve currently uneconomic resources for future recovery.

The Bureau of Land Management, on application from a qualified citizen or corporate group, opens specified parcels of land to competitive bids for leases if the Geological Survey has certified them to be phosphate bearing or may accept a noncompetitive bid for a prospecting lease on parcels on which no phosphate is certified.

There are no standard provisions regarding phosphate leases. Rents, royalties, and minimum-expenditure requirements are suggested by the Geological Survey, but royalties must not be less than 2 percent of the gross value of output of phosphate rock from the mine. The minimum expenditure requirements usually are nominal, to insure good faith of the lessee, before production is begun.

PRICES

Prices for phosphate rock are based upon the tricalcium phosphate, $Ca_3(PO_4)_2$ (B.P.L.) content in percentage. Maximum limits of allowable iron and aluminum oxides are specified. Bonuses are paid and penalties assessed for variations above and below the base grade. Prices now are quoted in dollars per short ton after years of being quoted per long ton. This change took place on December 14, 1959, in the Oil, Paint and Drug Reporter.

Price quotations for Florida land-pebble phosphate rock from the Oil, Paint and Drug Reporter of January 7, 1963, and December 30, 1963, are given in table 4. The trade journals do not publish quotations for Tennessee or Western States phosphate rock. Price changes largely reflect the cost of fuel oil and labor. Much of the phosphate rock is sold on contract with price quotations used only as a guide.

TABLE 4.—*Prices of Florida land pebble, unground, washed, and dried phosphate rock, in bulk, carlots, at mine, in 1963*

[Per short ton]

Grade (percent B.P.L.)[1]	Jan. 7	Dec. 30
66 to 68	$5.385	$5.38
68 to 70	6.245	6.24
70 to 72	6.825	6.82
74 to 75	7.725	7.72
76 to 78 [2]	8.615	8.61

[1] Bone phosphate of lime, $Ca_3(PO_4)_2$.
[2] Percent changed to "76 to 77" July 15, 1963.

The average values at the mines of marketable production in 1963, by States and types of rock, as calculated from reports by the producers to the Federal Bureau of Mines, were as follows:

State and type: Florida:	*Average value per long ton at mines*
Land pebble	$7.01
Soft rock	8.11
Hard rock	9.48
Tennessee	7.64
Idaho	5.76
Other Western States	8.53

The Idaho value is a composite of the value of high-grade rock and electric-furnace-grade phosphatic shale. Other Western States include Montana, Utah, Wyoming, and a small production from Arkansas.

TRANSPORTATION

Much of the Florida phosphate rock used for manufacturing fertilizer is shipped by boat to the east and gulf coast centers. Florida soft rock, other Florida rock for inland manufacturing centers, and Tennessee and western phosphate rock all move by rail. Truck haulage is not used except locally.

The importance of transporting crude phosphate rock from the producing areas to the fertilizer manufacturing centers has decreased during the past several years. The trend is to manufacture high-analysis fertilizers in the phosphate-rock-producing areas and ship directly to the dealers or consumers, making the cost per unit of plant food cheaper to consumers.

RESEARCH

Both industry and the Federal Government are continuously engaged in research which either directly or indirectly is associated with phosphate rock.

Research by industry has been active particularly in the areas of ore beneficiation and manufactured fertilizers. Most of the larger firms maintain research staffs and laboratories.

The Geological Survey studies the geology of various regions in the United States, determines the phosphate-bearing areas on public lands, and evaluates ore deposits to estimate mineral reserves. Several publications related to studies of phosphate rock occurrences are included in the list of references.

The Federal Bureau of Mines is conducting research to develop an economic flotation method for the recovery of acid- or furnace-grade concentrates from marginal ores of the Western field. A report on a petrographic study of these ores as a part of this project has been published (*13*). Continued investigations are underway to find a feasible method for dewatering the Florida and Tennessee phosphate rock waste slimes. The results of some of these studies have been published (*6*, *24*). Mining research is conducted with an objective to develop lower cost mining techniques to enable the economic recovery of phosphatic shales. An experimental phosphate rock planer was developed and the results of testing were encouraging in longwall-mining of underground beds (*10*, *22*). Additional tests with some alterations made on the planer are scheduled.

In addition, the Bureau scientists are working to develop a method for extracting phosphorus as well as vanadium from ferrophosphorus which is a byproduct from the electric furnace production of elemental phosphorus.

In 1933, TVA was established by an act of Congress, and soon undertook a fertilizer program comprising research, development, design, mining, production, and other phases of the fertilizer industry. The primary purpose of the research and development operations at Muscle Shoals is to provide new and improved fertilizers for the use of the Nation's farmers. The various fertilizers produced in the experimental operations are used chiefly in educational programs in cooperation with land-grant colleges, fertilizer manufacturers, and dealers. A large number of royalty-free, nonexclusive licenses have been issued to fertilizer producers to use TVA patented processes and equipment. TVA has been quite active in recent years with technological developments in the production and use of higher analysis plant foods.

The U.S. Department of Agriculture has been conducting fertilizer-technology research for over 45 years. The Soil and Water Conservation Research Division and its predecessor units have been responsible for the department's fertilizer-technology research since 1911, when this work was first placed on a continuing basis in the former Bureau of Soils. The division maintains close contact with Federal, State, and private agencies interested in fertilizer resources, technology, production, and use, as well as with industry associations, companies, and individuals. These contacts include studies and cooperative investigations. Since 1929 the Department of Agriculture has directed its efforts chiefly toward (1) converting ammonia, phosphoric acid, and potash into high-analysis compounds for fertilizers; (2) improving the processing of phosphate and potash raw materials; (3) developing suitable high-analysis mixed fertilizers; (4) evaluating fertilizer materials and mixtures as plant food; and (5) continuing the study of production, consumption of plant food, and trends in fertilizer use (*4*).

OUTLOOK

It is estimated that the demand for phosphate rock in the United States will increase gradually to about 12 million tons (P_2O_5 content) annually by 1980.

The basic factors affecting the increased use of phosphate rock are: Population growth; higher standards of living; increased knowledge of the benefits of high-analysis fertilizers, both at home and abroad; and advancement in technology of the use of phosphorus compounds in the chemical and metallurgical industries. Land is being continually removed from agricultural production which leads to the use of more fertilizer to compensate for this reduced acreage.

Large increases in the consumption of phosphatic fertilizer by the underdeveloped nations are expected. Foreign phosphate production has been increasing and is likely to continue to do so; however, consumption in other countries will probably tend to exceed foreign production in greater proportions than in previous years, due chiefly to greater knowledge of the benefits from the use of fertilizers. Hence, increased exports of phosphates from the United States can be anticipated, provided world competitive and economic conditions remain favorable.

The demand for elemental phosphorus to manufacture chemicals for industrial purposes should become greater as new uses are continually being discovered. Certain metal phosphides and alloys show promise of increasing use in the field of special construction materials.

Domestic reserves are available to supply several times this expected demand and total resources are believed to be adequate for several hundred years. In addition to the ore bodies presently being mined, substantial phosphate rock deposits in the vicinity of central Arkansas and along the Pamlico River in North Carolina are being explored and developed.

Mining and processing capacities will be expanded to meet the anticipated increased demand. Exploration, development, and improvement of beneficiation techniques can be expected to maintain reserves ahead of mining.

The Florida land-pebble field will increase production slowly but steadily with present producers increasing their mining and plant capacities. Improved and new beneficiation methods may lead to the recovery of the phosphate content of the minus 200-mesh material now being discharged as waste in the Florida land-pebble field and in the Tennessee brown-rock area. This could prolong the life of these reserves by about 25 percent.

The production of phosphate products will increase more rapidly in the Western States since they have about 60 percent of the Nation's known phosphate rock reserves and a large potential market. Open pit mining reserves are large but topography, depth of overburden, and dip of the phosphoria deposits dictate that more and more underground mining will become necessary. Improved methods and larger operations, however, may extend the open pit reserves.

PROBLEMS

Much of the Western States' phosphate rock reserve eventually will need to be mined by underground methods. Present technology will permit only the high-grade ore to be extracted profitably by such methods. Improved techniques must be developed to recover the lower grade phosphatic ore and permit better utilization of this large resource (*29*).

Both open pit and underground mining operations would be more efficient if the information on the grade of the ore and of the tonnage available were more precisely known. Numerous sampling problems exist in obtaining accurate determinations of the grade and reserves. These problems need to be solved as an aid to the improvement of mining technology.

One of the biggest operating problems in exploiting the Florida deposits is the disposition of the slimes. About 30 percent of the mined ore matrix is slime material which is removed in the washer plant and discarded into ponds. The slimes occupy approximately 50 percent more volume than the original phosphate matrix mined. Thus, even though a mined-out pit is used for their storage, one-third more volume is required and must be provided for by the construction of expensive earthen dikes or dams. This constitutes a costly and unsightly storage problem. In addition, the recovery of the water from phosphate slimes for reuse presents another problem of great magnitude. It is complicated by the fact that dewatering must be accomplished at a cost of a few cents per ton in order to be economically satisfactory.

Control of fluorine is a serious operating problem. All phosphate rock ores contain fluorine, some as much as 4 percent. In either the wet or the electric-furnace process, about one-half of the fluorine is tied up innocuously in residue or slag and discarded, but the remainder forms hydrofluoric acid or silicon tetrafluoride which are noxious gases. All plants must have

expensive installations to collect these gases, together with other dust and fume. Attempts to recover the fluorine have not been economic as the scrubber sludge is not sufficiently rich in fluorine to compete with commercial fluorspar.

A problem of long standing is to determine what can be done with the iron phosphide obtained in the electric-furnace production of phosphorus. In electric smelting all the iron in the furnace charge is reduced to iron phosphide which is tapped separately from the bottom taphole of the furnace. A small amount of iron phosphide is sold as an alloying agent, but most of its serves only to create a warehousing problem and lower the overall phosphorus recovery.

PLATINUM-GROUP METALS

By Glen C. Ware [1]

THE METALS of the platinum group include platinum, palladium, iridium, osmium, rhodium, and ruthenium. Platinum is the most abundant and most important member of the group, but each has important industrial uses. All the platinum-group metals except palladium command prices much higher than that of gold.

Platinum-group metals are recovered principally as the chief product of some placers, as a byproduct of nickel-copper ores, and as the main product of platinum ores.

From the early 19th century until 1934 placers in the Ural Mountains in the U.S.S.R. produced most of the world supply of platinum-group metals. The Republic of South Africa and Canada led in production from 1934 until after World War II, when metal from Siberia allowed the U.S.S.R. to increase its estimated output to more than half that of the world.

World ore reserves will support consumption at the present rate for the foreseeable future. However, potential uses loom, which cannot be supplied under present conditions, and alternate materials must be found. Catalysts for fuel cells, for example, reasonably could demand many times the present output of platinum. Platinum-group metals are an essential part of our highly sophisticated industrial complex upon which our national security depends, quite apart from their specific military uses. They are among strategic and critical metals held in our stockpiles. United States production is insignificant; domestic consumption exceeds free world production and is likely to continue to do so in spite of expanding production in the Republic of South Africa. In the foreseeable future more than half of U.S. imports must be from the U.S.S.R.

BACKGROUND

In the 7th century B.C. an Egyptian artisan forged a single grain of platinum into a hieroglyphic character which he included with the silver characters used to decorate an etui, probably not distinguishing platinum from silver. Twenty-five centuries elapsed before the science of chemistry solved the riddle of the natural alloys of platinum and found ways to produce malleable metal suitable for the jeweler's art. Platinum found in placer sands along with gold was unavoidably recovered with the gold, and the artisan was obliged to separate the two metals because they fused readily to form hard alloys which he could not fashion into objects of art. Throughout the centuries, platinum grains were plucked one by one from the miner's pan, even into modern times. Indeed, gold placers have been abandoned because the work of separating the platinum was too costly.

The Spanish explorers in South America found platinum objects fashioned by Indian metal smiths who had developed techniques of soldering and alloying the refractory metal and of making from it articles of jewelry and objects of art. However, platinum had no value for the Spaniards because European artisans could not work it.

A firm basis for the chemistry of platinum was laid by an English doctor, William Lewis, who published in 1763 the first authoritative description of the metal and some of its alloys. He recognized the heterogeneous character of the crude platinum, but his most useful discovery was the use of ammonia to precipitate platinum from the solution obtained by treating crude platiniferous material with aqua regia. This practice remains in common use today. Meanwhile, Marggraf in Germany in 1757 had demonstrated the presence of iron in native platinum and had removed it, effecting the first recorded separation of the platinum-group metals from the crude mineral.

[1] Commodity specialist.

French workers, notably Macquer and Baumé unwittingly prepared platinum pure enough that it could be welded, forged, and rolled. Baumé noted that these properties and its noble character made it a desirable metal of commerce. Von Sickingen in Germany was able to draw wire 0.0113 of an inch in diameter, but he too did not realize that the secret of his success was iridium-free metal. Lavoisier in France contributed the oxyhydrogen flame which was hot enough to fuse the ammonia precipitates into massive metal.

In 1784, in Germany Achard fused platinum with arsenic and ground the brittle residue to a powder which he enclosed in a clay mold. The assembly was heated to drive off the arsenic, leaving a sintered shape of platinum. When this piece was forged cold on a mandrel, it became the first platinum cruicible. Daumy in France noted that fusion with arsenic refined the metal. Janety, in Paris, by 1787 had improved the process and expanded the scale to the point that massive metal was available for the arts and sciences.

Credit belongs to the English for the isolation of the separate platinum-group metals. Wollaston announced the discovery of palladium in 1803 and rhodium in 1804. Tennant isolated and named osmium and iridium in 1804. Claus, working at the University of Kazan, discovered ruthenium in 1844 and named the metal after his adopted country, Russia, but used the latinized name Ruthenia. During the 19th century, the last of the basic techniques for working platinum was developed when Hare, in 1801, melted platinum with a blowpipe and noted the refining effect of an oxidizing atmosphere upon the molten metal. Deville reduced melting to practice.

By the close of the 19th century platinum ware was in common use in laboratories. It had reached the scale of boilers to concentrate acids in commercial plants. An ingot weighing 100 kilograms had been cast. The catalytic properties of the metal had been applied to the oxidation of several elements and compounds, including the preparation of the anhydrides of sulfuric and nitric acids, the flameless oxidation of inflammable vapors, and the ignition of hydrogen in air. All of these and the catalytic application in oil refining were destined to replace the arts as the greatest users of platinum. Meanwhile changes were taking place in supply and marketing.

Russian metal had displaced that from Colombia, and Russia remained virtually the only source of platinum metals for nearly a century. A world trade had been established, centered in Paris, and the firms which now control the industry were beginning to emerge from the competing refineries in Europe.

Sales of platinum-group metals from Canadian nickel ore began about 1909, and in the early 1930's Canada became the world's chief source of these metals. The first metal from South Africa was marketed in 1925 and exports reached 60,000 ounces per year by 1941. It continued at this rate until 1950, when it began a sustained rise which is still in progress and is projected through 1965. South African production surpassed that of Canada from 1951 to 1957.

The U.S.S.R. does not report production or exports, but, based upon the amount of metal reaching world markets and the free world production, it is estimated that more than one-half of the world's platinum-group metals is produced in the Soviet Union.

All categories of use have increased, but unevenly. The application of platinum catalysts to petroleum refining brought a surge in the demand for platinum through the mid-1950's, and the application of palladium to electrical contacts in communication switch gear made a heavy demand on palladium throughout 1960–65. Presently, the need for refractory ware in which to melt laser compositions has increased the demand for iridium. These surges in demand are superposed upon the steadily increasing need to supply an economy which is growing in size and complexity.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

World output of platinum-group metals in 1963 was estimated at 2 million ounces, 66 percent of it produced by the U.S.S.R. Canada produced 16 percent, the Republic of South Africa 14 percent, and the rest of the world 4 percent.

U.S.S.R. production is believed to come chiefly from the Norilsk region of Siberia where the platinum minerals occur in basic and ultrabasic rock formations similar to the deposits of South Africa. The production from placer deposits in the Ural Mountains is of secondary importance, although platinum placers and platinum-bearing gold placers are found from the Urals to the Pacific (*4*).[2]

The Bushveld complex, a geological feature in the Republic of South Africa, is the source of nearly all of that nation's platinum-group metal output. The Rustenburg Platinum Mines,

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Ltd., operates the mines and recovers a crude metal which averages about 70 percent platinum, 25 percent palladium, and 5 percent of combined iridium, osmium, rhodium, and ruthenium. The crude metal is refined by Johnson, Matthey & Co., Ltd., in England, which serves as importer, refiner and exporter. Through its affiliate, J. Bishop & Co. Platinum Works, Malvern, Pa., it fabricates and distributes the finished products. In 1964 a consortium of three mining companies led by Rand Mines contracted with the Rustenburg Platinum Mines, Ltd., to exploit the Brakspruit Mine, which adjoins the Rustenburg Mine at Rustenburg, and produce a crude concentrate. Engelhard Industries of Newark, N.J., will refine the crude and market refined metal and metal products. In the past Englehard has obtained all of its platinum-group metals from Canada. A small amount of osmiridium from gold ore reaches refiners outside England, including refiners in the United States.

The current expansion of production to full mill capacity, 675,000 ounces, is expected to be completed in late 1965, putting the Republic of South Africa in second rank. The amount and the grade of their reserve will permit further expansion if market conditions justify it.

Canadian production of platinum-group metals arises as a byproduct of the smelting of copper-nickel ores of the Sudbury district. When these ores are smelted the precious metals appear in the bessemer matte, and a crude precious-metal concentrate. They are recovered from the matte by chemical methods. The International Nickel Co. of Canada, Ltd., the chief producer, has a refinery in Acton, England, where the concentrate is refined and the metals are returned to Canada. Some are fabricated and some are exported to the United States. Englehard Industries, Inc., handles the refining and distributing of the metals in plants in Newark, N.J., and Toronto, Canada. Falconbridge Mines, Ltd., produces matte from Sudbury ore but ships it to Kristiansand, Norway, where platinum and palladium are recovered, and the remaining precious metal concentrate is returned.

The United States produced 50,000 ounces of platinum-group metals in 1963, 3 percent of the estimated world production. Output from Goodnews Bay, Alaska, is purchased by Johnson, Matthey & Co. and refined for them by its affiliated J. Bishop & Co. Platinum Works. Additional output comes from gold placers and from the refining of copper. Output from the latter source may increase with demand for copper, but output from placers is likely to remain static.

In addition to new supply of platinum-group metals, refiners reprocess scrap, worn equipment, spent catalysts, and other secondary material, returning to use an amount of metal virtually equal to the new supply.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

In world markets, platinum-group metals are measured in kilograms, but, where the English system of weights prevails, the troy ounce is used. A kilogram equals 32.15 troy ounces, and for comparison, equals 35.27 avoirdupois ounces. In the United States the troy ounce is used exclusively. The term fine ounce, referring to a troy ounce of contained metal, is seldom encountered.

Sponge is a term applied to an imperfectly consolidated chemical precipitate, the end product of chemical refining. Subsequent forging or melting is required to produce massive metal.

Rolled metal refers to metal such as silver or stainless steel which has been clad with a precious metal and rolled to reduce the thickness of the coat.

Normally the metals of the platinum-group are produced at a purity of more than 99.9 percent. However, platinum 99.999 percent pure is required for thermocouples and resistance thermometers. Chemically pure platinum contains less than 0.001 percent of impurities. Platinum 99.9+ percent pure is suitable for platinum utensils and electrical contacts, and, above 99.7 percent pure, it is graded commercial. A purity of better than 99.9 percent is required for the minor metals to be used as alloy constitutents.

According to Federal regulations an article of trade may be marked platinum if it contains 98.5 percent platinum-group metals with a minimum of 93.5 percent platinum. Special stamping provisions cover some of the alloys developed for the jewelry trade. Some States have stamping regulations in addition to Federal requirements.

TECHNOLOGY

Platinum-group metals occur in basic or ultrabasic eruptive rock. In basic rock they are usually too widely disseminated to be recovered profitably except as a byproduct of nickel and copper smelting. In ultrabasic rock, dunite for example, the crude alloys of platinum-group metals, often containing iron, are found as crystals or irregularly shaped solids where they are separated from the magma as the molten intrusion cools. Deposits of them are found in pipes, pockets, and lenses.

When weathering liberates the crude platinum, placer deposits are formed from which the heavier metal can be separated from the lighter rock by gravity. When the deposits are mined, these natural alloys are liberated by crushing and are separated by a suitable means such as with zinc amalgam, by flotation, or by tabling. When they occur in sulfide deposits they are smelted and appear in the matte of the other metals in the ore. In any case, the crude concentrate is refined chemically.

Platinum-group metals are not amenable to fire refining because of their high melting point and the lack of a parting method to separate the individual metals. Consequently, chemical methods are used to separate and refine them. But they are also resistant to chemical action, and aqua regia is needed for the initial attack. Methods vary, but in general they involve dissolving away the platinum, palladium, and gold with aqua regia, leaving a residue containing iridium, osmium, rhodium, and ruthenium. After the gold has been removed from the solution with ferrous sulfate, platinum chloride is precipitated with ammonium chloride. Palladium may be precipitated as a chloride by excess ammonia and hydrogen chloride. The chlorides of platinum and palladium separately are reduced to sponge metal which can be compacted and melted to massive metal. In analogous ways the undissolved residue from the aqua regia treatment can be put into solution; the metals iridium, osmium, rhodium, and ruthenium can be separated, reduced to metal, and fused to massive condition. Refining steps are needed for each metal before it is pure enough to use, generally more than 99.9 percent pure. Adaptations of these procedures are used; other methods may be employed, but those given here are typical.

Byproduct platinum-group metals from gold or copper ores are sometimes refined by electrolysis as well as by chemical means.

USES

Platinum finds its greatest use in the chemical industry where most of its special properties are exploited. In chemical ware it resists attack, in thermocouples it resists heat and oxidation, and in making nitric acid it is a catalyst which resists attack by the corrosive product. In spinnerets for spinning synthetic fibers it withstands both corrosion and erosion. Platinum's resistance to atmospheric corrosion is used in electrical heating elements and in pressure-rupture disks which would not respond reliably if atmospheric corrosion occurred. Delicate sensing instruments such as platinum resistance thermometers depend upon this same property for reliable performance.

Electrical uses make the second heaviest demand for platinum. It is wound into heating elements for furnaces and into resistance coils for precision instruments such as potentiometers. Where heat or mechanical conditions are more severe, iridium or ruthenium is alloyed with platinum to impart resistance to wear. Platinum is used as an inert anode material in electrodeposition and in cathodic protection of ships' hulls and other base metal fabrications. It is used for grids in high-power amplifier tubes, in reigniters for jet engines, and in platinum-mercury contacts in relays. A platinum-cobalt alloy containing 23.3 percent cobalt by weight is the most powerful magnet material known.

Pots for melting glass are made of platinum and its alloys, 10-percent rhodium being a common admixture for glass fiber manufacture. Platinum-rhodium alloy is used in pots to melt laser materials. Platinum cladding is satisfactory under less severe conditions.

Platinum and palladium are both used in the petroleum industry to catalyze the reforming of cracked petroleum fractions into high-octane gasoline. Both are used in jewelry to impart a brilliant luster. Palladium even exceeds platinum in amount used in dentistry and medicine.

The chief use of palladium, however, is in the field of communication where it is used largely to face electrical contacts in automatic switch gear, accounting for about 60 percent of its total use. Chemical use is second at 28 percent.

The minor metals, iridium, osmium, rhodium and ruthenium are used chiefly to harden platinum and palladium but electroplated rhodium is used in reflectors, electronic components, and in jewelry. Osmium and iridium are used to harden pen points and record-player needles. Radioactive iridium-192 is used in radiography.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Virtually all of the output of platinum-group metals produced is coproduct or byproduct in origin. Gold is always recovered with platinum-group metals from placers. Platinum-group minerals generally occur in ultrabasic or basic host rocks such as dunite and norite and are associated with other metal minerals, generally copper, nickel, or chromium. In Canada, copper and nickel are the main products, and presumably this is true in the U.S.S.R. In the Republic of South Africa, platinum-group minerals are the main product but are

associated more often with chromium than with nickel.

ALTERNATE MATERIALS

The high price of the platinum-group metals exposes their field of use to inroads by substitutes, and it restricts the expansion of their use. For example, in the field of catalysis, nickel boride and the oxides of nickel and cobalt compete for use in fuel cells. The life of the platinum reforming catalysts in petroleum refining is extended by treating the reformed distillate with a nickel catalyst. Vanadium is used in place of platinum in making sulfuric acid. The useful life of the platinum gauze catalyst used in the manufacture of nitric acid is extended by alloying it with rhodium.

Platinum is hardened with gold for use in spinnerets for the manufacture of rayon. There is considerable substitution within the group itself as well as alloying with metals of the group to increase hardness or strength. Nickel alloy wire is used for resistors instead of platinum wire where extreme stability is not required. Tungsten competes with platinum and palladium for use as electrical contacts where arcing occurs.

Cladding with platinum-group metals is a form of substitution where reliance is put on cheaper metals for mechanical strength and upon the noble metal for surface properties. This is common in glass melting pots and in other chemical ware. Rhenium is sometimes used where corrosion resistance is required.

SECONDARY SOURCES

The uses of platinum-group metals are generally not dissipative. An important exception is the use of palladium in electrical contacts. But, for the most part, outmoded jewelry, worn equipment, scrap, and sweeps can be processed to reclaim its platinum-metals content. Refined metal equal to more than 10 percent of the requirement for new metal is returned to domestic supply from such sources. Most of the spent catalysts and some of the material referred to above are refined on toll and returned to the user. The amount of metal returning to use through this channel is about the same as that of new supply.

RESERVES

The platinum-group metals reserves of Canada can be set at 12 million ounces from estimates based on reported reserves of nickel and their precious metal content. Canadian ore does not yield osmium. Not enough data are available to estimate the reserves of the rest of the world which accounts for 83 percent of current production.

In the absence of reported values the reserves were estimated from related information such as mineralization in host rocks which contain platinum-group metals, or, in the absence of this kind of information, from production itself, provided it was stable. Production from domestic placers is low and declining, hence, in the absence of proven measurements, U.S. reserves must be considered inconsequential. They may be about 50,000 ounces. Supply from domestic copper refining is not high, and it is more meaningfully given as projected production, since it cannot be exploited independently of copper.

Ultrabasic host rocks contain the bulk of the known reserves of platinum and related metals. In the Sudbury district of Canada the host rock is primarily norite and peridotite, and the platinum values are closely linked to nickel mineralization. Canadian reserves have been estimated at 12 million ounces, essentially the same value that would be derived from the published reserves of nickel-copper ore and its content of platinum-group metals (*1*). However, the reserves at Thompson are reputed to be adequate for 100 years, and certain operations at Sudbury are alleged to be projected beyond the end of the century. These values of reserves lead to an estimate of platinum-group metal reserves three times that based on reported ore reserves.

The platinum-group metal reserves in the Merensky Reef in the Republic of South Africa have been reported to be the world's largest known reserves, but the amount of metal is not stated nor are other reserves cited for comparison. Accordingly, these reserves must be estimated from projected production. Milling capacity in this area is known, and the periodic increases in it have been reported. By late 1964 it is projected to be 3.25 million tons of ore annually, yielding nearly 700,000 ounces of platinum-group metals (*6*). Prudent investment policy requires that minimum known reserves be a sizeable multiple of annual production, perhaps 10 to 20 times as much. On this basis the reserves in the Republic of South Africa are set at 7 to 14 million ounces. Of this reserve 12 to 24 percent may be palladium and 66 to 78 percent may be platinum. A proportion of 70 percent platinum, 25 percent palladium, and 5 percent minor metals is generally accepted. This estimate does not consider the reserve of osmiridium in gold ore.

Information about the nature and the amount of the reserves of U.S.S.R. is not available, but it is believed that the Ural placers are not rich

780–887 O—65——46

or extensive enough to support that nation's estimated production, even when augmented with byproduct metal from nickel smelters. It is believed that the major part of that nation's output comes from Norilsk and from cupriferous pentlandites of the Kola peninsula.

The Norilsk copper-nickel sulfide ores are reported to have a low content of platinum-group metals, but some may contain as much as 10 ounces per ton. Since the composition of the Soviet Union's exports indicates that the palladium to platinum ratio is 60:40 it would seem that the palladium-poor output of the Urals is a minor contribution to the total, supporting the belief that the Norilsk region and the Kola peninsula are the major producing areas.

If one assumes that a mining industry would not be developed to the size of that in the U.S.S.R. unless at least a 10-year supply of ore were in sight, one may set U.S.S.R. reserves at a minimum of 10 million ounces of platinum-group metals. Apparent expansion of U.S.S.R. production points to a significantly higher figure for their reserves.

CONSERVATION PRACTICES

The high cost of platinum-group metals stimulates the adoption of ways to recover them from the residues from copper and nickel refining and from gold placers. Most of the production of these metals in North America is derived from these sources.

Platinum-group metals are reclaimed from used chemical ware, worn spinnerets, spent catalysts, and the like. The amount recovered is of the same order as that of new metal sold to consumers. The properties of these metals can be utilized by the expedient of coating or cladding other materials which furnish the desired form and mechanical strength. Alloying platinum and palladium with minor metals of the group increases their hardness and durability to a remarkable degree without appreciably affecting their noble properties. Even the catalytic properties of platinum are retained when it is strengthened with rhodium.

SOURCES OF STATISTICAL INFORMATION

In the United States, data on platinum-group metals including domestic mine production, recovery of refined metals from both new and secondary sources, sales to consuming industries by metals and uses, and dealer's stocks are gathered and compiled by the Bureau of Mines through canvassing of the industry. Data on imports and exports are supplied to the Bureau by the Department of Commerce. Statistical reports covering all these phases are issued by the Bureau quarterly and annually.

No foreign country reports its consumption of platinum-group metals. Canada reports production, but only for the group as a whole. Trade news items and company annual reports give enough information to estimate the production of the Republic of South Africa. Vague estimates of potential production in the U.S.S.R. can be projected from early geological reports; but at best, they can only help to make reasonable the estimates of actual production deduced from estimated world consumption and free world production. Colombian production is estimated from its exports to the United States.

TABLE 1.—*Annual averages for platinum-group metals, 1954–63*

[Troy ounces]

Domestic production from crude platinum and byproduct platinum metals	26,253
Domestic refining:	
New metals	58,732
Secondary metals	95,342
Imports of refined metals [1]	861,746
Domestic consumption as measured by sales:	
Platinum	352,937
Palladium	420,530
Iridium	6,702
Osmium, rhodium, ruthenium	28,820
Total	808,989
Exports (unmanufactured)	46,922
World production [2]	1,222,000
Stocks of refiners and dealers in the United States (Dec. 31, 1963)	699,575

[1] Includes acquisitions for stockpile.
[2] Revised figure.

TABLE 2.—*Domestic consumption of platinum-group metals by uses, in percent, 1949–58*

Use	Platinum	Palladium	Iridium, osmium, rhodium, and ruthenium
Chemical, petroleum and glass	60.0	11.9	44.6
Electrical	18.4	65.4	14.1
Dental and medical	4.6	10.4	1.4
Jewelry	15.7	11.0	25.9
Miscellaneous	1.3	1.3	14.0
Total	100.0	100.0	100.0

Jewelry and decorative	10.3	4.0	42.7	18.8
Miscellaneous	1.5	1.0	2.5	5.9
Total	100.0	100.0	100.0	100.0

PRODUCTION, CONSUMPTION, AND TRADE

In 1963 the world consumed an estimated 2.5 million ounces of platinum-group metals. Reportedly the Republic of South Africa drew upon stocks for about 10 percent of its sales, and the U.S.S.R. also may have drawn upon stocks. After taking these withdrawals into account the estimated world production in 1963 was more than 2 million ounces, two-thirds of it coming from the U.S.S.R. The output of the U.S.S.R. is high in palladium and may account for as much as 80 percent of the world's production of palladium.

Production in the United States comes from placers in the Goodnews Bay district in Alaska, from gold placers in California, and from the refining of gold bullion and blister copper. Total U.S. production amounts to about 2.5 percent of the world total.

As of February 1964 unwrought platinum-group metals and ore continued to enter the United States duty free. Platinum-group metals in the form of unwrought alloys, however, are taxed 40 percent ad valorem. Rate of duty for gold-plated and silver-plated semifinished articles of platinum-group metals is 50 and 24 percent ad valorem, respectively. Statutory rates of duty for unwrought alloys of platinum-group metals and the gold and silver-plated semifinished articles are all 65 percent ad valorem.

STRATEGIC CONSIDERATIONS

The domestic new supply of platinum-group metals ranges from 3 to 5 percent of consumption, and there is little chance that output can be increased significantly. Only a relatively small amount of these metals is refined in the Western Hemisphere. Most of the free world refining capacity is in England and Norway. Consequently the supply lines are long, requiring up to 9 months for the metal in mined ore to reach market in refined condition. Of greater concern, however, is the fact that supply is inadequate. The free world does not produce enough platinum-group metals to supply U.S. industry. During 1958–63 the United States obtained an estimated average of 374,000 ounces of these metals per year from the output of the U.S.S.R. In 1963, the amount may have been more than 700,000 ounces. By merely withholding its platinum-group metals from the world market, the U.S.S.R. would not only cut off about one-half of U.S. new supply but would engender strenuous competition for the output of the free world.

In an emergency some metal could be diverted from nonessential uses, and the supply could be stretched by more expeditious processing of secondary metal. Since about as much secondary metal returns to use as comes through new supply, the potential may be of consequence. Curtailing exports could be only a minor factor. Dealers stocks tend to amount to about two-thirds of annual consumption.

GOVERNMENT PROGRAMS

Platinum-group metals have important defense applications. Owing to this fact and to a short domestic supply, their sales for nonessential uses were prohibited during World War II and the Korean war. In 1953, the Business and Defense Services Administration (BDSA), Department of Commerce established regulations giving top priority ratings to the platinum-group metals for defense purposes. These metals were also placed on the preferred list, which required a validated license for export to the Communist countries and to other countries that have no similar restrictions with Communist countries.

To enhance a possible domestic supply of platinum-group metals, prospectors are eligible for 50 percent financial assistance under a program administered by the Office of Mineral Exploration (OME), Department of the Interior.

On account of their strategic importance platinum, palladium, and iridium were specifically put on the Government's list of strategic materials. Although osmium, rhodium, and ruthenium were not on the list, they were periodically acquired by the Government. To assure the country a supply of platinum-group metals in the event of an emergency, the Government continually reappraises the needs of national security and revises the stockpile objectives accordingly. As of June 30, 1964, there was 13,937 troy ounces of iridium in the national (strategic) stockpile; 737,935 troy ounces of palladium, of which 89,811 ounces was in the national (strategic) stockpile and 648,124 in the supplemental stockpile; 766,309 troy ounces of platnium, of which 716,310 ounces was in the national (strategic) stockpile and 49,999 ounces was in the supplemental stockpile. An additional 33 troy ounces of platinum did not meet stockpile specifications.

Some disposals of the platinum-group metals were made during 1959–63. In September 1959 Congress approved the disposal of approximately 2,600 troy ounces of osmium, rhodium, and ruthenium. They were sold through sealed bids. Sales were carried by monthly quota at a rate designed not to disrupt the normal market. The disposal of these metals was com-

pleted during the first half of 1962. In addition, 7,884 troy ounces of palladium was sold during the second half of 1963.

PRICES

The prices of the platinum-group metals were essentially the same at the close of 1963 as they were in 1960. However, the prices of platinum and palladium declined during the year under the pressure of heavy offerings from the U.S.S.R., but regained their earlier levels when the pressure relaxed as a result of record imports by the United States and Japan. Near the end of 1963, trading in futures resumed on the New York Mercantile Exchange and January 1965 futures were traded as high as $102 per ounce.

During 1963, the price range per troy ounce for platinum declined from $80 to $85 to $75 to $80 and returned to $82 to $85 by yearend. The price range for palladium declined from $24 to $26 to $22 to $24 and then regained its previous level. Throughout the year the other metals of the group were quoted as follows: Iridium, $70 to $75; osmium, $60 to $70; rhodium, $137 to $140; and ruthenium, $55 to $60.

TAXES

Domestic platinum producers are granted a depletion allowance of 23 percent on income from domestic production and 15 percent on income from foreign production.

In addition to a 15-percent depletion allowance (of salable value of minerals), taxable incomes of operations outside the United States and within the Western Hemisphere are taxed at a rate of 34 percent, well below the U.S. corporate income tax rate of 48 percent.

Jewelry and other luxury items made of platinum-group metals are subject to 10-percent Federal excise tax on the sale price.

EMPLOYMENT

Employment in the platinum-group industry is highly diversified, ranging from top management, in both business and research, down through all levels of employment. It involves scientific talent and craft skills over a wide range of applications, including catalysts, manufacturing of jewelry, electroplating, chemical ware, and research.

Engelhard Industries, Inc., reported a total of 4,515 employees in 1963, but employee-years devoted specifically to platinum-group metals was not given. Figures from other refineries and from electroplaters and other employers are not available.

RESEARCH

Vigorous research is being pursued by industrial concerns on all phases of the technology of the platinum-group metals. The reports and patents which result are too numerous to cite, but certain fields of investigation are worthy of note.

Substantial effort is directed toward developing catalysts for fuel cells (*2*, *5*).

Homogeneous catalysis by platinum-group-metal salts attracted interest because it promises greater specificity than heterogeneous catalysis (*7*). Many applications of platinum-group metals to printed circuitry are under investigation (*2*, *8*). The classical applications to petroleum refining, hydrogen purification, resistance heating, catalytic oxidation, and to other uses have not been neglected by industrial research programs (*3*). A recent contribution was a cobalt-platinum alloy having the highest magnetic flux of any material known.

OUTLOOK

Worldwide use of platinum-group metals is increasing. This upward trend is expected to persist and become stronger as underdeveloped countries industrialize. In 1963, the United States consumed 37 percent more of these metals than were produced in the free world, and consumption will continue to increase; but by percent, other nations may increase faster. Japan's imports have risen rapidly recently owing to her industrial expansion.

Production in Canada is expected to increase at a moderate rate from the base set in 1963. The recent expansion in nickel capacity in Manitoba will treat ore with a lower precious metal content than the Sudbury ores, and it will not augment the supply of platinum-group metals as much as would a corresponding increase at Sudbury. A placer deposit is being developed in northern British Columbia. Estimates of its expected production are not available, but its immediate contribution will be minor.

Production in the Republic of South Africa is being expanded, and it should reach 675,000 ounces of platinum-group metals per year by late 1965. Further expansion is possible if the world market is favorable, but it would be at

a slower rate than the present one in which only the mining rate was increased to supply existing mills to full capacity.

Production in the U.S.S.R. is not known with certainty, but estimates of current output indicate that reserves have been adequate to support a large expansion in recent years, raising it to first place in world production. In addition to placers, the U.S.S.R. has platinum-bearing nickel ores similar to those in Canada, and it has platinum-group metal ores like those of the Republic of South Africa. It now appears that the U.S.S.R. has metal for internal development and will remain the chief supplier to the world markets.

The United States production is inconsequential in world supply and is more likely to contract than to expand. Reports from other sources of platinum-group metals, including Colombia, are too sparse to permit a useful prediction of production beyond the statement that only the three major producers will contribute significantly to world supply in the immediate future.

The categories of use will remain about the same as now and be subject to the same fluctuation as in the past. New uses cannot be ruled out, but the extremely high prices of platinum-group metals and the inflexibility of the supply of the minor metals discourages the development of new uses. For instance, should fuel cells attain successful application to power generation, their demand for platinum would exceed present world production. The four minor metals of the group are coproducts of and are held in rigid supply by the demand for platinum and palladium. New or expanded uses of them face the threat of price instability. The prices of platinum and palladium make them vulnerable to substitutes. Therefore, it is expected that except for periods of dislocation in supply, prices will remain stable for the present, but they may drift lower after South African production reaches full capacity.

PROBLEMS

The high price of platinum-group metals seems to be a secondary problem when considering their inherently unstable prices. Domestic production of these metals is negligible compared with consumption, leaving demand to be supplied by purchases on the open market. However, a great measure of stability is provided by the threat of substitutes in some of the larger categories of use. The major suppliers have met this threat by allocating metal to their regular customers at prices significantly below the highs reached on world markets, and price increases to these customers have been moderate. They have lagged behind the price movements in the world markets and in futures trading. This market policy has for a time, at least, successfully met the disruption caused when the U.S.S.R. virtually discontinued offerings of platinum-group metals on the world market during 1964 after glutting it in 1963. However, such a price control is not a reassuring substitute for a flexible supply in a free market.

The inflexibility of supply of the minor metals of the group hampers the development of techniques that use them. These metals are produced in smaller amounts as coproducts during the production of platinum and palladium which, in turn, are to a great extent byproducts or coproducts Although the amounts of the minor metal products and the proportion of the metals in them varies with the source, it seems not to be feasible to mine them selectively on a significant scale. Hence, the market for the minor metals is destined to remain thin, and prices capricious. The development of uses is further restricted because data covering the production and stocks of the minor metals are not available. New or expanded uses are not likely to be developed unless adequate supplies of the metals are assured.

POTASSIUM

By Richard W. Lewis [1]

POTASSIUM is one of the triad of major elements necessary to sustain plant life. Although its chief use is as a fertilizer, there is a growing list of chemical uses for potassium compounds.

The largest deposits of potassium minerals occur in West Germany, East Germany, the U.S.S.R., and Canada; the major producing countries are the United States, West Germany, East Germany, France, and Spain. In the United States, the largest producing country in 1963, approximately 90 percent of production came from New Mexico; the remainder largely from California and Utah.

The need to eliminate dependence upon German imports, accented by the shortage during World War I, provided impetus to a search for potassium compounds by both Government and industry, which resulted in the discovery of commercial deposits in New Mexico in 1925. The Geological Survey and the Bureau of Mines participated in the search, and the Bureau of Mines engaged in beneficiation studies.

Although potassium compounds occur in many rocks and minerals, the commercial sources are limited to soluble salts in bedded salt deposits and brines. The major deposits of potassium compounds in the United States are part of the Permian salt basin that underlies parts of Colorado, Kansas, Oklahoma, Texas, and New Mexico, and the Paradox basin of southwestern Colorado and southeastern Utah.

Recovery from bedded deposits is by the room-and-pillar method and from brine reservoirs by pumping. Beneficiation includes ore dressing and fractional crystallization methods.

Resources in the United States are sufficient to meet the expected demand for more than 100 years. In addition, producers are developing huge deposits in Canada (*1*).[2]

Of the potassium compounds consumed in the United States, 94 percent is used by agriculture and the other 6 percent by the chemical industry in manufacturing diverse products, such as detergents, soap, glass, ceramics, textiles, dyes, and drugs. The consumption of potassium compounds largely follows that of fertilizers, for which there has been an ever-increasing demand. This trend is expected to continue.

There is no substitute for potassium compounds in agriculture; they are essential to maintain and expand food production.

Problems of the potash industry are concerned with economic means of utilizing the low-grade soluble and insoluble sources of potassium compounds.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Before World War I, supplies and prices of potassium compounds were controlled by a German cartel and regulated by the German Government.

Realizing the need for a domestic supply of potassium compounds, Congress passed an act in 1911 providing funds to search for domestic sources and to perfect processes for extracting potassium compounds from materials of various types. The problem was originally assigned to the Bureau of Soils, U.S. Department of Agriculture, and the Geological Survey, U.S. Department of the Interior.

The blockade of Germany by Great Britain during World War I cut off imports and caused intensified efforts to produce potassium compounds domestically. By 1918, at least 128 plants were producing potassium compounds

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

from kelp, wood ashes, lake brines, alunite, cement dust, beet sugar waste, blast furnace dust, and other sources. After the war foreign supplies again became available, and all but one domestic plant ceased operations.

Germany and France (which gained control of many former German potash mines as a result of the war) formed a syndicate to eliminate competition by dividing the U.S. market between them. New producing companies in Palestine, Poland, the U.S.S.R., and Spain gained admittance to the syndicate, and the sphere of operation expanded to include the world market. Owing to an antitrust suit by the United States, the syndicate closed its New York sales office in 1927 and established a Netherlands company to sell potassium compounds from the syndicate-member countries in the United States. This arrangement continued until the outbreak of World War II in 1939.

Meanwhile, a law was enacted in 1924 "authorizing investigation by the U.S. Geological Survey to determine location and extent of potash deposits in the United States." The law was amended to include the Bureau of Soils and later amended again to substitute the Bureau of Mines for the Bureau of Soils. The Geological Survey did the geological work and determined drill-hole sites, and the Bureau of Mines supervised the drilling. Under this authority, which covered the period 1926–31, 24 holes were drilled in Texas, New Mexico, and Utah, and cuttings were examined from oil wells throughout the United States. Salt beds, ranging from 1½ to more than 8 feet in thickness and containing 9 to 14 percent K_2O equivalent, were found in New Mexico and Texas.

The occurrence of potassium compounds in the Permian basin was widely publicized, and oil drillers in the region began to examine cuttings for salines. Oil well drillers east of Carlsbad, N. Mex., in 1925 encountered unusually thick beds of salines. Samples taken during drilling contained significant traces of potassium-bearing minerals. In 1926, the operating company put down a core drill hole close to the first drill hole and obtained a vertical cross section of the saline strata. The core revealed a substantial thickness of potassium-bearing minerals. Of major significance was the disclosure of a potentially commercial bed of sylvinite. Further exploration by Federal and private agencies revealed the presence, at a depth of approximately 1,000 feet, of a deposit of sylvinite equal in concentration of potassium chloride (KCl) and other essential characteristics to the better European deposits, and large enough to warrant development of mines and refineries.

A later exploration program by the Bureau of Mines blocked out a National Potash Reserve about 14 miles northeast of Carlsbad. This deposit was held by the Federal Government until 1957, when it was leased to a producing company.

On the basis of the earlier drilling, United States Borax & Chemical Corp. began mine development in 1929 and production in 1931. A second producer, Potash Co. of America, began development in 1933 and production in 1934. A third producer, International Minerals and Chemical Corp., began development in 1936 as Union Potash Co. and production in 1940.

Duval Sulphur & Potash Co., now Duval Corp. (beginning in 1951), Southwest Potash Corp. (1952), and National Potash Co. (1957), now operate mines and refineries in New Mexico. Kermac Potash Co., owned jointly by National Potash Co. and Kerr-McGee Oil Industries, Inc., was developing a mine near Carlsbad in 1964, expecting production in 1965. Annual capacity of the New Mexico field, the largest U.S. producing area, was about 2.9 million tons of K_2O equivalent in 1964.

The second most important producing area in the United States is southeastern California, where American Potash & Chemical Corp. recovers potassium salts and other industrial and agricultural chemicals from brine in the crystalline salt mass of Searles Lake (*3*). Operations began in 1916, and annual capacity of this plant was about 200,000 tons of K_2O in 1964.

These two areas supplied over 90 percent of all domestic production in 1963; the remainder came from Salduro Marsh, near Wendover, Utah (Bonneville, Ltd.); the wells of The Dow Chemical Co. at Midland, Mich.; and, as a byproduct, from cement plants in Maryland.

Texas Gulf Sulphur Co. started development of the first potash mine in Utah near Moab in 1961. The facility was completed and production was scheduled for early in 1965. Several other companies were exploring the potential of the Utah deposits, but no mines were in developing stages at the end of 1964.

Potash Co. of America began producing potash in Saskatchewan, Canada, in 1958 but operations were suspended in 1959 because of failure of the mine shaft. The shaft was repaired and the mine and facilities were ready for operation by the end of 1964. In 1957 International Minerals and Chemical Corp. began shaft sinking at its Esterhazy, Saskatchewan, property, and after considerable trouble and expense started producing in 1962. Kalium Corp. began production late in 1964, using

solution-mining methods on its deep deposits. By the end of 1964, two other companies, United States Borax & Chemical Corp., and Alwinsal Potash of Canada Ltd., had begun development operations, expecting production by 1968.

DEFINITION OF TERMS AND GRADES

The term "potash" was derived from pot ashes, which were originally obtained by evaporating, in iron pots, solutions leached from wood ashes. The present worldwide meaning of potash is twofold. When used as a noun it means K_2O equivalent, and when used as an adjective it means potassium compounds or potassium-bearing materials.

Sylvinite, the major ore from underground mines in New Mexico, Canada, and Europe, is a mixture of sylvite (KCl) and halite (NaCl).

Three potassium salts are produced in the United States for fertilizer use—chloride (muriate), sulfate, and potassium-magnesium sulfate. The chloride is produced in two grades—60 percent muriate and manure salts (20 to 22 percent K_2O). Potassium sulfate contains a minimum of 50 percent K_2O. The double sulfate contains 22 percent K_2O equivalent and 18 percent MgO.

Chemical-grade potassium chloride, containing less than 1 percent impurities, also is produced in the United States. This chloride is the basic material for producing many other potassium compounds used by the chemical industry.

The term "crop year," as referred to in this chapter, is the 12-month period ending June 30.

TECHNOLOGY

Geology

Potassium is found in rocks of many types and in the waters of lakes, rivers, and oceans. It has been estimated that 3.11 percent of the lithosphere is potash (K_2O equivalent). Sea water contains an average of 0.04 percent K_2O equivalent. Minerals generally classified as potash minerals are given in table 1. Carnallite, kainite, langbeinite, niter, and sylvite are soluble potassium-bearing minerals of current economic value. Alunite, glauconite, leucite, and polyhalite are considered potential mineral sources of potash. The other minerals listed are not likely to be of any commercial value, many being quite rare.

The principal deposits of soluble potassium salts occur in formations of Devonian age in Canada; of Permian age in the United States, the United Kingdom, central Europe, and the Urals; of Miocene age in Sicily and the Ukraine; and of Tertiary age in Spain.

The Permian salt basin in the United States underlies parts of Colorado, Kansas, Oklahoma, Texas, and New Mexico, but commercial beds of potassium minerals have been found only in New Mexico. Deposits in the Texas-New Mexico region are irregular in shape, thickness, and quality. On the basis of scattered drill holes, indications of deposits have been found over an area of approximately 3,000 square miles (*4*). Commercial operations have been limited to about 55 square miles east of Carlsbad, N. Mex. (*8*).

In the Carlsbad area the overburden comprises about 80 feet of sand, caliche, and gypsum. Underlying this cover is the Rustler formation, consisting of several hundred feet of gypsum, dolomite, and sand and gravel beds. Under this is the Salado salt formation, having a maximum thickness of 1,600 feet. The Salado formation comprises about 45 sulfate beds (gypsum, anhydrite, and polyhalite) and 45 halite beds. The potassium-rich horizons, approximately in the middle of the formation, are from 650 to nearly 2,000 feet beneath the surface and consist of numerous thin beds, chiefly sylvite mixed with halite, with some langbeinite and carnallite.

An extensive potash-bearing salt basin of growing importance, known as the Paradox basin, lies in southeast Utah and southwest Colorado. The potash deposits occur in the "saline facies" of the Paradox member of the Hermosa formation of the Pennsylvanian age. The saline facies consists of at least 29 evaporite cycles, 11 of which contain potentially valuable potash deposits. The area covers about 11,000 square miles, and nearly two-thirds is underlain by potash deposits ranging from 1,700 to 14,000 feet below the surface. The evaporite cycles were assigned numbers in a detailed study by R. J. Hite in 1960 (*7*). The most important of the deposits at the present time is salt bed 19, which was traced from Crescent Junction, Grand County, Utah, to northern Montezuma County, Colo., a distance of nearly 110 miles. Owing to extensive folding of the beds, potash at present is minable only in salt anticlines. Exploitation of the Cane Creek anticline deposit was begun by one company late in 1964. Several companies were exploring

TABLE 1.—*Potassium-bearing minerals*

Name	Composition	Potassium (K) content, percent [1]
Borates:		
Kaliborite	$KMg_2B_{11}O_{19}\cdot 9H_2O$	5.0–6.6
Rhodizite	$NaKL:Al_4Be_2B_{10}O_{27}$(?)	Variable
Carbonates:		
Buetschliite	$K_6Ca_2(CO_3)_5\cdot 6H_2O$	32.5 (t)
Fairchildite	$K_2Ca(CO_3)_2$	32.8 (t)
Kalicinite	$KHCO_3$	39.1 (t)
Chromates:		
Lopezite	$K_2(Cr_2O_7)$	26.6 (t)
Tarapacaite	$K_2(CrO_4)$	40.3 (t)
Halides:		
Avogadrite	$(K,Cs)BF_4$	Variable
Carnallite	$KMgCl_3\cdot 6H_2O$	14.1
Chlormanganokalite	K_4MnCl_6	36.4
Chlorocalcite	$KCaCl_3$	21.4
Douglasite	$K_2FeCl_4\cdot 2H_2O$(?)	
Elpasolite	K_2NaAlF_6	28.9
Erythrosiderite	$K_2FeCl_5\cdot H_2O$	12–24
Hieratite	K_2SiF_6	35.4
Kremersite	$(NH_4,K)_2FeCl_5\cdot H_2O$	12.1
Mitscherlichite	$K_2CuCl_4\cdot 2H_2O$	24.5 (t)
Pseudocotunnite	K_2PbCl_4	17.1
Rinneite	NaK_3FeCl_6	28.9
Sylvite	KCl	52.4
Nitrates: Niter (saltpeter).	KNO_3	38.6
Phosphates:		
Dehrnite	$(Ca,Na,K)_5(PO_4)_3(OH)$	1.0
Englishite	$K_2Ca_4Al_8(PO_4)_8(OH)_{10}\cdot 9H_2O$	4.5
Lehiite	$(Na,K)_2Ca_5Al_8(PO_4)_8(OH)_{12}\cdot 6H_2O$(?)	1.9
Leucophosphite	$K_2(Fe,Al)_7(PO_4)_4(OH)_{11}\cdot 6H_2O$.	6.6
Lewistonite	$(Ca,K,Na)_5(PO_4)_3(OH)$	4.9
Millisite	$(Na,K)CaAl_6(PO_4)_4(OH)_9\cdot 3H_2O$.	1.4
Minyulite	$KAl_2(PO_4)_2(OH)\cdot 3\frac{1}{2}H_2O$(?)	10.2
Taranakite	$K_2Al_6(PO_4)_6(OH)_2\cdot 18H_2O$(?)	6.6
Silicates:		
Apophyllite	$KCa_4(Si_4O_{10})_2F\cdot 8H_2O$	4.3 (t)
Feldspars:		
Anorthoclase	$K(AlSi_3O_8)$–$Na(AlSi_3O_8)$	2.0–5.8
Microcline	$K(AlSi_3O_8)$	14.0
Orthoclase	$K(AlSi_3O_8)$	14.0
Glauconite (greensand).	$K_2(Mg,Fe)_2Al_6(Si_4O_{10})_3(OH)_{12}$	1.9–7.1
Silicates—Continued		
Leucite	$K(AlSi_2O_6)$	17.8
Micas:		
Biotite	$K(Mg,Fe)_3(AlSi_3O_{10})(OH)_2$	7.5
Lepidolite	$K_2Li_3Al_3(AlSi_3O_{10})_3(O,OH,F)_4$.	10.0 (t)
Muscovite	$KAl_2(AlSi_3O_{10})(OH)_2$	9.9 (t)
Phlogopite	$KMg_3(AlSi_3O_{10})(OH)_2$	9.4 (t)
Roscoelite	$K_2V_4(AlSi_3O_{10})(OH)_4$	6.9
Nepheline	$(Na,K)(AlSiO_4)$	.7–5.8
Sulfates:		
Alunite	$KAl_3(SO_4)_2(OH)_6$	8.7
Aphthitalite (glaserite).	$K_3Na(SO_4)_2$	19.7–35.3
Arcanite	K_2SO_4	44.9 (t)
Chlorothionite	$K_2Cu(SO_4)Cl_2$	26.3
Cyanochroite	$K_2Cu(SO_4)_2\cdot 6H_2O$	17.7
Euchlorin	K,Na,Cu basic sulfate	6.0–8.5
Hanskite	$Na_{23}K(SO_4)_9(CO_3)_2Cl$	2.4
Jarosite	$KFe_3(SO_4)_2(OH)_6$	7.6
Kainite	$KMg(SO_4)Cl\cdot 3H_2O$	11.0
Kalinite	$KAl(SO_4)_2\cdot 11H_2O$	8.6 (t)
Krausite	$KFe(SO_4)_2\cdot H_2O$	12.2
Krugite	$K_2Ca_2Mg(SO_4)_4\cdot 2H_2O$	13.0
Langbeinite	$K_2Mg_2(SO_4)_3$	18.8
Lecontite	$Na(NH_4,K)SO_4\cdot 2H_2O$	2.2
Leightonite	$K_2CaCu(SO_4)_4\cdot 2H_2O$	11.5
Leonite	$K_2Mg(SO_4)_2\cdot 4H_2O$	21.3
Manganolangbeinite	$K_2Mn_2(SO_4)_3$	16.4
Mercallite	$KHSO_4$	22.0
Metavoltine	$(K,Na,Fe)_6Fe_2(SO_4)_6(OH)_2\cdot 9H_2O$(?).	17.4
Misenite	$K_8H_6(SO_4)_7$	31.8
Palmierite	$(K,Na)_2Pb(SO_4)_2$	
Pieromerite (schoenite)	$K_2Mg(SO_4)_2\cdot 6H_2O$	19.4
Polyhalite	$K_2Ca_2Mg(SO_4)_4\cdot 2H_2O$	13.0
Potash alum	$KAl(SO_4)_2\cdot 12H_2O$	4.8
Syngenite	$K_2Ca(SO_4)_2\cdot H_2O$	23.9
Taylorite	$(K,NH_4)_2SO_4$(?)	36.0
Ungemachite	$Na_9K_3Fe(SO_4)_6(OH)_2\cdot 9H_2O$	9.6
Voltaite	$(K,Fe)_3Fe(SO_4)_3\cdot 4H_2O$(?)	3.7
Vanadium oxysalts: Carnotite.	$K_2(VO_3)_2(VO_4)_2\cdot 3H_2O$	8.6

the potash potential of other anticlines in the area.

The brine deposits of Searles Lake, Calif., and the Bonneville Salt Flats, Utah, resulted from the evaporation of large inland seas and contain various quantities of potassium in complex brines.

Mining

Potassium compounds are recovered in the United States from three types of deposits: The large salt beds of the Salado formation in New Mexico, the folded and faulted beds in the salt anticlines of the Paradox basin in Utah, and the brines of Searles Lake, Calif., and Bonneville Salt Flats, Utah.

In the bedded salt formations, the room-and-pillar method predominates, and recovery is about 60 percent. Subsequent pillar robbing, widely used throughout New Mexico, increases recovery to as much as 90 percent. All mines are highly mechanized, and both electric and diesel equipment is used (*6*, *14*). Undercutters and drilling jumbos prepare the mining face for blasting. Continuous-mining machines are used in some areas. Crawler-type loading machines load the broken ore into shuttle cars or onto belt conveyors for delivery to underground transfer points. From the transfer points the ore is hauled to the shaft by electric or diesel-driven trains or on belt conveyors. Belt haulage is rapidly replacing trains. One mine has a main belt line more than 7 miles long fed by shuttle cars and feeder belts; another has all belt conveyor haulage.

Primary crushing is done underground before hoisting. Skip loading and hoisting are automatic at most mines; the loading, hoisting, and dumping cycle usually is 2 minutes or less.

The mines in Eddy County, N. Mex., are about 1,000 feet deep. The National Potash Co. operation in Lea County, mines from a depth of approximately 1,800 feet. All mines produce from one level except that of International Minerals and Chemical Corp., which has workings on three levels. The ore in the

operating mines ranges from 4 to 14 feet in thickness and averages of 18 percent K_2O equivalent.

Room-and-pillar mining will be practiced by Texas Gulf Sulphur Co. at its new mine near Moab, Utah. The mine is highly mechanized, using continuous-mining machines and the usual undercutters, drills, and loaders. Ore haulage from ore body to the shaft, about 3,000 feet, will be by belt conveyor. As the mine development progresses, the main line conveyors will be extended and section conveyors added, with diesel shuttle cars transporting ore from the face to the conveyor.

Mining is expected to be on one level for several years, at a depth of about 2,800 feet. Primary crushing will be done underground before hoisting.

One circular shaft, 22 feet in diameter, is divided to provide for ventilation to the mine, an 80-man cage, and two 20-ton ore skips. A second shaft is to be added in the near future.

The recovery methods used at Searles Lake, Calif., described in the "Boron" and "Sodium and Sodium Compounds" chapters, exemplify methods of working brine deposits. About 3.7 million gallons of brine, containing about 2.5 percent K_2O equivalent, is pumped daily to the refinery from about 40 wells, 70 to 120 feet deep. Dissolved salts constitute over one-third of the weight of the brine.

Milling and Refining

Two basic methods of ore treatment—flotation and fractional crystallization—are used in the Carlsbad area to recover sylvite from the ore. Sylvite is separated from halite, the principal impurity in the ore, in a brine saturated with both sodium and potassium chlorides by either floating or depressing the sylvite. In general, sylvinite is mixed with the saturated brine and deslimed to remove most of the clay impurities. Then the flotation reagent, usually amine chloride or amine acetate, is added and the pulp is conditioned and sent to flotation cells where the sylvite is separated from the halite. The halite fraction is repulped and pumped to tailings, and the sylvite concentrate is dried and shipped or sent to storage.

Fractional crystallization is based on the relative solubilities of sodium chloride and potassium chloride in saturated solutions at changing temperatures. Crushed ore is mixed with the hot, saturated sodium chloride brine, which selectively dissolves the potassium chloride. The brine is then cooled, and the potassium chloride crystallizes as a 99-percent-pure product.

Langbeinite, produced in the United States by International Minerals and Chemical Corp., is separated from halite, its principal impurity, by selective solution of halite.

Potassium compounds are recovered from brines by evaporation and fractional crystallization. First, the sodium salts are separated in triple-effect evaporators, leaving a hot liquor rich in potash and borax. Rapid cooling under vacuum causes the potassium salts to crystallize. They are removed by settling and centrifuging.

USES

Potassium is one of the three major plant-nutrient elements, and approximately 94 percent of the potassium consumed in the United States is used in agriculture—usually in mixed fertilizers. The remaining 6 percent is consumed by the chemical industry.

Potassium chloride is the most widely used potassium compound in fertilizers; next in use are the sulfate and the double salt, potassium-magnesium sulfate. Several grades of potassium chloride (muriate) are utilized in fertilizers, standard, granular, and coarse, all containing a minimum of 60 percent K_2O equivalent, and run-of-mine or manure salts (20–22 percent K_2O). Some muriate with a 50 percent K_2O minimum is imported, but most of the foreign producers have raised the grade of their exports to that of the U.S. producers. Much of the potassium chloride, 62 percent K_2O and better, is used in the chemical industry.

Potassium sulfate contains 50 percent K_2O (minimum), and potassium-magnesium sulfate (sulfate of potassium magnesia) contains 20 percent K_2O and 18 percent MgO.

Crude potassium and crude potassium-sodium nitrate mixtures are imported from Chile for use as fertilizer materials. Potassium nitrate has been manufactured in very recent years for use as a fertilizer.

Of the potassium compounds used for agriculture, a small part is applied directly as a single-element fertilizer. The remainder is shipped to fertilizer factories, where it is blended with other plant foods to produce mixed fertilizers.

Metallic potassium has not been used commercially, because it costs more than sodium and is more difficult to handle. However, in recent research studies, the use of potassium vapor for driving reactor-powered turbines appeared promising. Small quantities of alloys containing potassium have special applications. Liquid mixtures of sodium and potassium have been used experimentally as coolants in atomic reactors, but the results were not encouraging.

Over 265,000 tons of chemical-grade potassium chloride was consumed in 1963; most was used to produce potassium hydroxide (caustic potash), the major chemical potassium compound. Most other potassium chemicals are made from potassium hydroxide. The major potash-chemical-consuming industries include detergents and soap, 35 percent; glass and ceramics, 25 percent; textiles and dyes, 20 percent; and chemicals and drugs, 13 percent.

Potassium hydroxide is used in manufacturing soaps and detergents, ceramics and glass, and textile dyes.

Potassium carbonate has diverse industrial and chemical uses. It is an ingredient of ceramics and glass, especially electrical glass. Potassium carbonate also is used in making textile dyes and in printing fabrics; in producing cocoa and chocolate, effervescent mineral waters, and special leavening agents; and in cleaning, treating, and electroplating metals.

More than 10,000 tons of potassium sulfate is used annually by the chemical industry. The major use (75 percent) is as an accelerator in manufacturing gypsum plasterboard and gypsum tile. About 6 percent of the industrial potassium sulfate is used in producing titanium pigments. About 1,400 tons, or 14 percent, is consumed annually in producing potash alums for water purification, fur treatment, leather tanning, pickle making, textile dyeing, and fireproofing and in manufacturing pigments, vegetable glue, artificial stones, porcelain cement, medicines, and photographic chemicals.

Potassium chlorates are used in making matches, explosives, propellants, and permanent-wave preparations. Potassium bromide is used chiefly in photography, photoengraving, and medicines. Potassium nitrate is used in manufacturing certain types of glass and ceramic glazes and in meat curing, pickling, and medicines. Potassium phosphates are used in detergents, penicillin processing, liquid soaps, and metal-plating baths. Potassium peroxydisulfate is a necessary ingredient in synthetic rubber manufacture. Potassium iodide is used in iodizing salt. Potassium bromate acts as an oxidizing agent in milling wheat flour.

There are many more chemical compounds containing potassium that have special research and industrial uses.

BYPROUCTS AND COPRODUCT RELATIONSHIPS

In the Carlsbad area, a small quantity of sodium chloride is sold as a byproduct of the potash industry for animal-feed supplements. Other byproducts include magnesium oxide and hydrochloric acid. Small quantities of cesium and rubidium are present in the Carlsbad potash ores, and other rare elements are associated with potash in this and other localities.

Potassium compounds recovered from brines are only one of many coproduct chemicals produced. For example, the principal products of the Searles Lake operations are soda ash, salt cake, potassium chloride, borax, bromine, and lithium carbonate.

Some potash is recovered as a byproduct in the manufacture of cement in Maryland.

The largest use of potassium compounds is as a source of potassium in mixed fertilizer containing phosphorus and nitrogen. Demand for and consumption of these three materials are closely related.

ALTERNATE MATERIALS

There is no substitute for potassium compounds in agriculture. They are not only necessary for plant growth but regulate the intake by plants of the other minerals and elements needed for normal plant growth. Some sodium compounds might be used in place of potassium compounds in certain chemical applications if the need arose.

RESERVES AND RESOURCES [3]

World resources of potassium compounds are sufficient for several thousand years at the present rate of consumption. The figures shown in table 2 are not necessarily comparable because the basis for measuring is not known for all countries. In general, the figures represent the total K_2O equivalent of the deposits.

The U.S. reserves are of two types, brines and bedded deposits. The brines of California, and Utah are estimated to contain approximately 120 million tons K_2O, while the bedded deposits of Utah and New Mexico have known reserves totaling about 340 million tons. The estimated reserves of potash in the United States follow:

	K_2O
	million tons
Brines:	
Great Salt Lake, known reserve	91
Great Salt Lake Desert including Wendover, Utah, inferred reserve	7.8
Searles Lake, Calif., known reserve	20
Michigan brine	Not available
Bedded deposits:	
Paradox basin (southeastern Utah and extending into southwestern Colorado):	
Known reserve	254
Inferred reserve	161
Permian basin (Carlsbad, N. Mex.):	
Known reserve	85
Inferred reserve	400

[3] Data for potash reserves in Utah and Colorado supplied by R. J. Hite, letter from U.S. Geological Survey. Other data for United States taken from "Potash Reserves of the United States," by Samuel H. Dolbear (American Potash Institute, Inc., Washington, D.C., 1946).

The estimate for the bedded deposits was based on a minimum bed thickness of 4 feet and a minimum equivalent K_2O content of 14 percent. A cutoff at 4,000 feet in depth was used in calculating the Paradox basin reserve. If solution mining of the deeper deposits of the Paradox basin was considered, the reserve figure for this area would be much larger.

TABLE 2.—*Estimated world reserves of soluble potassium compounds*

[Million short tons of equivalent K_2O]

Country	Quantity
Canada	17,500
France	350
Germany:	
East	10,000
West	9,500
Israel and Jordan (Dead Sea)	2,000
Spain	300
United States	450
U.S.S.R.	24,000

The Canadian reserve is based on an average equivalent K_2O content of 25 percent and bed thickness ranging from 5 to 10 feet. Because of unknown mining conditions in zones of multiple beds, only one bed was included in the estimate. The figure in the table for Canada is the total reserve. Assuming yields of 40 percent for mining and 90 percent for refining, the recoverable reserve would be 6.4 billion tons of K_2O.

Rich potash deposits with a combined reserve amounting to about 20 million tons have been discovered in Ethiopia and the Congo (Brazzaville).

Other possible sources of potassium compounds are alunite (*16*), carnallite, polyhalite (*4*), wyomingite (*16*), greensands (*15*), and porphyry-copper tailings (*11*). These sources, if commercial recovery methods were developed, would supply the United States for many hundreds of years.

Sea water contains about 0.04 percent equivalent K_2O, and each cubic mile contains the equivalent of 1.8 million tons of K_2O. Methods have been reported to recover 70 percent, but indicated costs are several times the 1963 selling price. Ultimately, however, the sea could provide a virtually unlimited supply of potash.

CONSERVATION PRACTICES

Improved mining practices have enabled recovery of up to 90 percent in the underground mines in New Mexico. Prior to the development of pillar robbing, mine recovery averaged 60 percent. Refinery recovery averages 90 percent of the contained K_2O equivalent.

A new flotation process, separating sylvite from langbeinite, was developed and put into operation during 1963. Langbeinite-sylvinite ores, previously uneconomical to mine and process, were made available, thus increasing the minable reserve.

SOURCES OF STATISTICAL INFORMATION

Data on crude ore production, marketable production and value, stocks, and total sales are collected semiannually by the Bureau of Mines, and 12-month data are published for years ending June 30 and December 31. Data on imports and exports of potassium compounds and production of certain potash compounds are collected by the Bureau of the Census, U.S. Department of Commerce. A canvass on consumption of potassium compounds in fertilizers, as measured by dealers' shipments, is conducted semiannually by the U.S. Department of Agriculture and published for years ending June 30. The American Potash Institute compiles and publishes quarterly data on potassium compounds deliveries (K_2O equivalent) in North America by destination. This statistical coverage is adequate for the needs of industry and government.

PRODUCTION, CONSUMPTION, AND TRADE

U.S. production, sales, imports, exports, and apparent consumption of potassium compounds are given in table 3. The marketable production of potassium salts (K_2O equivalent) in 1963 was 33 percent greater than in 1958. The only year not registering increased production during this 5-year period was 1962, when production dropped off 10 percent due to a 58-day labor strike in the potash mines of Carlsbad, N. Mex.

From 1959 through 1961, France, West Germany, and Spain were the leading countries from which potash was imported. In 1962, with the advent of Canadian potash production, Canada ranked third in U.S. imports; in 1963 it advanced to first place by contributing over 54 percent of the total.

Exports of potassium compounds rose 506,000 short tons K_2O equivalent in 1962 but dropped 16 percent in 1963.

All potassium compounds for fertilizer enter the United States duty free. The tariff on potassium chemicals ranges from 0.5 cent per pound for potassium hydroxide to 25 cents per pound for potassium iodide. On other potassium chemicals, not separately classified, the rate is 10.5 percent ad valorem.

The apparent consumption of potassium materials remained fairly level during 1959, 1960, and 1961 but started climbing in 1962 and in 1963 was over 25 percent greater than in 1958. This consumption amounted to about 30.5 pounds per year per capita.

Table 4 shows world production of potassium compounds in tons of K_2O equivalent.

TABLE 3.—*Salient potash statistics*

[1] Estimate.

[2] Partly estimated and rounded. Includes minor producing countries.

STRATEGIC CONSIDERATIONS

Although import tonnage totaled nearly 21 percent of domestic consumption in 1963 and annual increases are expected from Canada, the United States is more than self-sufficient in potassium.

Potassium compounds are not on the Government list of strategic and critical materials even though they are essential for maintaining and expanding the agricultural output of the United States. Domestic production has been concentrated in southeastern New Mexico and is likely to remain so for several years. In addition, southeastern Utah is expected to become a major producing area within the next 5 years.

GOVERNMENT PROGRAMS

The potassium-bearing lands of New Mexico are owned largely either by the State or Federal Government and are leased from them by the individual firms. The brine deposits in California and Utah are partly Federally owned. Under an act of Congress approved February 7, 1927, entitled "An Act To Promote the Mining of Potash on the Public Domain" (44 Stat. 1057, 30 U.S.C. 281), the Secretary of the Interior is authoried to issue prospecting permits for a period not to exceed 2 years, sub-

ject to such rules and regulations as he may prescribe. The Code of Federal Regulations, Title 43—Public Lands, Interior, Part 194, Potassium Permits and Leases, governs exploration, development, and production on the public domain. Rental for Federal land is 25 cents per acre for the first year, 50 cents per acre for the second through the fifth years, and $1 per acre for each subsequent year. Rental is credited toward any royalties due. After a "startup" period of reduced royalty, all producers pay a 5-percent royalty on gross value of potassium compounds and related products.

As almost all the major producing areas in the United States are on the public domain, the rules and regulations under which the Secretary of the Interior issues permits have a vital effect upon the industry.

In addition to these controls, the Geological Survey supervises potash operations on the public domain under terms of the lease.

PRICES

Prices for potassium compounds are quoted on the short-ton unit (1 percent, or 20 pounds, K_2O per ton) and f.o.b. the mine. Bulk prices for New Mexico muriate, 60 percent K_2O minimum, in the crop year 1963–64, depending upon the order and delivery dates, ranged from 35 to 40 cents per unit for standard grade, 36 to 41.5 cents for coarse, and 37 to 44 cents for granular. Sulfate of potash, 50 percent K_2O minimum, ranged from 67 to 76 cents per unit, and manure salts (run-of-mine) remained steady at 17.65 cents.

TAXES

No special Federal taxes are imposed on the potassium-compounds industry. Producers in New Mexico are subject to a severance tax of 2.5 percent of the gross value of sales. Producers are granted a depletion allowance of 15 percent on both domestic and foreign production.

TRANSPORTATION

Potash ores are usually processed in refineries adjacent to the mines, and the marketable product is shipped by rail to the consuming areas. Table 5 gives the February 1964 freight rates for domestic shipments to selected cities from Carlsbad, N. Mex., Trona, Calif., Wendover and Potash, Utah, and Yarbo, Saskatchewan, Canada. Shipments for export are given a lower freight rate to the port of embarkation. In the major consuming areas, mainly east of the Mississippi, transportation costs amount to about one-half the price of the muriate. The eight States bordering the Great Lakes account for more than 40 percent of the total U.S. consumption. Canadian potash has a slight freight advantage over potash from Carlsbad in much of this area and is competitive in the rest.

Freight advantage for imported potash from Europe extends inland 100 to 150 miles from the Atlantic seaboard ports of entry.

TABLE 5.—*Freight rates per short ton for muriate of potash (including manure salts) and sulfate of potash from the major producing centers for domestic shipments, minimum weight 80,000 pounds, February 1964*

Destination	From Carlsbad, N. Mex.	From Trona, Calif.	From Wendover, Utah	From Potash, Utah	From Yarbo, Saskatchewan

RESEARCH

As a result of the shortage of potassium compounds during World War I, Government agencies, private research organizations, and individuals investigated all the then known sources. In an attempt to increase the supply in the United States, the Bureau of Mines devised methods of recovering potassium salts from alunite, wyomingite, polyhalite, greensands, and porphyry-copper tailings. The methods were not perfected, because the indicated cost was excessive, domestic deposits of soluble ores were discovered, and imports again became available. As a result of research, participated in by the Bureau of Mines in the early 1930's, to devise ore dressing techniques adaptable to soluble salts, flotation is now used extensively in the New Mexico potash field.

Dry beneficiation techniques to separate sylvite from halite ore have been sought; however, experiments with laboratory-scale equipment were only partly successful. Fines and

small quantities of sulfate minerals caused incomplete separation.

Fertilizer research by the U.S. Department of Agriculture includes projects on producing and using high-analysis potassium-bearing fertilizers.

The American Potash Institute research program, active for more than 25 years in North America, deals largely with correct fertilizer usage.

Attempts have been made in the United States, Canada, and England to recover soluble potassium compounds from underground deposits by solution mining. Until recently none of these attempts have been successful. Late in 1964, however, a solution method was used for commercial production in Saskatchewan, Canada. Several other firms in the area are studying the technology and economics of using the solution technique on their properties.

OUTLOOK

Potassium mineral resources are adequate to meet any forseeable future demand. Present capacity is capable of meeting the short-term demand. Expansion of operating properties and development of new deposits are expected which should make it possible to supply the anticipated world demand of 20 million tons K_2O by 1980.

Further development of Canadian deposits will enable production of over 3 million tons of K_2O equivalent by 1970. Canadian material will continue to compete with domestic material in the major consuming areas of the United States. In addition, Canadian potash will be a strong competitor of domestic potash for foreign markets.

No new agricultural uses for potassium compounds are foreseen; however, demand for higher analysis materials will continue to increase. The agricultural need also will expand. With years of growing crops which use somewhat more potassium than is added annually as fertilizer, the soil becomes more and more deficient in this important plant nutrient. It thus becomes necessary to add as much potassium to the soil as the amount removed by the crops. An estimated 5 million tons, K_2O equivalent, are removed annually by cropping.

Discovery of deposits nearer the major consumer areas would encourage increased utilization. New industrial uses of potassium compounds will be developed, such as new explosives and propellents, but the requirements probably will not be large compared with total consumption of potassium compounds.

Although the reserves are enormous, insoluble potassium-bearing minerals will not contribute materially to the world supply in the foreseeable future.

PROBLEMS

The removal of potassium compounds from the soil by crops, solution, and erosion presents an obstacle to providing agricultural products needed for a continually rising standard of living for an increasing population.

Increased competition from imports, especially from Canada and Europe, hinders expansion of the domestic producing industry.

Technologic problems are the lack of economic mining and beneficiating techniques for recovering potassium compounds from lower grade sylvinite and polyhalite beds, such as those that could be exploited from present mine workings in New Mexico.

A long-range problem—to insure complete self-sufficiency for the United States virtually forever—is to find ways of utilizing the potassium compounds found in insoluble minerals and in saline water.

PUMICE

By Timothy C. May [1]

ONE of the products of volcanic action is a sponge like cellular rock, pumice, which floats on water and is exceptionally resistant to both chemical and physical destruction. Its unusual characteristics have made pumice a useful construction material and abrasive throughout man's history.

In the United States pumice in consolidated form was used for building construction in California as early as 1851. From that date through 1963 the domestic pumice industry has grown to 2.6 million short tons of annual domestic output, valued at $6.6 million, produced from 103 operations in 15 States. Arizona is the leading domestic source, and Italy and Greece are the major foreign sources.

Of all domestic pumice and pumiceous materials used in 1963, the principal uses were 34 percent as aggregate and concrete mixtures, 32 percent for road construction, and 23 percent as railroad ballast.

Pumice deposits have been formed from lava flows and particles ejected explosively from volcanoes and transported and classified by air currents. Commercial pumicite deposits range from Tertiary to Recent, and older rocks formed from pyroclastic materials occur in strata as old as Ordovician.

Mining is usually open pit, and the overburden and pumice are removed by standard earth-moving equipment. Processing includes crushing, screening, and sometimes drying. For producing abrasive grades, grinding and air separation are usually employed.

Pumice resources are ample, but many deposits are in remote areas.

The problems of industry include the high cost of transportation to markets, health hazards, nuisance difficulties caused by dust, lack of sufficient research on mining, processing, and marketing, and stockpiling of excessive quantities to meet various size requirements of consumers.

BACKGROUND

As early as 1851 buildings in California were constructed of rhyolite tuff, a rock composed of consolidated pumice fragments. Probably the earliest record of domestic pumice production for abrasive purposes was in 1883, when 70 tons was mined from a deposit at Lake Merced near San Francisco. Ground pumice was mixed with cement and used as lining for the Los Angeles Aqueduct, constructed from 1908 to 1918 (*4*).[2]

Notwithstanding the early use of pumice in the domestic construction industry, the United States lagged behind other countries in recognizing the utility of pumice in the lightweight aggregate field. Before World War II Germany had built up a substantial export trade in lightweight building-construction units. However, the large-scale use of pumice as concrete aggregate in the United States did begin in 1935 and has increased rapidly since then.

Vesuvius has been the source of much of the Italian pozzolan cement, so named from the town of Pozzuoli near Naples. Cement containing volcanic debris was used in constructing parts of the famous Roman walls, aqueducts, the old Roman harbor works at Porto Trejano, Porto d'Anzio, and in other historic structures. These have proved the lasting qualities of pozzolanic cements.

SIZE ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1963, 97 companies, individuals, or local government agencies operated 103 mines pro-

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

ducing pumice or pumiceous materials. Those handling the largest tonnages shipped relatively low-value products used for railroad ballast, road construction, and lightweight aggregate. In 1963 the total domestic production, including scoria and related material, was 2.6 million short tons valued at $6.6 million at the mines.

Pumice or other detrital volcanic material is widely distributed. Commercial production in 1963 was confined to deposits of relatively recent geologic age in 14 Western States and Hawaii. These producing States were Arizona, California, Colorado, Idaho, Kansas, Nebraska, Nevada, New Mexico, Oklahoma, Oregon, Texas, Utah, Washington, and Wyoming. Deposits of pumice and pumicite have been mined in Alaska (*12*).

Important foreign sources include the Lipari Islands off the northern coast of Sicily, Santorin Island of the Greek Archipelago, the Rhine Valley, Germany, Austria, Japan, and southern France. Canada has unworked deposits in Saskatchewan and British Columbia.

Although volcanic explosions of past geologic periods have distributed volcanic ash and dust over a large part of the world's surface, only the more geologically recent eruptive areas now provide commercial pumice deposits.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Pumice is a highly cellular, glassy lava, acid to basic in chemical composition and essentially unaltered since formation. Much of it will float on water. The vesicles in pumice were formed by expanding water vapor and possibly other gases while the lava was in a plastic condition. Most pumice is white to gray, although other constituents sometimes impart a red, yellow, brown, or black color. The dark-colored pumiceous materials are formed from basic magmas and usually called *volcanic cinder*, *cinder*, or *scoria*. Other terms frequently applied to pumiceous or scoriaceous materials are *lapilli*, *black ash*, *volcanic ash*, or *volcanic dust* (*13*). All these terms are applied loosely and have not been defined by way of chemical composition other than that the light-colored materials are trachytic or acidic and those of dark color are basic.

Pumicite denotes concentrated sand-size particles of natural volcanic glass ejected from volcanoes during periods of eruption and subsequently more or less classified while transported by winds. The particles may be wholly unconsolidated or somewhat cemented. In the latter instance the resulting rock is usually defined as a *tuff*. *Welded tuffs* are the result of the cementation of pumice particles caused by volcanic heat. *Trass* is a German term applied to a light-colored, silicified, trachytic tuff occurring especially in the lower Rhine valley.

In addition to pumice, in commercial parlance a concentration of detrital volcanic material such as pumicite, volcanic cinder, volcanic ash, and scoria is frequently grouped as pumice. Except where specifically qualified in this chapter, the term will be used in the inclusive commercial sense.

An average chemical analysis of eight domestic and foreign pumice samples, in percent, is: SiO_2, 70.86; Al_2O_3, 1.41; Fe_2O_3, 1.33; FeO, 2.05; MgO, .74; CaO, 1.72; Na_2O, 3.60; K_2O, 3.28; H_2O, 2.88.

Standard screen sizes of ground pumice offered by the trade ordinarily range from minus 6-mesh for use in tumbling barrels or coarse metal finishing to minus 200-mesh for fine polishing. Finer particle sizes are obtained by air floating in air cyclones and other forms of air separation. These fine sizes are used for special cleaning and polishing compounds, principally in the glass industry.

Pumice for abrasive use should be extremely vesicular, with vesicle walls thin but strong. It should be uniform in composition, free from oversize particles or particles harder than the homogeneous pumiceous mass. Flat, platey grains are undesirable; the ideal shape would be cubic. It is customary for most grades to be selected on an experience basis owing to the difficulty of anticipating the performance of pumice of various grain sizes and sources on specific materials under various abrasive operating conditions.

Specifications of pumice used for railroad ballast, road surfacing, and aggregate are much less stringent than for abrasive use. Such material is often used with little preparation and sells at a relatively low price.

Pumice, while in itself possesses no cementitious value, will in finely divided form and in the presence of moisture chemically react with calcium hydroxide at ordinary temperatures to form compounds possessing cementitious properties (*8*).

The actual specific gravity of pumice is about 2.5. The bulk density, of course, varies with the percentage of voids present. Fine material from Deming, N. Mex., after crushing, weighs 1,200 to 1,300 pounds a cubic yard, and the coarse weighs 800 to 900 pounds a cubic yard. The moisture content of this pumice varies from 5 to 20 percent, depending on the season.

TECHNOLOGY

Geology

Pumice and associated materials are products of explosive volcanism, and commercial deposits usually are found as concentrations near active or geologically recent volcanoes. Many pumicite deposits are composed of pumiceous particles transported many miles by air currents; other deposits are found on the flanks of volcanic cones.

This transported material extends to the Eastern States forming impure, noncommercial, pumiceous accumulations. Many have been consolildated into beds, which are only slightly altered. Frequently earlier beds have undergone severe metamorphism. The geologic age of most domestic, commercial pumice and pumicite deposits ranges from Tertiary to Recent (*11*).

The light colored pumice and volcanic ash are acidic to subacidic in chemical composition, whereas volcanic cinder, scoria, and dark pumiceous materials are much more basic. On the basis of mode of deposition, size distribution of the particles or fragments, and origin of the material, deposits of pumice and pumicite have been grouped into a number of types (*7*) : (1) subaerial deposits, (2) subaqueous deposits, (3) vesiculated surfaces of obsidian domes or flows, (4) reworked deposits, and (5) "nuée ardente" deposits—deposits formed by a swiftly moving, often violent horizontal ejection of gas-charged, highly heated viscous lava, carrying large and small lava fragments and accompanied by a cloud of gas and ash.

Mining

Although some pumice mining in California has been underground, almost all current production is from open pits.

Overburden usually is present and is removed by standard methods. Well-consolidated tuffs sometimes must be blasted. Loose pumice particles and loosely consolidated tuffs generally can be excavated with a bulldozer or dragline.

The bulldozer can move the material to storage piles near loading chutes or directly over tunnels enclosing belt conveyors for delivery to trucks or screening plants.

Milling

A scalping screen usually removes vegetable matter and oversize lumps. Rolls and hammer mills may be used to reduce oversize fractions; various screening and blending systems are used to produce the desired gradings.

Pumice may be dried in rotary driers either before or after crushing. The finer sized products, for abrasives, are produced with air separators and screens. Some pumice has been beneficiated on pneumatic concentrating tables.

Pumice products for abrasive use are packed in paper or burlap bags or barrels for shipment. Aggregates are shipped in bulk.

Domestic pumice is prepared for market near the mine; foreign pumice usually is imported in the crude state. Imported abrasive grades are crushed, ground, dried, screened, and air separated at plants on the eastern seaboard. Foreign crude pumice requires little preparation for use as a lightweight aggregate.

USES

Until the mid-1930's the only important domestic use for pumice was as an abrasive. Thereafter, its use developed as a lightweight aggregate for concrete and with gypsum in acoustic fire-retardant building plaster. The use of volcanic cinder and scoria for road surfacing and railroad ballast has become a major use for this material. Pumice is also becoming important as a pozzolan in hydraulic cements (*1*). Ground pumice and volcanic ash, added to hydraulic cements, improve workability of the concrete, counteract excessive free lime, increase strength, and improve durability (*4*).

Smaller quantities are used for many purposes including cleansing and scouring compounds and hand soaps, other abrasive uses, diluents, absorbents, and carriers for insecticides, herbicides and fungicides, filter beds,

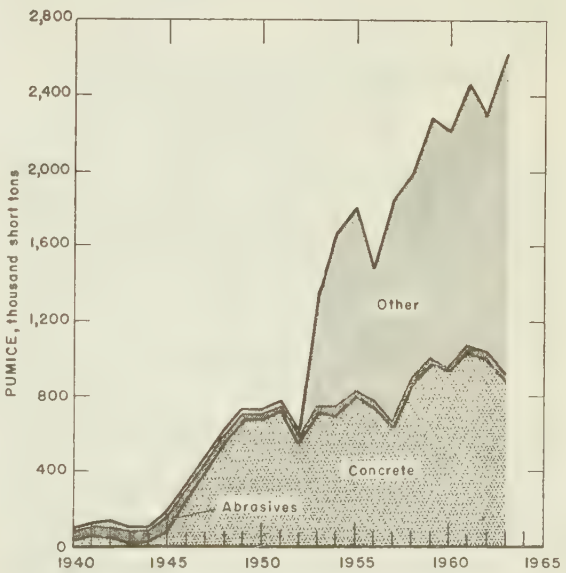

FIGURE 1.—Trends in Pumice by Uses.

lightweight refractory brick, soil conditioning, catalyst carrier, decolorizing and purifying agents, packing, filler and extenders for paints, enamels, varnishes, plastics, paper and rubber goods.

ALTERNATE MATERIALS

Under various conditions pumice competes as a lightweight aggregate with expanded clays and shales, expanded perlite, exfoliated vermiculite, slag, cinders, and diatomite. Expanded perlite and foamed glass are virtually synthetic pumices (*10*).

As an abrasive in block form, pumice competes in the market with brick made from silicon carbide, aluminum oxide, and natural rock such as novaculite and sandstone.

In the form of loose abrasive grain, pumice and pumicite encounter competition from garnet, silica sand, tripoli, diatomite, aluminum oxide, and silicon carbide.

Among the substitutes for pumice and pumicite used as pozzolans are fly ash and diatomite.

Exfoliated vermiculite and expanded perlite compete with pumice in the acoustic plaster market.

RESERVES

Domestic resources occur principally in Arizona, California, Hawaii, and Oregon. They are very large and appear adequate to meet foreseeable demands.

Foreign localities where major pumice resources occur are France, West Germany, Greece, Italy, and New Zealand. These deposits should provide ample quantities for importation into the United States. Recent exploration reveals substantial deposits in the lesser Antilles Islands.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines canvasses all known pumice operators annually. Most pumice miners are comparatively small-scale producers and many operate intermittently. Thus only a minimum of statistical detail has been accumulated.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic pumice sold or used by producers in the United States is shown in table 1.

Fourteen States west of the Mississippi and Hawaii produced pumice or pumiceous materials in 1963. Arizona with 10 active mines was the largest producer. California with 33 mines was next as shown in table 2.

TABLE 1.—*Pumice sold or used by producers in the United States*

[Thousand short tons and thousand dollars]

Year	Pumice and pumicite		Volcanic cinder		Total	
	Quantity	Value	Quantity	Value	Quantity	Value
1954–58 (average)	933	$2,869	813	$1,332	1,746	$4,201
1959	784	3,267	1,492	2,596	2,276	5,863
1960	601	2,767	1,609	2,802	2,210	5,569
1961	936	4,203	1,527	2,596	2,463	6,799
1962	533	3,206	1,738	3,095	2,271	6,301
1963	1,050	3,321	1,568	3,257	2,618	6,578

During 1963, 34 percent of all pumice consumed was used as aggregate and concrete mixtures, 32 percent for road construction, and 23 percent as railroad ballast.

TABLE 2.—*Pumice sold or used by producers in the United States*

[Thousand short tons and thousand dollars]

State	1962		1963	
	Quantity	Value	Quantity	Value
Arizona	756	$1,640	800	$1,877
California	573	2,615	460	2,017
Colorado	76	82	60	87
Hawaii	232	380	274	469

Pumice used as a concrete aggregate, railroad ballast, and for road surfacing is sold in a low-price market and must compete with many substitutes. Hence the market area for any deposit is limited by transportation costs and the availability of competitive materials. As abrasives, pumice sells at a much higher average unit price; transportation is a smaller part of the total cost, and shipments are made over much greater distances. High-quality pumice is imported from foreign sources in crude form for processing domestically for abrasive purposes.

Greece and Italy have been important sources of imported pumice for many years. Unmanufactured pumice imports during 1963 valued at $15 per short ton or less, not including freight, were 6,345 tons from Italy valued at $54,000. Unmanufactured imports valued at more than $15 per ton were 1,230 tons valued at $30,000, all from Italy.

Wholly or partially manufactured pumice imports totaled 3,555 tons valued at $119,000. All of this was from Italy.

Imported abrasive-grade pumice is preferred by some users. Much of the low-cost imported pumice goes to the New England seaboard for use as a lightweight aggregate because the delivered cost is less than that for Western domestic pumice of similar quality.

The domestic duty for pumice per pound at the end of 1963 was: crude valued at $15 a short ton and under, 0.0425¢; crude valued over $15 a ton, 0.08¢; wholly or partly manufactured, 0.35¢.

STRATEGIC CONSIDERATIONS

The United States is considered to be self-sufficient in pumice supplies. During World War II no imports of Greek or Italian pumice were permitted, and although foreign pumice is claimed to be superior for some abrasive applications, there were no serious effects as a result of the embargo.

PRICES

There is a wide difference between the price of pumiceous materials suitable for abrasive purposes and that of those used for railroad ballast, road surfacing, and similar large-scale requirements. The price of domestically produced processed pumice in 1963, in ton lots, in bags, was $86 for fine and coarse ground, f.o.b. New York. During this period imported Italian, sundried, coarse and fine pumice, in bags, was $75 per short ton, f.o.b. New York.

TAXES

There are no special taxes imposed on the pumice industry. A 5-percent depletion allowance is permitted on domestic and foreign pumice operations.

TRANSPORTATION

Transportation cost is an important factor in the economics of the pumice industry. Abrasive grades can be shipped great distances to markets, even from foreign sources, but pumice of low-market value usually is limited to a few hundred miles by rail or truck. As ocean freight rates are less than land freight rates, oceanic shipments can be made over relatively longer distances.

RESEARCH

No comprehensive program of research on pumice has been announced. The relatively small income from most pumice operations makes it difficult to support a research program.

Publications outlining Government research in lightweight aggregates that involved pumice are shown in the references (*2*, *3*, *6*, *7*, *9*, *10*).

The Bureau of Reclamation and the U.S. Army Corps of Engineers conduct applied research on pozzolanic additives, including pumice, for cement.

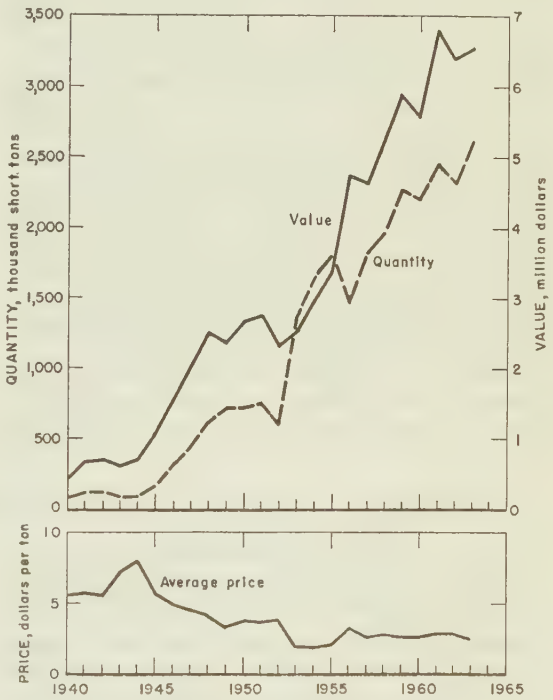

FIGURE 2.—Total Value, Quantity, and Average Price per Ton of Pumice.

OUTLOOK

Trends indicate that pumice production, during the 5-year period ending in 1969, may approach 16 million short tons compared with 12 million tons in the 1960–64 period.

With the rate of population growth increasing in the West and Southwest, local demand for pumice aggregate to be used in housing, roads, and industrial and commercial construction is expected to increase.

The results of studies made on the properties of lime-silica mixtures indicate a possible increase in use of pumice, pumicite, and volcanic

cinders as pozzolans in construction of dams and bridges.

The growth of manufacturing industries in the Western States may increase demand for the better grades of pumice used in scouring and rubbing blocks, as abrasives for glass and metal finishing, insecticide carriers, mechanics' soaps and paint fillers.

New deposits may be developed as demand increases, but exhaustion of present resources is not likely in the foreseeable future at present rate of consumption.

PROBLEMS

Specifications for pumice aggregates are not consistent but vary with different users; therefore, some producers or suppliers are required to stockpile excessive quantities of pumice materials to meet the various aggregate size requirements of consumers.

Production of uniform standardized pumiceous products is usually impractical because pumice from different deposits varies in physical characteristics. The lack of standardization in some areas tends to discourage the movement of pumice from one State to another, even though an interstate source may be within a more economical hauling range than the nearest intrastate source. Although some high-priced abrasive grades may be shipped long distances, the average value of most pumice is so low that high-shipping costs cannot be absorbed; thus the marketing area is restricted. Shipping distance for lower quality pumice used in road construction and as a lightweight aggregate is usually limited to only a few hundred miles and must compete with locally produced expanded clay, shale, or perlite, and slag or cinders.

Inasmuch as the product is sold at a low price, producers find it difficult to finance research that might increase usage or acceptability of the material. Technical information concerning mining, processing, and uses is limited or unavailable to some producers, and the growth of the industry is consequently limited.

Through research that has been done by some end-use industries, such as lime-silicate plants, additional problems have been noted:

(a) Some pumices have a flaky structure that makes them weaker and more absorptive than those having more normal vesicular form. This tends to promote higher shrinkage values and, in addition, the degree of fineness to which these pumices can be reduced for maximum strength and hydraulicity is limited.

(b) Absorption of moisture through hairline cracks between flakes and pores is a critical and undesirable characteristic, influencing changes during wetting and drying cycles. This excessive capacity for absorbing water possessed by pumice makes it difficult to use conventional concrete mix designs based on water-cement ratios.

(c) The small particle size and dusty nature of some pumices pose problems in the heat treatment process used to reduce or close pores and also presents a health hazard and a community nuisance problem.

QUARTZ CRYSTAL

By Benjamin Petkof[1]

SINCE 1921 quartz crystal has been the preferred material for accurate frequency control in radio transmitters and many other electronic devices. These applications utilize the piezoelectric properties of quartz, by which a mechanical force produces an electrical charge and vice versa.

Thus, quartz crystal has become vital to civilian and military radio and communications activities. Its reliable frequency control and signal selection capability enable numerous radio transmitters to operate in narrow and crowded wavelength bands and multiple conversations to be carried on a single cable or carrier frequency.

Brazil is the only significant producer of optical and electronic quality natural quartz crystal. With technical and financial assistance from the United States during World War II, Brazil produced enough quartz crystal to meet U.S. requirements.

Since World War II the U.S. Army Signal Corps has sponsored and subsidized a comprehensive synthetic quartz crystal program in cooperation with industry and with private and government research organizations. Parallel studies of substitute materials have declined gradually in importance, and by 1958 the technical and commercial success of quartz crystal synthesis was assured.

The outlook is for expansion of industrial applications and a narrowing of the wide gap between peacetime and full mobilization requirements.

If manufactured electronic-grade quartz crystal replaces a substantial part of natural crystal for piezoelectric uses, complete self-sufficiency in all grades of clear quartz will require the establishment of domestic sources of suitable materials to replace Brazilian lasca, a byproduct of Brazilian electronic-grade quartz production now used in manufacturing fused quartz and as a nutrient for electronic-grade quartz synthesis.

BACKGROUND

The piezoelectric properties of quartz were discovered by Pierre and Jacques Curie in 1880–81. In 1917 Professor Langevin developed an ultrasonic submarine detection device for the French Navy, in which a generator of quartz crystal plates produced ultrasonic impulses. Although this submarine detector was not perfected until after World War I, this development stimulated interest in practical applications of ultrasonics and related phenomena.

In 1921 Professor Walter G. Cady of Wesleyan University, Middletown, Conn., discovered that quartz crystal could be used to control the frequency of radio oscillator circuits. A quartz plate of selected area and thickness serves as a piezoelectric resonator with a fixed mechanical vibration frequency that reacts electrically to control the frequency of the driving circuit (*2*, *9*).[2]

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

PROCESSING INDUSTRY ORGANIZATION

Electronic-grade quartz crystals are consumed by producers of quartz plates and other forms for piezoelectric applications. At the peak of World War II demand, 113 quartz crystal processing plants were in operation. In 1963, 34 crystal cutters in 15 States reported consumption of 325,000 pounds of quartz crystals. Most cutters produced finished units, although some supplied blanks to other firms. A total of 13 million quartz piezoelectric units was made by 53 manufacturers.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

All crystalline materials lacking a center of symmetry are piezoelectric (*11*). Among such piezoelectric crystalline substances, quartz has

the highest known efficiency of transfer back and forth between strain and motion or from potential to kinetic energy.

Electronic-grade quartz crystal must be free from certain defects but not necessarily colorless. The smoky variety can be used for oscillators. If necessary to permit inspection, the color may be removed by heating to about 400° C, or windows may be trimmed in opposite sides of a surface-strained crystal to permit internal visual inspection.

The grading and classification of electronic- and optical-grade quartz crystal involve sorting according to size ranges, separation of faced and unfaced crystal, and estimation of the percentage of usable crystal by inspection and testing to detect and evaluate imperfections and flaws (*14*).

The defects in both electronic- and optical-grade quartz occur as optical twinning, cracks, inclusions, veils, bubbles, needles, ghosts or phantoms, and electrical twinning. An experienced inspector can detect optically all defects except electrical twinning when the crystals are properly illuminated in an oil bath having the same refractive index as quartz. Electrical twinning, however, can be inferred by surface irregularities in the crystals. Monochromatic polarized light is used to detect optical (crystallographic) twinning, and the other defects are detected with moderate arc-lamp illumination in the same oil bath. It is desirable to establish suitable facilities and acceptable inspection practices near the primary source of supply of raw quartz to reduce transportation on material that would be rejected by processors. Buyers of raw quartz for piezoelectric uses usually depend on visual- and oil-bath grading. Electrical twinning is normally detected in the early stages of manufacturing piezoelectric units by etching sawed surfaces with ammonium bifluoride or hydrofluoric acid.

National Stockpile Material Purchase Specification P–43 (September 12, 1951) provides 133 different categories for stockpiled crystals. Industry uses smaller crystals than are acceptable for the strategic stockpile. Most of the industrial consumption in 1963 was of crystals weighing less than 500 grams, and there was substantial consumption of quartz crystal weighing under 200 grams.

TECHNOLOGY

Geology

By far the greater part of the commercial deposits of electronic-grade quartz in the free world occurs in Brazil. The clear quartz crystals from which electronic-grade crystals are selected usually occur in vugs or pockets in deeply weathered quartz veins or in blanket deposits of milky quartz. The deposits are small and irregular and are distributed over a large area, principally in the States of Minas Gerais, Goiás, Bahía, and Pará. Very few single deposits produced more than 500 pounds of usable crystal per month during World War II. The ratio of eye-clear crystal to excavated material range from 1 : 1,000 to 1 : 100,000 (*10, 17*).

Present data indicate that the typical characteristics of the Brazilian deposits generally are applicable to quartz crystal deposits elsewhere.

Mining

Because of the irregular occurrence of quartz crystal deposits and the need to avoid damage to crystals by heavy blasting or rough handling, recovery has been restricted almost entirely to hand mining.

Marketing

Much of the quartz crystal in Brazil is bought by itinerant buyers who deal with individuals, small groups of primary producers, or local merchants. The itinerant buyers channel their purchases to exporters who use oil-bath grading to supplement visual observation. About 10 exporters handle most of the trade. Exporters who ship to the United States usually deal with an individual U.S. importing firm or have a U.S. affiliate or branch office.

Manufacturing of Quartz Crystal Units (*14*)

Before cutting, crystals are reexamined for optical and electrical twinning. Accepted crystals are oriented in a diamond saw frame, and oscillator wafers are cut along a predetermined crystallographic plane to a thickness slightly greater than the desired final thickness. Each wafer is inspected, defective areas are marked for removal, and the wafer is diced into blanks of the desired dimensions. The blanks then progress through a series of lapping stages until they reach the desired final thickness, and electrodes are attached. The finished plates are usually 0.25 to 0.75 inch in diameter and about 0.01 inch thick, and are mounted in suitable holders. The assembly is termed a quartz crystal unit and is ready for insertion in an electronic circuit.

USES

The major use of electronic-grade quartz crystal is for the production of crystal-controlled oscillator units to provide accurate

frequency control for radio transmitters, radio-frequency telephone circuits, and crystal-controlled chronograph and emission counters. Quartz crystal units also are used as wave filters in receiving circuits to exclude incoming signals of undesired frequencies. In other applications quartz and other piezoelectric materials are used electrostrictively as transducers to convert electrical forces into mechanical forces, as in loudspeakers and supersonic generators.

A small proportion of the reported imports of electronic-grade quartz crystal is used for prisms, wedges, lenses, and other optical purposes.

Lasca is used as the nutrient material for manufactured-quartz research and production. Selected quartzites, flints, and other highly siliceous materials are potentially suitable as nutrients for quartz crystal synthesis (*1*).

Plates of flawless natural quartz crystal are cut to predetermined axial orientations and used as seed plates to produce manufactured quartz.

Some quartz crystal is cut and polished for semiprecious gem stones. Clear stones, free from inclusions and flaws, are required for this purpose, but either type of twinning may be present.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

A small proportion of the reported imports of electronic-grade quartz crystal is classified as optical-grade quartz. Optical-grade quartz generally comprises the crystals of highest quality in the medium- to large-size groups. Electrical twinning is not harmful, but freedom from optical twinning, stains, inclusions, and other visual or crystallographic flaws is essential.

As of December 1958, fusing-grade quartz for the production of clear fused quartz (*6*, *21*) was obtained entirely by hand selection and hand trimming of rejects from the production of electronic-grade quartz crystal in Brazil. The material, known as lasca, must meet consumer specifications of size and visual appearance. The Lamp Division, General Electric Co., Nela Park, Cleveland, Ohio, in April 1957 supplied revised specifications covering two classes of crystals. In both classes crystals must be water white and have a median weight of 15 to 25 grams, with specific limits on the allowable percentage of larger and smaller sizes. Specifications for the two classes of crystals differ principally in the permissible content of visual defects.

ALTERNATE MATERIALS

In radio and television transmission, quartz is by far the best material for frequency-control oscillators. Synthetic ammonium dihydrogen phosphate has been used for, and is preferred in, sonar work; and synthetic ethylene diamine tartrate has been substituted successfully for quartz in telephone filters. However, the latter substitution is not completely satisfactory, and the trend toward the use of quartz in telephone filters has resumed. Other materials for specific applications are dipotassium tartrate, usable for oscillators and filters, and lithium sulfate monohydrate for ultrasonic applications.

In ultrasonic generators for industrial applications, quartz crystal does not hold the supremacy it enjoys in frequency-control devices (*11*). Ultrasonic sirens activated by compressed air are used widely in agglomerating and precipitating aerosols. Barium and other titanate ceramics are used in some applications, and ferromagnetic materials are used in others in place of quartz.

Small quantities of fused quartz have been used in Germany in place of optical-grade crystal in making optical prisms.

Tourmaline, nephelite, and various other minerals possess piezoelectric properties. None of suitable quality is commercially available, and none is as good as quartz for frequency control; however, some might be useful commercially if adequate supplies could be established.

MANUFACTURE OF QUARTZ CRYSTAL (*3–4, 7–9, 13, 15–16, 18–20*)

Quartz crystals are grown in autoclaves at pressures ranging from 1,500 to 20,000 pounds per square inch or more, and at temperatures of 250° to 450° C. Growth takes place on seed plates cut from natural or manufactured quartz in a predetermined crystallographic plane. The solution usually used is sodium carbonate. Brazilian lasca has been used as the nutrient in most of the experimental work and production in the United States. In England, however, some local quartzites and flints have been used successfully as nutrients (*1*). Quartz crystal containing defects is also usable.

In 1958 Sawyer Research Products, Inc., Eastlake, Ohio, began commercial production of manufactured quartz and in 1963 reported sales of 18,000 pounds to foreign and domestic users. Western Electric Co., North Andover, Mass., produces manufactured quartz for the Bell telephone systems.

It is estimated that 1 pound of manufactured quartz is equivalent to 3 to 4 pounds of natural

quartz of the qualities and sizes most commonly used by industry.

RESERVES

The quantity of quartz suitable for nutrient material for the production of manufactured quartz crystal is unlimited.

There are no domestic reserves of natural quartz crystal suitable for electronic use. Intensive field investigations during and after World War II revealed no deposits.

Brazil, the world's largest producer of quartz crystal, is thought to have large but undetermined reserves of natural quartz. The future development of these resources will be controlled by the country's internal political situation and world demand for high-quality electronic-grade crystal.

No other major world reserves are known. However, the U.S.S.R. and China are thought to have large reserves.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines, through a canvass of importers and consumers of electronic-grade quartz crystal, obtains substantially complete data on the quantities of raw quartz consumed and the number of piezoelectric units produced. At intervals the Bureau obtains data from industry on the prices of quartz crystal and on progress in the output of synthetically produced quartz crystal.

The U.S. Department of Commerce compiles statistics on the quantity and declared value of imports of quartz crystal by country of origin, and on the declared value of exports and reexports of uncut and manufactured quartz crystal by country of destination. Lack of data on the quantity and quality of exports and reexports of uncut quartz crystal is the dominant factor in preventing reconciliation of consumption and imports for consumption.

PRODUCTION, CONSUMPTION, AND TRADE

As domestic production of electronic-grade quartz crystal is neglible, the United States is dependent on imports for its supply. The difference between imports and consumption represents rejections after reinspection, stockpiling, exports (unaccountable except for value), and small quantities used for optical and ornamental quartz (fig. 1).

The consumption of quartz crystal varies not only with the overall demand for quartz crystal piezoelectric units but also with the predominant types and sizes of units required and with industry practices regarding the use of large-

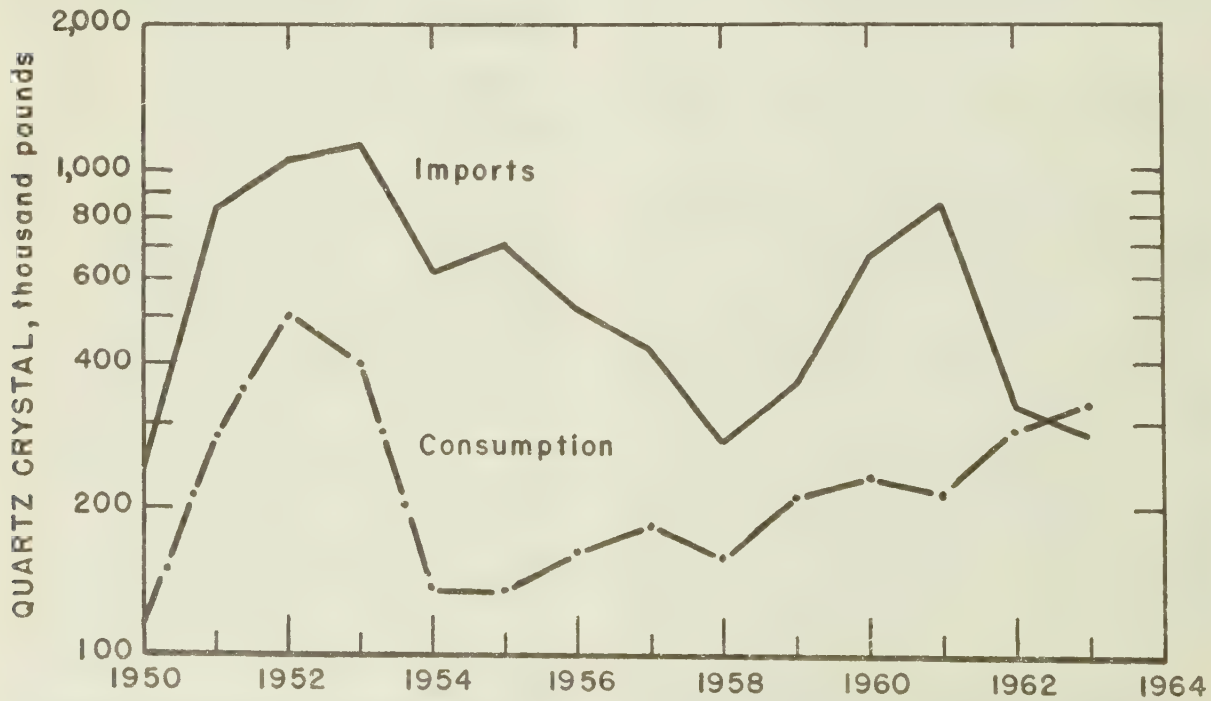

FIGURE 1.—U.S. Imports and Reported Consumption of Electronic- and Optical-Grade Quartz Crystal.

versus-small crystals. The number of piezoelectric units per pound of quartz, as reported by domestic consumers, fluctuated from 10.1 to 20.3 in 1942–50, from 11.7 to 33.6 in 1951–58, and from 28.6 to 43.4 in 1959–63.

Imports of electronic- and optical-grade quartz in 1963 totaled 282,176 pounds with a declared value of $446,719. About 99 percent of the imports of quartz crystal has come from Brazil. The remainder has come from the Malagasy Republic. Imports credited to France probably originated in the Malagasy Republic, and those credited to Japan originated principally in Brazil.

There is no tariff on imports of raw quartz crystal.

STRATEGIC CONSIDERATIONS

The U.S. quartz crystal fabricating industry has been completely dependent on foreign sources of raw quartz. The industry's dependence on imported material has decreased with the successful development of industrial methods for the manufacture of electronic-grade crystal. At the close of 1963 the total production capacity for manufactured quartz was estimated to be in excess of 70,000 pounds per year. This can be considered equivalent to about three times that quantity of natural quartz. Brazilian lasca has been used as nutrient material, but other varieties of quartz domestically available can be used.

The national stockpile of critical and strategic materials contains more than adequate stocks of natural quartz for use during any emergency. Inventories totaled 2,519 tons on June 30, 1964, of which 2,403 tons was in the national (strategic) stockpile, and 116 tons in the supplemental stockpile.

Brazilian production of natural quartz crystal is handicapped by remote sources, labor problems, and intricate political and commercial policies.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration, U.S. Department of the Interior, will advance 50 percent of approved costs on exploration programs for electronic-grade quartz crystal.

PRICES

Electronic-grade quartz crystal is priced according to weight, percentage of usability, type and distribution of flaws, and whether faced or unfaced. From 1958 to the present, prices have shown only minor variation. However, price is subject to negotiation between the buyer and seller on the basis of quality. Table 1 provides current price information on the basis of weight classes.

TABLE 1.—*Price range per pound of electronic-grade quartz crystal by weight class*

Weight class (grams)	Price per pound	Weight class (grams)	Price per pound
100–200	$2.00–$3.50	501–700	$12.00–20.00
201–300	4.00–12.50	701–1,000	18.00–24.00
301–500	8.00–14.00	1,001–2,000	24.00–35.00

At present, manufactured quartz crystal is quoted at $27.50 per pound. Crystals can be grown to the buyers' size specifications.

TAXES

Producers are granted a depletion allowance of 23 percent on domestic production and 15 percent on foreign production.

RESEARCH

The U.S. Army Research and Development Laboratory, through contracts with industry, universities, and others, sponsored an extensive program to develop and evaluate manufactured quartz crystal from 1946 to 1964. The program reached its peak effort during 1954 and 1955. At present, effort is primarily concentrated on the further development of quartz crystal units using both natural and manufactured quartz. The Laboratory also evaluates prospector samples of domestic crystal.

During World War II the Bureau of Mines examined numerous quartz crystal deposits in the United States and published more than 70 reports covering field investigations on occurrences. Since World War II, Bureau activity on quartz crystal has been confined to the collection and dissemination of technical and statistical data.

OUTLOOK

The domestic quartz crystal fabricating industry has entered a period of transition from the complete use of natural quartz crystal to the partial use of manufactured quartz for the production of quartz elements. In 10 to 20 years manufactured quartz may completely displace natural quartz crystal as the fabricator's starting material. The development of faster growth rate, better quality, and higher *Q-factors* for manufactured quartz will tend to accelerate the transition.

Quartz crystal units will be produced in increasing numbers owing to the increasing requirements of the electronic and communications industries. The quantity of raw quartz consumed will remain stable or decrease because

of improved cutting techniques for both natural and manufactured quartz, and the continuing trend toward greater miniaturization of crystal units.

Natural quartz crystal imports should decline as manufactured quartz becomes more generally accepted by the industry. The lower price of natural quartz and its higher *Q-factor* will be offset by greater labor and cutting efficiency, higher cut-crystal yield, and future improvement of the *Q-factor* of manufactured materials.

Since 1958, the production and consumption of manufactured quartz has increased slowly. As industry obtains greater experience and know-how in utilizing this material, production and consumption will continue to increase although the rate of increase cannot be predicted. Plant production capacity will increase owing to new plant construction and the improvement of growth rate in existing plants. In several years, production capacity will reach about 100,000 pounds per year.

PROBLEMS

The unavailability of domestic sources of piezoelectric quartz has always been a primary problem. With increased use of manufactured quartz, this problem will become less important and may completely vanish.

Decreasing use of Brazilian quartz may cause decreases of the available supply of Brazilian lasca, which has been used as the feed material for the manufacture of cultured and fused quartz. Development of suitable domestic sources for these purposes will be necessary.

The continuing necessity for improving finished crystal units will require constant research. Changing operational specifications also will demand continual applied research in such areas as frequency variation with temperature, effect of small impurities in the crystal, radiation, and vibration effects.

The strategic stockpile contains an excess of about 4.4 million pounds of electronic-grade quartz. With improvements in the quality of manufactured quartz and the expansion of production capacity, revision of Government stockpile requirements for both quantity and quality will occur. Disposal of excess stockpile material at reasonable prices will be a major problem.

RADIUM

By John G. Parker[1]

THE EXISTENCE of radium was first discovered by the Curies and G. Bémont. Several years later Mme. Curie isolated the first pure salt of radium and in 1910 she prepared the metal in cooperation with A. Debierne.

Pitchblende ore from Bohemia was the first source of radium, and Austria-Hungary was the main producer in the first decade of this century. From 1911 until the early 1920's, the United States was the major world producer of radium from Colorado Plateau carnotite deposits. U.S. production was curtailed by exploitation of high-grade pitchblende deposits in the former Belgian Congo. Belgium was the only primary radium producer until the 1930's when, through production from the Great Bear Lake pitchblende deposit in the Northwest Territories, Canada became a major supplier of radium. When Canadian production ceased about 10 years ago, Congolese pitchblende again became the principal source of radium. Although ore production was discontinued at the Shinkolobwe deposit in the Congo (Léopoldville) in 1960, radium-bearing slimes are still being processed in Belgium.

Radium has the distinctive property of emitting penetrating rays. It has been used by the medical profession in the treatment of cancer and by industry in radiography, in luminescent compounds, as a component of neutron sources for oil well logging, and in static elimination devices. In recent years competition from certain radioisotopes has increased greatly, but in some fields, especially in medical therapy, the long half life and radioactive spectrum of radium are its main advantages. However, radium has certain potential health hazards, and licensing of radium and inspection of facilities by various States are increasing.

BACKGROUND

Pierre Curie, Marie Curie, and G. Bémont discovered radium in 1898 while chemically treating pitchblende ore from the Joachimsthal silver mine in Bohemia, now the westernmost part of Czechoslovakia. In 1902 Mme. Curie isolated the first pure salt of radium—radium chloride—and in 1910 she and A. Debierne prepared the metal.

Joachimsthal was the main supplier during the early years of interest in radium. The ore was first processed for radium in France and shortly afterward in plants in Germany and in Austria. Because the Bohemian ores and plant were a monopoly of the Austro-Hungarian Government, the increasing interest in radium led to a worldwide search for other radium-bearing ores. Other foreign uranium mineral deposits from which radium was processed in this period are in Australia; Cornwall, England; the Malagasy Republic; Portugal; the U.S.S.R.; and the Republic of South Africa.

Although uranium minerals were discovered in Katanga in the former Belgian Congo in 1913, the first large production of radium-bearing ores outside Europe came from Colorado Plateau carnotite deposits in the United States, some of which had been mined years before. Beginning in 1911 Standard Chemical Co., Pittsburgh, Pa., exploited the U.S. ores, which were then shipped to France and to the Joachimsthal plant for treatment. By 1913 and 1914 several other companies had been formed and domestic processing plants had been started. To obtain supplies quickly for radium therapy, the Bureau of Mines entered into a cooperative agreement with the National Radium Institute in 1913 to study methods for producing and processing radioactive ores. By January 1917, shortly after the agreement expired, about 8,500 milligrams of radium had been extracted, processing costs had been greatly reduced, and methods for recovering by-product uranium and vanadium had been de-

[1] Commodity specialist.

veloped by Bureau technical personnel working at the plant erected by the Institute. The nearly 2,000 milligrams that had become the property of the Bureau of Mines was loaned to various medical and educational institutions until 1954, when most was transferred to the U.S. Atomic Energy Commission (AEC), Oak Ridge, Tenn.; the National Institutes of Health, Bethesda, Md.; and the National Bureau of Standards, Washington, D.C. A small quantity held in the Memorial Hospital, New York City, was recently transferred to the Public Health Service, U.S. Department of Health, Education, and Welfare, Washington, D.C.

The U.S. industry continued as the major supplier of radium until the early 1920's, at which time the rich Congolese uranium deposit at Shinkolobwe was exploited by Union Minière du Haut-Katanga. The refinery at Oolen, Belgium, which went into operation in 1922, produced radium so cheaply and abundantly that by 1925 all U.S. mining companies had ceased operations and Belgium was the only primary producer of radium.

Domestic radium refining has been sporadic, and production quantities have not been available since the early 1940's. Canadian Radium & Uranium Corp. operated a refinery at Mt. Kisco, N.Y., principally for secondary recovery, until about 1957.

With the discovery of pitchblende deposits at Great Bear Lake, Northwest Territories, in 1930 and the establishment of a refinery at Port Hope, Ontario, Canada became a major supplier of radium. A cartel agreement was soon reached between Belgian and Canadian producers to divide the world market on a 60–40 basis. The agreement was dissolved in 1941.

In 1939–40 Radium Chemical Co., Inc. of New York, the sales representative of Union Minière, imported enough pitchblende ore from Belgium to supply U.S. and Canadian refineries with raw material for 100 grams of radium, believed to be enough for the wartime emergency. Early atomic research by the Manhattan Project during World War II depended partly on this supply of 1,200 tons of stockpiled pitchblende ore. In addition, other Congolese ores were shipped directly from Africa to North America by fast freighters for refining, primarily for their uranium content. The war years were the last for the Canadian producer, Eldorado Mining & Refining, Ltd. which sold all stocks of refined radium to Atomic Energy of Canada, Ltd. in 1955. Since then, most primary radium has been derived from Congolese pitchblende ores processed at the Oolen, Belgium, refinery.

GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The principal domestic suppliers of radium and its compounds are the Canadian Radium & Uranium Division, Canrad Precision Industries, Inc., New York, N.Y.; Radium Chemical Co., Inc., New York, N.Y., the U.S. outlet for radium recovered and refined by the Belgian firm Union Minière du Haut-Katanga; United States Radium Corp., Morristown, N.J.; and A. Bruce Edwards, Bala-Cynwyd, Pa., sales representative for Atomic Energy of Canada, Ltd., Ottawa, Ontario, Canada.

Stocks of Congolese pitchblende concentrates and radium-bearing slimes produced prior to April 1960 by Union Minière are processed by Société Générale Métallurgiques de Hoboken at its refinery in Oolen, Belgium.

DEFINITION OF TERMS (*11*) [2]

The importance of radium and similar elements is due to their emission of rays or radiations. Radium and its related elements are unstable, implying that the nucleus of the element is capable of changing by emitting one or more of its particles or rays. The particles or rays emitted by unstable nuclei are called nuclear radiation, and atoms that give off such radiations are called radioactive.

Radiation intimately related to radium are alpha particles, beta particles, and gamma rays.

An *alpha particle* is identical with a helium nucleus. Although these particles are so small that 1×10^{20} of them are about as large as the head of a pin, they are the largest electrically charged particles known. They constitute the emission of major importance in radium but have little penetrating power; a few inches of air or a sheet of paper will stop them.

Beta particles, about 1/7200 as large as alpha particles, are identical with electrically negative electrons which can travel several yards through air and penetrate as much as one-third inch of body tissue.

Gamma rays are not particulate in nature but are electromagnetic radiations of high energy originating in atomic nuclei. They are physically the same as high-energy X-rays, can travel hundreds of feet through air, and are capable of penetrating many inches of almost any type of solid material. Radium emits small quantities of gamma rays, mostly from the beta-gamma decay of daughter elements radium B (lead 214) and radium C (bismuth 214).

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Neutrons are particles about one-fourth the size of alpha particles. Because they have no electrical charge, they can travel many feet through solid matter and hundreds of feet through air.

Radioactive transformations of unstable elements, resulting in their breakdown into new elements possessing different chemical properties, are caused primarily by the emission of alpha and beta particles. Such newly formed atoms are called decay products or daughter elements. In the three natural radioactive disintegration series they are unstable, forming other daughter elements, the end product being a stable isotope of lead. With radium 226 (atomic weight 226.0), the most common form of the element, the first decay product is radon (atomic weight 222). Radon is transformed into radium A (atomic weight 218) which decays to radium B (atomic weight 214) and so on until stable radium G, corresponding to lead 206 (atomic weight 206), is reached.

The *half life* of any particular radioisotope is the time required for the radioactivity of a given quantity of the isotope to decrease (or decay) to half of its original value. Radium 226, the most abundant isotope of the element, has a half life of over 1,600 years. Its very small annual decay or loss of about 0.04 percent is of great consequence in considering the usefulness of radium 226 in medical therapy.

A *curie*, named in honor of the Curies, is defined as the quantity of any radioactive species in which 3.7×10^{10} nuclear disintegrations occur per second. It is also defined as the activity associated with 1 gram of radium.

The name *curietherapy* has been applied to the use of radium for therapeutic purposes by the medical profession; the prefix *tele-* is added to indicate radium therapy from an exterior source not in physical contact with body tissues. Curietherapeutic dosage is expressed as the quantity of radiation received by the tissues. The *exposure dose*, expressed in roentgens, is a measure of the total ionization that the quantity of radiation could produce in air. This differs from the *absorbed dose*, usually expressed as rads, which represents the energy absorbed from the radiation per gram of specified body tissue.

Maximum permissible dose may be defined as the limit of radiation exposure below which no noticeable harm is expected for a person receiving it regularly over a lifetime (*1*).

Radium preparations, after measurement at an official institute possessing a primary or secondary standard, are sold on the basis of the quantity of the element present.

Two primary standards for determining radium content have been established. The first official International Standard was prepared by Mme. Curie in 1912 for deposit at the International Bureau of Weights and Measures at Sevres, France, and contains 21.99 mg of pure anhydrous radium chloride. The second International Standard was prepared in Austria and serves as a Reserve International Standard; it contains 31.17 mg of pure anhydrous radium chloride. Secondary standards, calibrated with the International Standard at Sevres, are employed in routine measurements. The National Bureau of Standards, Washington, D.C., has a secondary standard (*10*).

TECHNOLOGY

The extraction of radium from uranium ores has presented unusual problems because of the extremely small proportion of radium present. Bureau of Mines researchers often had to treat 200 tons of ore to obtain 1 gram of radium, a yield of 1 part in 180 million (*2–3*, *9*).

In recent years, the Congo (Léopoldville) has been the source of most primary radium. The direct acid leaching method used in opening Congolese pitchblende ore and subsequent processing of the enriched slimes at Oolen, Belgium, may be considered the most important industrial technique. Other pitchblende digestion processes consisted of the original Curie sodium sulfate fusion technique used on the Joachimsthal (Czech) ores, the modified Curie process of initially roasting the ore with sodium carbonate and nitrate, leaching Cornish (English) ores with hydrochloric acid, and oxidizing and chloridizing the more complex Eldorado (Canadian) ores by roasting followed by sulfuric acid leaching.

A different method used for the digestion of carnotite ore involved heating pulverized mineral with 80 percent sulfuric acid, then filtering through glass wool and allowing to cool. The result was the deposition of barium, previously added as a carrier for radium, and radium sulfates (*5*). In all cases, a residue of barium-lead-radium sulfate remains after the uranium is removed. This residue, called "white cake," often contains a significant quantity of silica and usually is subjected to sodium chloride leach for 3 to 4 hours to remove the bulk of the lead. The rest of the lead sulfate, silica, and mixed barium-radium sulfate in the residue is carbonated with soda ash (Na_2CO_3), which is subsequently washed free. The resulting carbonate cake is dissolved in hydrochloric acid, and the washed chloride filtrate, treated with excess sulfuric acid, forms a sulfate cake which is washed free of acid. Another carbonating step ensues and, with subsequent removal of the carbonate ion by washing, a reaction of the car-

780–887 O—65——48

bonate with hydrobromic acid provides a filtrate of barium-radium bromide and lead bromide. The last technique of fractional crystallization takes advantage of the relative enrichment of radium to that of barium in the crystal phase and, with many successive fractional crystallizations, more than 90-percent-pure radium bromide crystals may be produced (*6*). Ion exchange and solvent extraction with chelating agents have been used to separate radium from barium. Ion-exchange methods using synthetic organic resins reportedly afford complete separation of these elements. The resin is degraded by intense radiation from larger quantities of radium, with resulting formation of insoluble radium compounds in the ion-exchange column (*4*). Radium metal may be produced by electrolysis of the bromide in an aqueous solution, using a mercury cathode (*5*), and from a radium chloride solution using a mercury cathode and a platinum-iridium anode. A residue of pure radium metal is then obtained from the amalgam by thermal decomposition in a hydrogen atmosphere (*4*).

Secondary radium has been reclaimed domestically from old capsules and other applicators.

USES

The most important application for radium has been in medicine, particularly in cancer treatment. Radium as a salt sealed in tubes and needles is used directly in curietherapy and has been used in radium bombs in telecurietherapy. Radon, a daughter element of radium with a short half life, is compressed in small capsules, usually gold seeds, and is used principally for implants in tissue (*6*).

During World War II several hundred grams of radium were reportedly used in luminescent compounds. Mixed in small quantities with compounds such as zinc sulfide, radium is the activating component in self-luminous paint for dials of watches and instruments and for signs (*8*). Radium, usually in the form of the insoluble sulfate in gastight metal containers, is used in industrial radiography, particularly in nondestructive inspection of metal castings. Because of the high specific ionizing power of its alpha particle emission, radium has been used in devices to dissipate hazardous static electricity. The alpha particles are responsible also for the alpha-neutron reaction in beryllium compounds used as moderately intense neutron sources in oil well logging and as initiators of nuclear reactions in atomic reactors. Advantages of radium over most of its alternate materials are its long half life and stability in a fission process.

COPRODUCTS AND RELATIONSHIP TO OTHER COMMODITIES

Although radium is always associated with uranium, only a few uranium-bearing mineral deposits were sufficiently enriched to permit mining solely for radium. Pitchblende, a variety of the uranium oxide, uraninite, and canotite, a hydrated potassium-uranium vanadate of secondary origin, have been the major ore minerals of radium.

The more important decay products of radium are radium emanation (radon, a heavy inert gas), radium A, radium B, and radium C, with respective half life values of 3.825 days, 3.05 minutes, 26.8 minutes, and 19.7 minutes. These daughter products are useful in curietherapy but are of concern as health hazards. Other decay products are radium C′, radium C″, radium D, radium E, radium E″, radium F, and radium G, which is the stable end product chemically identical with lead (atomic weight 206).

Radioactive substances used in radium therapy include principally radon and radium sulfate, rarely radium bromide and chloride.

ALTERNATE MATERIALS

Many radioisotopes have been produced and marketed by AEC and have become available from private concerns. They are largely decay products, obtained from nuclear reactors, which are processed relatively cheaply and can be substituted for radium in a number of applications because of their similar radiation spectra. In the United States approximately 100 radioisotopes are now available from the AEC, compared with 4 in 1946, and about 30 can be purchased at reasonable terms from private firms. In the spring of 1964, cobalt 60 was being produced by at least eight of these companies.

Although only a relatively few of these isotopes can be used instead of radium, one of the most important—cobalt 60—has a large usage in industrial radiography and is being used increasingly in medical therapy. It has considerable usage in teletherapy, a field in which X-ray equipment is also of great value. Although radium formerly was dominant in medical therapy, tubes and needles of gold 198, cobalt 60, and cesium 137 are now being used as interstitial implants and intracavitary appliances. Many physicians and other medical personnel still prefer radium in sealed sources because of its long half life and because they are more familiar with its dosimetry and treatment techniques. In alpha sources and foils ameri-

cium 241 has a fairly long half life and is less subject to leakage than is radium 226. In addition to cobalt 60, high-voltage X-ray machines and such radioisotopes as cesium 137, iridium 192, and thulium 170 are used in industrial radiography. Luminescent compounds activated with beta emitters, hydrogen 3 (tritium) and krypton 85, reportedly reduce health hazards and deterioration and afford a constant-level, longer lived light output. Static elimination devices now usually contain americium, polonium, or krypton 85.

In neutron sources, mixtures of americium 241, polonium, plutonium, actinium 227, lead 210, antimony 124, or thorium 228 with beryllium metal can be used instead of beryllium-radium mixtures.

TABLE 1.—*U.S. imports for consumption of radium salts, radioactive substitutes, and useful radioactive substances*

Year	Radium salts [1]		Radioactive substitutes,[2] value (thousands)	Useful radioactive substances,[3] value (thousands)
	Milligrams	Value (thousands)		
1954–58 (average)	56,254	$813	[4] $521	
1959	32,967	518	1,145

RESERVES

Although radium was extracted formerly as a primary product from high-grade Colorado Plateau carnotite ores, in a sense there are currently no domestic mineral reserves of radium. Cessation of domestic production, brought about largely by competition from richer foreign sources, placed all domestic radium ores below the economic and technologic margin. The geochemical abundance of radium in rocks is seldom greater than 1 part per trillion (1×10^{-6} grams per ton), but the greatest enrichment is in granitic rocks. The commercial occurrences are in uranium ore deposits in which radium occurs with uranium in a ratio of 1 to approximately 3 million. Congolese ores from the rich Shinkolobwe pitchblende deposit are the source of most of the radium processed in recent years, but quantitative figures are lacking (*7*).

SOURCES OF STATISTICAL INFORMATION

Statistical information is obtained from the four companies or agents dealing in or producing radium and radium-bearing devices, from the weekly publication "Steel," from the Bureau of the Census, U.S. Department of Commerce, and from the annual reports of the Union Minière du Haut-Katanga.

PRODUCTION, CONSUMPTION, AND TRADE

No domestic production has been reported for a number of years, and over 75 percent of the radium salts imported in the last 10 years has been recovered from Congolese uranium ores at the Belgian radium refinery at Oolen.

The total production of radium is probably less than that of any other naturally occurring element. Since the first separation by the Curies in 1898 the annual world production of radium has fluctuated widely. Data for years of higher production during World War II are not available because of security reasons or because of company confidential figures. The U.S. domestic industry was at its peak in 1921 when radium salts were produced by five companies. Within 2 years, under the impact of Congolese radium, only United States Radium Corp. was isolating radium and by 1925 even this company had ceased production. Total production of radium in Colorado has been valued at $20 million. In 1964 it was estimated that the total world radium stock was about 3,000 grams, about 500 grams of which is in the United States.

From 1954 to 1963, about 65 percent by weight and 48 percent by value of U.S. exports of radium metal and alloys were shipped to Canada. Significant quantities were sent to Brazil, Libya, Switzerland, and Norway; lesser quantities were shipped to Venezuela, Italy, France, Belgium, the Netherlands, West Germany, Surinam, and Argentina. Canada has been the only consistent consignee of radium metal and alloys, averaging $16.58 per milligram which is about $6 less than the 10-year average for all these exports. Other high prices for material shipped to countries such as Italy and the Netherlands are due probably to the costs of new radium and new or expensive encapsulation.

Imports of radium salts during the period were received mostly from Belgium, with Canada supplying most of the remainder. The United Kingdom, the Netherlands, and Colom-

bia were the only other countries shipping any significant quantities. Low unit prices for some imports usually reflect reprocessing costs for old radium.

No rates of duty apply to imports of radium and radium salts or to the new inclusive tariff classification listed under item 494.5000 of the 1963 tariff schedule. Under the new tariff classification, however, it is impossible to differentiate radium from radioactive isotopes.

STRATEGIC CONSIDERATIONS

Demand for radium, considerably lessened by the impact of radioactive isotope substitutes, could be met from byproduct radium extracted from uranium-mill wastes or by recovery of secondary radium. Strategic and defense needs for luminescent materials are being satisfied increasingly by less hazardous luminescent materials activated with radioisotopes and by devices recently developed for seeing at night.

GOVERNMENT PROGRAMS

Radium has had increasingly strong competition in recent years from the radioisotopes which have become increasingly available under the production and distribution program conducted by AEC. A depletion allowance of 15 percent is still available on gross incomes from mining both domestic and foreign radium-bearing minerals.

PRICES

Radium is still the highest priced of all metal commodities. Although the quoted price in "Steel" and in E&MJ Metal & Mineral Markets has remained stationary for about 10 years, recently gram quantities of old or used radium have been sold for as little as $2 per milligram, equivalent to $1 million per pound. This is in strong contrast to the quoted market price of $16 to $21.50 per milligram of the metal in purified salts, dependent upon quantity. It is even further from the price of $120 per milligram for the first commercial radium and the peak price of $180 per milligram in effect just prior to World War I. For 10 years starting with 1953, the Bureau of the Census data indicate that the average of declared prices for radium-salt imports remained somewhat below the lowest quoted price but, in 1963, the average of declared prices dropped to less than half of those quoted, largely owing to the influx of low-priced imports from Canada and the United Kingdom. These anomalous prices do not pertain to primary uranium, and probably are reprocessing charges for secondary radium or reencapsulating of radium from old sources.

RESEARCH

Recently radium investigations have centered mostly on ascertaining health hazards and genetic results associated with the use of radium, improving methods for determining radium in various materials and in different environments, devising separatory techniques for the element, evaluating its therapeutic effects, devising better applicators, providing satisfactory storage facilities, and promoting better handling procedures. As shown in "Nuclear Science Abstracts," research is being conducted in the United States and in numerous European countries by national, State, and private laboratories, by cancer research institutes and hospitals, by universities, and by units working under various Government atomic energy commissions and authorities.

OUTLOOK

Primary radium, obtained mostly from Belgian and to a lesser extent from domestic company stocks, as well as some reclaimed radium, is adequate to meet anticipated requirements. A number of States which have recently assumed control of regulatory authority in the field of radiation hazards, a function formerly administered exclusively by AEC, make no discrimination in licensing between radium and radioisotopes. This has the effect of removing radium from its preferred status of ready availability, thereby encouraging more interest in and increased use of radioisotopes for former radium applications.

Radium will continue to be preferred in certain applications, principally in medical therapeutic uses in which its long half life allows storage for years with little change in radiation characteristics.

Conversely, certain health hazards connected with the use of radium may differ in comparison with those of radioisotopes.

PROBLEMS

Competition with increasingly abundant radioisotopes having distinctive radiation properties and available at lower prices is reducing the demand for radium.

Telecurietherapy, industrial radiography, and luminous compounds are requiring increasingly larger quantities of radioisotopes.

In common with other waste products from uranium processing plants, radium has caused water pollution. Other health hazards have been caused by improper handling and storage of the small containers of radium salts used in medical therapy and radiography. Also, workers preparing luminous compounds containing radium salts sometimes are subject to ingestion or inhalation of particles or radon in quantities greater than the maximum permissible concentration. A number of States still do not exercise a strict control over the use of radium.

RARE-EARTH ELEMENTS

By John G. Parker [1]

IN THIS chapter, the rare-earth metal group is considered to include the series of 15 chemically similar elements with atomic numbers 57, lanthanum, through 71, lutetium.

The term rare earths was applied to the oxides of the elements because of their apparent scarcity and their resemblance to the alkaline-earth oxides. Some scientists prefer the terms lanthanides or lanthanons. Industry, however, through long usage, favors the term "rare earths," often including the elements yttrium and sometimes scandium.

Monazite and bastnaesite are the principal commercial rare-earth ore minerals. Euxenite, mined in the 1950's for its columbium, tantalum, and uranium, yielded rare-earth byproducts enriched in elements of the heavy rare-earth subgroup. Apparent domestic production of concentrates in 1963 was nearly 2,350 tons of contained rare-earth oxides. Most of this was derived from imported and domestic monazite processed for its rare-earth element and thorium content. The remainder has been processed from bastnaesite shipped increasingly in recent years from the world's largest known rare-earth mineral deposit in California.

Rare-earth mineral concentrates usually are processed first to rare-earth sodium sulfate by digesting with sulfuric acid. This double salt is converted to other salts such as the chlorides, oxides, fluorides, nitrates, and carbonates. Alternatively the caustic soda method initially produces rare-earth and thorium hydroxides and byproduct trisodium phosphate. The crude salts produced from either method are used directly or may be converted into higher purity compounds. Rare-earth chloride can be electrolyzed into misch metal. Part of the crude production is separated into cerium, lanthanum, or didymium portions before further processing into metals or salts. A solid-state process has been developed to convert bastnaesite to an oxide polishing compound by roasting. Ion-exchange and solvent-extraction techniques are employed in separating the rare-earth elements and are greatly superior to older fractional-crystallization methods in most instances. In the form of metal or alloy, such as misch metal, cerium metal, and ferrocerium, rare-earth elements are used mostly in lighter flints or sparking metal; as deoxidizers, scavengers, and grain refiners in steel and other ferrous alloys; as nodularizers in certain types of cast iron; and as promoters of high strength and creep resistance at elevated temperatures in aluminum and magnesium alloys.

Rare-earth compounds find wide use as superior glass polishing powders and as glass colorants and decolorizers. The oxides and fluorides are used in the cores of arc-light carbons in searchlights and for high light intensity with good color balance in motion pictures. Newer or potential applications are as preventers of deterioration caused by ultra-violet light in some foods in glass containers and as photochromic materials in variable-transmission glass windows, as invaluable components in phosphors used in color television tubes, as activating dopants in materials used for laser research, and as control rod materials in nuclear reactors.

The outlook for the industry is for steady growth, especially for production of materials used by the glass and metals industry and of high-purity compounds and metals for newer or potential uses. Any of several recent discoveries concerning light absorption and fluorescence phenomena could bring about a rapid increase in consumption of certain rare-earth compounds. Partly affecting these potential uses is the availability of heavy subgroup elements from less common ores, such as euxenite and xenotime, and as byproducts from other mining ventures.

The principal problems of the industry are created by oversupply of certain byproduct rare-earth elements which necessitates intensi-

[1] Commodity specialist.

fied utilization and market research. On the other hand, determination of unusual properties of very high purity rare-earth metals and compounds and better knowledge of new sources, extraction, separation, and metal reduction procedures are necessary for a broader base upon which to establish the foundation of newer portions of the rare-earth industry. Many research institutions, much of the industry, and a number of Federal agencies including the Bureau of Mines are conducting research on rare-earth metals and compounds.

BACKGROUND

The first recorded domestic shipment of monazite was in 1887 from Burke County, N.C. Production reached a peak of 787 tons in 1895 and averaged 300 short tons per year through 1910. German firms dominated the production of thorium nitrate from monazite mined in Brazil and in India. Mine production started in Brazil in 1895 and in India in 1911. Because the average thorium oxide content of monazite from the Carolinas was only 3.5 to 4 percent while that from Brazil and India averaged 6 and 8 percent, respectively, domestic producers found it difficult to compete. Consequently, German manufacturers soon built up an almost complete monopoly of the thorium nitrate industry. As a result, the total domestic output of monazite from 1911 through 1947 was only about 50 tons. Larger quantities of monazite were produced from 1948 through 1963. In 1949, bastnaesite, a mineralogical curiosity until that time, was discovered in large quantities in the Mountain Pass, Calif., district in carbonate rocks cutting a metamorphic complex. Production at and shipments of rare-earth mineral concentrates from the site have increased in recent years.

The domestic industry has grown from a few small, closely held companies that started using thorium nitrate in the manufacture of incandescent gas mantles around 1900. At first, most of the thorium nitrate was imported from Germany, but World War I forced the companies to process monazite from Brazil and India. Initially, the rare-earth metals produced as byproducts from the monazite were of little value, but uses for them were found. As electric lights replaced gas mantles, monazite was then processed for over a score of years mainly for its rare-earth content. After World War II, the situation was reversed, and monazite was again produced largely for thorium. Moreover, the rapid advances in science and technology after World War II indicated that the rare-earth metals had important industrial uses, and the discovery of large deposits made the term "rare" a misnomer. The result was that in the early 1950's interest in the rare-earth metals was stimulated, and the industry expanded. Early enthusiasm proved unwarranted, but through corporate consolidations a stable industry was developed to undertake solution of the many problems confronting development of rare-earth resources.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Since 1955 rare-earth minerals have been mined sporadically in at least eight States. Bastnaesite concentrate has been produced since 1952 by Molybdenum Corp. of America at its mine and beneficiation plant at Mountain Pass, San Bernardino County, Calif. In 1956, bastnaesite was shipped from a mine in Lincoln County, N. Mex., operated by New Mexico Copper Corp. Monazite dredging operations in the middle 1950's in Valley County, Idaho, by Baumhoff-Marshall, Inc., and Idaho-Canadian Dredging Co. were extended into 1959 by Baumhoff-Marshall and later by J. R. Simplot Co. Through 1959 Porter Bros. Corp. dredged euxenite in Valley County, Idaho, principally for its columbium-tantalum and uranium content with byproduct recovery of rare-earth elements of the heavy subgroup. The only current production of monazite is from dredging in Duval County, Fla., where Titanium Alloy Manufacturing Division of National Lead Co. recovers it as a byproduct of ilmenite and rutile.

The principal chemical processors of concentrates and producers of rare-earth compounds, including sulfates, oxides, chlorides, fluorides, nitrates, and other salts of mixed and individual rare-earth elements, are as follows: Rare Earth Division, American Potash & Chemical Corp., West Chicago, Ill.; Davison Chemical Division, W. R. Grace & Co., Pompton Plains, N.J.; Lunex Co., Pleasant Valley, Iowa; Michigan Chemical Corp., St. Louis, Mich.; Molybdenum Corp. of America, York, Pa.; Research Chemicals Division, Nuclear Corp. of America, Phoenix, Ariz.; and Vitro Chemical Co., Chattanooga, Tenn.

Metals and alloys such as misch metal are produced from individual or mixed rare-earth chlorides or fluorides purchased from the chemical processors. Some of the latter, including American Potash & Chemical Corp. and Michigan

Chemical Corp., also produce high-purity metals. Research Chemicals Division and Lunex Co. are principally refiners and producers of high-purity compounds and metals. The principal producers of misch metal and ferrocerium (lighter flints) are Ronson Metals Corp., Newark, N.J. and American Metallurgical Products Co., Inc., New Castle, Pa. Vanadium Corp. of America, Union Carbide Corp., and Vitro Chemical Co. manufacture rare-earth-bearing silicon alloys.

In Brazil, rare-earth chlorides and other mixed rare-earth compounds are processed principally by Orquima Industrias Quimicas Reunidas, S.A., from monazite sands extracted from beach sand deposits in the States of Bahia, Rio de Janeiro, and Espirito Santo. Monazite is extracted from black sands in the States of Kerala and Madras in the southwestern part of India and processed at a plant in Alwaye operated by Indian Rare Earths Ltd., Bombay, for the Indian and Kerala Governments. Europe and Japan are the chief markets for most of the rare-earth materials produced by the Indian and Brazilian processors. A large vein monazite deposit at Van Rhynsdorp, Republic of South Africa, has provided large tonnages to the United States until recently. After having been closed since March 1959, it reopened again early in 1962 and supplied a large quantity of monazite to an American processor, again closing down in the middle of 1963. Monazite has been recovered increasingly, since the first production in 1948, from Australian beach sands which apparently will become one of the major sources now that the South African production has ceased. The Malagasy Republic, also one of the larger suppliers of monazite concentrate, has a large concentration plant operated by the French Atomic Energy Commission and Pechiney at Antete which has been increasing production in recent years. Byproduct production of monazite from alluvial tin mining takes place in Indonesia and Malaysia. Other less important monazite sand deposits have been worked in Ceylon, Korea, Nigeria, and Egypt.

Foreign companies which process rare-earth mineral concentrates and produce compounds include—Treibacher Chemische Werke A.G., Treibach, Austria; Orquima Industrias Quimicas Reunidas, S.A., Sao Paulo, Brazil; Johnson Matthey & Co., Ltd. and Thorium Ltd., London, England; Typpi Oy, Oulu, Finland; Société Pechiney-St. Gobain, Paris, France; Th. Goldschmidt A.G., Essen, West Germany; Indian Rare Earths, Ltd., Alwaye, India; and Santoku Metal Industry Co., Kobe, Japan. The Finnish company has a unique plant that was established in 1963 to extract the rare-earth elements contained in apatite.

Misch metal and other rare-earth metals and alloys are produced by the following foreign firms: Treibacher Chemische Werke A.G.; British Flint & Cerium Manufacturing, Ltd., Kent, England; Société Pechiney-St. Gobain and Société Kuhlman, Paris, and Société d'Electrochimie du Centre, Dijon, France; Th. Goldschmidt A.G., Essen, and Prometheus Metallwerke, Kempten, West Germany; and Santoku Metal Industry Co., Kobe, and Ogino Chemical Institute, Hyogo, Japan.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Webster's New Collegiate Dictionary (1960) defines "*rare earth*" as "any of a series of very similar oxides of the rare-earth elements," and "rare-earth element or metal" as "any of a group of very similar elements of successive atomic numbers, beginning with cerium 58 (sometimes with lanthanum 57) and extending through lutecium [sic] 71." In this chapter and in most commercial and scientific usage the rare-earth metals are taken to be the 15-element group from atomic number 57 through 71. In commercial usage the group is frequently expanded to include yttrium, atomic number 39, and occasionally to include scandium, atomic number 21. The rare-earth group also is referred to scientifically as the *lanthanides*; or, less commonly, as the *lanthanons*, terms proposed by the chemists V. M. Goldschmidt and J. K. Marsh. The scientific grouping of rare-earth elements is based on a characteristic known as the *lanthanide contraction*. As a result of the lanthanide contraction changes in the atomic structure as the atomic number increases do not strongly affect the valence force between atoms. This accounts for the striking similarity in chemical behavior of the elements within the group. Scientists use the term *actinide rare earths* for the group of 15 elements from atomic number 89 through 103 in the periodic table. These are chemically similar radioactive elements and comprise a distinct group unrelated to the rare-earth elements.

The rare-earth metal group name was assigned when the elements were considered to be scarce and because of the earthy appearance of their oxides. It is now realized that these elements as a whole are actually more abundant than many better known and commonly available elements.

Writings on the rare-earth elements and compounds are confused by frequent use of the term "rare earth," without a hyphen, to mean different things. (*3, 9, 19*).[2] As a noun the term is

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

used to mean both an element and the oxide of an element. As an adjective, the term frequently is used without the proper accompanying noun, sometimes confronting the reader with an ambiguous expression. For specificity of language the present discussion follows Webster in using the hyphenated adjective form, such as, *rare-earth elements*, *rare-earth minerals*, *rare-earth metals*, or the redundant *rare-earth oxides*. Sometimes when referring to the individual oxides the suffix *-a* may be used to replace *-um*, for example in *ceria*, *gadolinia*, and *samaria*.

Sufficient differences have been found to permit classifying the rare-earth elements into subgroups, based on their chemical behavior. Current practice is to break the 15 successive elements plus yttrium into a *light* and *heavy subgroup*. The light subgroup incorporates the elements from lanthanum through europium and the heavy subgroup, from gadolinium through lutetium plus yttrium (*22*). They are also called the *cerium* and *yttrium* subgroups after the most abundant elements which they contain. Some researchers have used a tripartite division into a *cerium subgroup* of elements with atomic numbers 57 through 62; a *terbium subgroup*, numbers 63 through 66; and an *yttrium subgroup*, with yttrium and elements with numbers 67 through 71 (*15*). Some properties of the rare-earth elements are shown in table 1.

TABLE 1.—*Selected properties of the rare-earth metals*

The principal companies in the field market rare-earth compounds, metals, and alloys under a variety of trade names. Those without a trademark name are sold by purity designation. So-called *production chemicals* with lower purities have less exact specifications than those of high-purity materials. Metals and compounds of high purity are usually available in from two to four grades. Purity designations usually refer to the content of the particular rare-earth metal present in the total contained rare-earth metal or of the particular rare-earth oxide in the total contained rare-earth oxide. Analyses of rare-earth ores, metals, and compounds are usually reported as rare-earth oxide, frequently abbreviated to REO.

Cerium, the most abundant element in the group, can be readily separated from the others. The term *didymium* is usually applied or prefixed to the compounds or metals produced from the mixture of rare-earth elements after removal of cerium. Analysis of a typical didymium oxide derived from monazite shows the following percentages of rare-earth oxides: lanthanum, 42.8; neodymium, 30.6; praseodymium, 8.9; samarium, 5.2; gadolinium, 3.3; and other rare-earth and yttrium oxides, 3.2 (*2*). Didymium metal, made from a crude neodymium chloride, is considered by one metal producer as mostly neodymium and praseodymium.

The term *misch metal* is used to denote combinations of the rare-earth elements in metallic form. It may be made from the unseparated elements, usually containing about 50 percent cerium. When it is made from rare-earth elements from which nearly all the cerium has been removed it is called cerium-free misch metal. The metals and misch metal are cast in a variety of forms, such as *ingots* of ¼ and 1 pound; *donuts* of 1, 2, and 5 pounds; *cast pellets* of about 1 ounce each; *extruded pellets* of nearly 1,000 to a pound; and small *granules*, *rods*, *turnings*, and *powder*. Other alloys are made from misch metal and small quantities of aluminum or magnesium. *Ferrocerium* is an alloy of misch metal and iron.

Chemical processing companies, setting their individual requirements for purchase of monazite concentrate, generally want at least 55 percent contained REO. Monazite to be incorporated into the national stockpile must contain 50 percent REO. After leaching with dilute hydrochloric acid, bastnaesite mill concentrate contains about 70 percent REO and after roasting, over 90 percent REO.

TECHNOLOGY

Geochemistry, Mineralogy, and Geology

Geochemical abundance estimates of the rare-earth element content of igneous rocks, which comprise 90 percent of the earth's crust, are derived from data on granitic rocks. These abundance data prove the inapplicability of the prefix "rare" to this group of elements. For example, the three more abundant rare-earth elements—cerium, neodymium, and lanthanum—are collectively greater in abundance than metals such as nickel or copper, and even thulium, the rarest of the rare-earth elements, is more prevalent than silver, gold and platinum combined. In its entirety, the rare-earth element group is greater in abundance than zinc. The rare-earth elements are more abundant in granitic than in basic rocks. Although relatively little research has been conducted on the abundance of rare-earth elements in sedimentary rocks, some data indicate that the content in shales is nearly the same as the average crustal content, but that limestones contain substantially less.

In igneous rocks, rare-earth elements are found in accessory minerals such as monazite, xenotime, and allanite, and sometimes within the crystal lattices of principal rock-forming minerals such as feldspar and biotite.

Monazite has been of principal economic interest because it usually is recovered from sands derived from weathered granitic and pegmatitic rocks. This rare-earth and thorium phosphate mineral contains from about 50 to 70 percent REO, mostly of the cerium subgroup. In some foreign monazite, the thorium oxide content may exceed 10 percent. To date, monazite has been the principal ore mineral for thorium and rare-earth elements. Xenotime, a phosphate mineral analogous to monazite and usually associated with it in small quantities, contains yttrium and yttrium subgroup elements. Apatite, another phosphate mineral, sometimes contains significant quantities of rare-earth elements, notably those of the cerium subgroup, replacing calcium. Of the most common rare-earth silicates, allanite is richer in the cerium subgroup; gadolinite, a beryllium-bearing rare-earth silicate, is richer in the yttrium subgroup. Locally allanite is abundant and occurs in granitic rocks, pegmatites, some metamorphic rocks, and altered marbles and skarns. Some gadolinite has been mined, but it is not a common species and is almost exclusively a mineral of granitic pegmatites. Many early-crystallized minerals such as pyroxenes, amphiboles, and garnets contain heavy rare-earth elements and yttrium replacing bivalent calcium, an element with a similar ionic radius.

Within the past 10 years the mineral bastnaesite, a fluocarbonate with up to about 75 percent REO, mostly of the cerium subgroup, has become an important raw material. The typical occurrence of bastnaesite is in carbonatites, which are carbonate-silicate rocks occurring with and genetically related to complexes of alkalic intrusive igneous rocks. Carbonatites form the rare-earth deposit in the Mountain Pass district, San Bernardino County, Calif., probably the world's largest source of the cerium subgroup elements. Bastnaesite was said to form 5 to 15 percent of much of the Sulphide Queen mass, the largest carbonatite body in the area. A similar association exists in Gunnison County, Colo., where rare-earth and thorium minerals have been recognized in carbonate veins occurring in an alkalic stock.

The multiple oxide minerals containing columbium, tantalum, and titanium, also contain substantial quantities of the rare-earth elements and sometimes significant uranium. These minerals, including euxenite, samarskite, and fergusonite, occur mostly in granite pegmatites and as detrital grains in placers derived from pegmatites and other granitic rocks. Euxenite has been mined in small quantities from placer deposits in the Northwestern United States.

The economic sources of monazite are usually placer and beach sand deposits from which the mineral is recovered as a byproduct of titanium and zirconium mineral mining. In the United States, monazite occurs in the Piedmont province, chiefly in North and South Carolina and Georgia. Crystalline rock belts, the westernmost extending from east central Virginia southwestward into Alabama and the eastern from near Fredericksburg, Va., south-southwestward into North Carolina, are the probable sources of the monazite which has been recovered from southeastern streams and beach placers. Fluviatile placers in streams heading within the Coastal Plain yield monazite and xenotime, as at Aiken, S.C. Littoral deposits are found in present and old beaches. The Pleistocene terraces, some as high as 250 feet above sea level, are in general richer in monazite than are the Recent sites. In Florida, an alluvial deposit near Jacksonville was the only domestic source of monazite in 1963, being a byproduct from dredging for titanium minerals.

Until 1946, Indian deposits, mostly on the southwest coast of Travancore near Chavara and Manavalakurichi, had supplied a great deal of the world's monazite. These beach deposits, containing up to 80 percent heavy minerals, occur in present, barrier, and old elevated inland beaches derived from crystalline granitic and migmatitic basement rocks. The largest

Australian beach sand monazite deposits stretch from northeastern New South Wales north into southeastern Queensland and occur in southwestern Western Australia near Albany. Brazilian deposits consist of the following four types: Elevated beaches, elevated bars, modern beaches, and rare dune deposits formed by wind modification of the other three types (*10*). In general, they were derived by peneplanation of Precambrian rocks during Cretaceous time, subsequent faulting paralleling the coast, formation of sea cliffs, wave undercutting and deposition of concentrated resistates at the bases of the cliffs, enrichment of offshore bars, and finally recent uplift. Deposits in the States of Espirito Santo and Rio de Janeiro are the largest, averaging about 30 percent heavy minerals with some up to 75 percent. Monazite averages 1 to 20 percent of the heavy mineral content in the rich deposit at Comoxatiba in Bahia. A large number of gold river placers in interior Brazil contain monazite.

A unique vein deposit of monazite, until recently the most important source of the mineral, was discovered in 1950 at Van Rhynsdorp, about 200 miles north of Capetown, Republic of South Africa. The vein, which was formed along a shear zone in Precambrian granite, locally contained significant quantities of supergene copper minerals, thereby creating a mineral dressing problem.

Mining and Milling

Dredges, shaking tables, jigs, and Humphreys spirals are some of the equipment used to recover monazite, xenotime, euxenite, and other rare-earth minerals from placers. The bulk concentrate of heavy sands acquired thereby usually contains titanium and zirconium minerals, the main products of the processing of Florida beach sands. Some foreign heavy sands from which monazite is extracted contain cassiterite (tin oxide) as a primary product. Monazite is separated from the other components by various combinations of electromagnetic and electrostatic separation.

In Indian beach sands, leucoxene, an alteration product of ilmenite with magnetic susceptibility close to that of monazite, must be reduced first by roasting at 600° C, a process which does not affect the conductivity of monazite. Flotation also is used for Indian monazite separation and for the vein monazite ore from South Africa which, because of its association with various gangue minerals and sulfides, is not amenable to primary high-tension separation. An improved froth flotation technique uses sodium silicate as a conditioner and sodium or potassium permanganate to improve monazite flotability.

Gangue minerals in the Mountain Pass, Calif., bastnaesite deposit are principally barite, carbonates, and quartz. In a five-stage flotation process ammonium lignin sulfate and heat are used to upgrade an ore averaging 7 to 10 percent REO to a mineral concentrate containing 63 percent REO in the froth. By leaching with 10 percent hydrochloric acid and countercurrent decantation, calcite is removed. The bastnaesite is not dissolved by this treatment and the concentrate is further upgraded to 72 percent REO. Finally, this product can be roasted to remove the carbonate and fluorine ions, resulting in a product with over 90 percent REO.

Concentrate Processing

Industrial chemical processing of monazite concentrates consists initially of digestion in sulfuric acid or caustic soda, subsequent separation of the thorium and other elements, and finally recovery of the rare-earth metals as a group in a pure state. Many variations on standard processing techniques have been devised, some based on sintering and chlorination, but are not applied commercially and are not discussed in this publication.

In the acid process, finely ground concentrate is mixed with concentrated sulfuric acid in externally heated cast iron pots. After roasting under certain conditions of concentration and temperature, the thorium and rare-earth metal portions are dissolved as sulfate in water. Then, in all commonly used methods, the insoluble impurities are separated by filtration. Methods used are proprietary and details can not be given, but in one of the most commonly used acid breakdown schemes thorium pyrophosphate is precipitated from solution by neutralizing any free acid and adding an approximately stoichiometric quantity of sodium pyrophosphate solution. The rare-earth elements are precipitated as an insoluble double sulfate salt by reacting with sodium sulfate solution or as rare-earth oxalate with oxalic acid. Reaction of the double salt with sodium hydroxide provides hydroxide which is treated with hydrochloric acid to form rare-earth chloride. The oxalate can be marketed as such or converted to oxide by ignition. The acid process is adaptable to a wide variety of rare-earth ores, but it has severe corrosion problems and extra processing steps.

In the alkaline process, the monazite concentrate must be finely ground before reacting with a hot concentrated solution of caustic soda in externally heated stainless steel vessels or nickel-clad-steel autoclaves provided with heavy agitators. A one- or two-stage operation is possible,

with the latter reported to require less excess of alkali. In the reaction, the hydroxides of the rare-earth metals and thorium are left undissolved and trisodium phosphate remains in solution to be recovered by crystallization from the filtrate. The hydroxides are washed, dissolved in hydrochloric acid, and subjected to partial neutralization to allow separation of crude thorium hydroxide from the filtrate containing the rare-earth hydroxides. Mixed rare-earth chlorides can be recovered after evaporation in cast iron pans or, with further neutralization of the thorium-free, rare-earth-rich filtrate, a high-grade rare-earth oxide product can be obtained. This method, used by one domestic chemical processor and by plants in France, India, and Brazil, is simpler to use because it removes phosphate and permits separation of pure mixed rare-earth concentrate early in the process, has fewer steps, and makes marketable trisodium phosphate as a byproduct. However, the reagent cost is higher and the process is not amenable to lower grade ores.

Besides the large-scale use of bastnaesite and monazite by standardized industrial processing methods, techniques have been worked out for other, less common rare-earth minerals and sources. For example, in the treatment of the multiple oxide mineral euxenite, which contains yttrium subgroup elements, tantalum, and columbium, chlorination has been used to convert constituents to chlorides. Subsequently, solvent extraction is used to remove tantalum-columbium chloride and hydrometallurgical processing is used to remove rare-earth metals from the chlorination residue (*16*). Other techniques which have been used on euxenite concentrate include digestion with hydrofluoric acid, sulfuric acid, and mixtures of the two, the last reported to be the most effective (*25*).

In Finland rare-earth compounds are extracted from apatite. It has been reported that an apatite deposit on the Kola Peninsula, U.S.S.R., contains large potential reserves of REO and that plants in Russia and in Poland were recovering these oxides during the production of phosphoric acid and fertilizer. The process used includes decomposition with concentrated nitric acid, salting-out of silicic and fluosilicic acids with sodium nitrate, filtering, precipitation of the rare-earth phosphates from the filtrate by partial neutralization with ammonia, dissolution of the rare-earth concentrate in nitric acid, and final purification by oxalate precipitation. A new chlorination procedure for purifying crude rare-earth phosphate was said to eliminate the need for oxalic acid (*3*).

Separation of the Rare Earth Elements

Most commercial rare-earth salts contain individual elements in about the same ratio as in the ore treated. In the separation process, cerium is always the first to be extracted from the mixture. It is oxidized to the tetravalent ceric state and precipitated from solution as a basic ceric salt or crystallized as ceric ammonium nitrate. After the cerium has been removed, the basic rare-earth chlorides are precipitated by adding strong ammonium hydroxide-ammonium chloride solution at 50° C in stages, filtering after each addition. Precipitation is continued until the absorption spectra of the filtrate shows that only lanthanum and ammonium chlorides remain. Lanthanum is the last to precipitate.

Recent advances in the technology of rare-earth element separation suggest that techniques be described under classical and modern methods. The principal classical methods are fractional crystallization, fractional precipitation, and thermal reactions, which include fusion and volatilization. These are the methods used in producing large-scale quantities of the separated salts of lanthanum, cerium, and neodymium. Modern methods include ion-exchange separation and solvent extraction which are used primarily to separate and recover the individual rare-earth elements.

In fractional crystallization, part of a rare-earth mixture is precipitated, usually by evaporating to change the concentration of the salt or by varying the temperature or solvent to affect the solubility of the salt. Fractional precipitation is accomplished by introducing the precipitating agent in small increments allowing certain of the rare-earth compounds to precipitate preferentially to others. Thermal methods have been used to decompose partially rare-earth nitrate salts according to their basicity, which is followed by partial leaching of the salts or the method combined with fractional precipitation (*9*).

Ion-exchange methods consist of elution chromatography and displacement chromatography. In elution chromatography, the driving ion in the eluant is not efficient in displacing the ions sorbed in the column, as the individual rare-earth ions move down the column at different rates. The method is effective only for small quantities obtained for analytical purposes. Displacement chromatography permits the use of a larger fraction of the exchange capacity of a given resin bed and the full driving potential of the eluant. This is the method used commercially to obtain larger quantities of highly purified individual rare-earth elements (*21*).

Ion-exchange equipment consists of columns or tall tanks filled with a resin, such as sulfonated styrene-divinylbenzene copolymer (Amberlite IR–120, Dowex 50, Nalcite HCR, or Permutit Q). Columns used in laboratory work were composed of glass tubing from ½ to 4 inches in diameter by 4 feet high and columns used in commercial operations are from 4 to 60 inches in diameter and up to 20 feet high.

In commercial practice a measured quantity of mixed rare-earth chloride solution is flowed into the top of the column, and the rare-earth cations replace the cations (hydrogen, ammonium, or copper) of the resin; hence, the term ion exchange or, more specifically, cation exchange. In this manner a saturated band of rare-earth elements is formed at the top of the column, and the remaining resin is unaffected. Very little separation occurs in this loading step.

Next, a solution of some negative-ion species which forms a complex ion with the rare-earth elements is passed downflow through the column. Among such solutions, called eluants, are citric acid buffered with ammonium hydroxide to a pH of 2.5 to 3.0 and ammonium citrate with a pH of 5.0 to 8.0. The positive ions in the complexing solution replace the rare-earth ions selectively, so that ions of the most firmly or most strongly complexed element move most rapidly down the column, and the different elements gradually spread into individual bands. As the elution process is continued, each individual rare-earth element can be removed successively at the bottom of the column. The heaviest rare-earth element present is complexed most strongly and moves the fastest, while the next heaviest follows directly behind it. The order of elution then is lutetium, ytterbium, thulium, erbium, holmium, dysprosium, terbium, gadolinium, europium, samarium, neodymium, and praseodymium. If yttrium is in the solution, it is separated after dysprosium and before terbium. Although the bands of individual elements are fairly sharp, there is some overlap where binary mixtures are obtained. The effluent solution is collected in fractions which contain either separated individual elements or binary mixtures of overlapping elements. The separated individual elements are recovered chemically, usually by precipitation with oxalic acid, and the binary mixtures are recycled.

Recently, chelating agents have been used to enhance separation factors, thereby affording greater ease of separation between certain metal ion pairs. Some of these chelating agents are the eluants nitrilotriacetic acid (NTA) used at higher pH's of 7 and 8 to elute elements of the cerium subgroup, ethylenediaminetetraacetic acid (EDTA), and hydroxyethylethylenediaminetriacetic acid (HEDTA). Some afford greater efficiencies under conditions of elevated temperature and are selective with respect to separation of elements within subgroups. Most are necessarily used with the correct special retaining ions. For example, some must be used only with metal ions in the resin from which it is difficult to recover, but others such as HEDTA can be used on hydrogen-state resin beds from which it and water can be recovered and reused. The use of certain expensive eluants, such as ammonium alpha-hydroxyisobutyrate, ammonium thiocyanate, and Zn $(EDTA)^{2-}$, are justified only in elution chromatography.

The outstanding advantage of ion-exchange techniques is the ability to produce very high-purity rare-earth materials. On the other hand, flow rate through the columns must be slow to permit optimum exchange, the equipment is limited in size, and there are limitations on the maximum concentration ranges of currently available complexing agents (*13*).

Solvent Extraction

Although solvent extraction is being used by some segments of the rare-earth industry, details are lacking. The rare-earth elements may be separated from associated impurities as a whole which then is fractionated into subgroups. A typical solvent extraction operation consists of extracting rare-earth ions from an aqueous feed solution, usually of nitric acid, by contacting with an organic solvent such as pure or diluted tributyl phosphate (TBP). The extractability into undiluted TBP from 50 percent nitric acid was shown to increase with increasing atomic number. The rare-earth values are then stripped from the organic phase by a dilute solution, in this case, of hydrogen peroxide. Results of laboratory research indicate the adaptability of solvent extraction to continuous feed operation and the ease of mass transfer from one phase to another. Its primary advantage seems to be in separating mixtures of rare-earth elements into small moderately pure groups or fractions preliminary to final extraction of individual elements by other techniques, such as that of ion exchange.

Metal Reduction

The most common method for preparing cerium and misch metals is by the electrolysis of fused anhydrous rare-earth chloride at about 900° C. Using iron pots as cathodes and graphite rods as anodes, molten metal accumulates at the bottom of the pot. Until recently, rare-

earth elements beyond neodymium—from atomic number 62 onward—had been difficult to prepare electrolytically because of their high melting points, chloride volatility, and high reactivity with cell linings. Other electrolytic methods that have been employed include (1) electrolysis of oxides and fluorides in mixed molten fluoride baths, reported to provide a better metal product with high throughput (*20*); (2) electrolysis of oxides and fluorides in mixed fluoride-chloride baths; (3) electrolysis from molten electrolytes into low-melting-point metals such as zinc and cadmium; and (4) aqueous electrolysis into mercury and amalgam cathodes.

Metallothermic reduction of rare-earth compounds, using lithium, sodium, potassium, and magnesium, also is used to obtain the metals. It has been reported that reduction by calcium has been accomplished in a tantalum crucible or a magnesia-lined steel bomb at 1,300° to 1,500° C (*26*). An alloy of calcium and the rare-earth metal is formed, and the calcium must be removed at a high temperature in high vacuum (*4*). It is difficult to produce high-purity metals by this process, and samarium, europium, and ytterbium cannot be produced as they reduce only to a bivalent compound (*24*).

It has been reported that samarium, europium, and ytterbium can be prepared successfully by reducing their oxides with other rare-earth elements, zirconium, or misch metal (*13*). Purification of rare-earth metals has been accomplished by various methods, chiefly those of distillation and solid-state electrolysis.

By controlling the variables of composition, atmosphere, temperature, and pressure and using a mixed fluoride electrolyte, high-purity cerium and lanthanum have been electrowon by the Bureau on a laboratory scale. Much emphasis has been placed by the Bureau on developing continuous and larger scale electrowining methods, improving metal coalescence, and devising techniques to purify rare-earth metals by solid-state electrolysis. Contamination problems arise from the presence of impurities such as carbon from graphite anodes and from carbon oxide gases. Some of the contamination has been overcome by the use of other, corrosion-resistant materials such as tungsten instead of graphite in cell construction.

USES

The uses of rare-earth elements, as compounds, metals, and alloys, may be grouped by importance into the following categories: (1) In the glass industry; (2) in carbons for arc lighting; (3) in metals and alloys; and (4) in miscellaneous applications.

Rare-earth materials, such as cerium oxide and oxides of the cerium subgroup, are rapid, clean polishing powders used for polishing camera, eyeglass, and instrument lenses, mirrors, plate glass, precision optics, and television tubes. Cerium oxide, added to the melt in small quantities, acts as a glass decolorizer because of its powerful oxidizing action on impurities such as iron. In larger quantities, cerium and neodymium oxides make glass opaque to ultraviolet light, and are used in welders' lenses, better grade sun glasses, and special optical filters. Neodymium, praseodymium, or samarium oxide increase infrared absorption in glass. Some rare-earth oxides, such as that of lanthanum, greatly improve the optical quality of nonsilicate camera lenses having high-refractive indices and sharp definition for light over a large range of colors. A purple glass, using neodymium, absorbs yellow light and is ideal for glassblowers' goggles. In windows exposed to radiation, for example in nuclear reactors, cerium oxide is particularly applicable because of its resistance to color changes caused by alpha-rays. It is used also in color-television tubes, presumably to reduce discoloration. Depending upon the quantities added, neodymium and praseodymium color glass yellow, green, red, or lilac, without changing its index of refraction. The absorptive qualities of glasses containing as little as 1.5 percent cerium oxide appear to afford a great potential use in glass containers to protect perishable food from oxidation, photochemical reactions, or decomposition due to ultraviolet radiation. Research on photochromic materials indicates the probable use of rare-earth ions, such as europium and cerium, in glass that darkens in light of certain wavelengths and loses its hue when the rays are removed.

A yellow ceramic stain uses a praseodymium-zirconium oxide mixture, and some porcelain enamels are opacified by adding cerium oxide.

Rare-earth fluorides and oxides are used in the cores of arc-light carbons in motion picture photography and projectors to provide a light quality close to that of natural sunlight and in searchlights to achieve high light intensity.

An old established use of misch metal is in the production of pyrophoric alloys such as ferrocerium lighter flints. The addition of up to 50 percent iron and small quantities of other metal impurities creates a rare-earth alloy with sparking due to the low ignition temperature and high heat of combustion of cerium. Recently increasing attention has been paid to the application of rare-earth elements in the fields of ferrous and nonferrous metallurgy. In ferrous metallurgy, rare-earth metals and compounds act as deoxidizers, desulfurizers, and

grain refiners. When rare-earth materials are added to certain types of steel under proper conditions, ductility and hot workability is promoted and impact resistance is improved. Misch metal has proved beneficial in improving the ductility of inherently brittle special highly alloyed stainless steels. In the presence of excess quantities of certain harmful elements, such as titanium and antimony, ferrocerium and misch metal were reported to assist in nodularizing cast iron, improving mechanical properties and making possible large castings of high quality.

In nonferrous metallurgy, rare-earth elements, primarily are cerium and misch metal, have been used to retain strength at moderately elevated temperatures in magnesium and aluminum alloys. Some recent uses are in aircraft parts and in flatbed plates in printing equipment. Lanthanum, neodymium, and didymium have been used to promote oxidation resistance and creep resistance in such alloys at elevated temperatures. Attempts have been made to use rare-earth materials in improving properties of high-temperature and refractory alloys such as those containing nickel, chromium, and molybdenum. Cerium added to brass alloys under carefully controlled conditions improves elongation, and addition of small quantities of rare-earth elements reduces the high-temperature oxidation rate of copper without affecting its electrical conductivity.

Important miscellaneous applications include well-established uses and those being developed which show great promise. A large number of chemical reactions including petroleum cracking and chlorine recovery from hydrochloric acid have been accomplished or aided by the use of rare-earth catalysts. Electronic and magnetic applications are in microwave devices such as rare-earth iron garnets and as rare-earth titanates and stannates in ceramic capacitors. Misch metal is used as a "getter" to scavenge the last trace of gas from vacuum tubes. In fluorescent lamp and television tube phosphors, rare-earth elements cerium, gadolinium, and europium act as activators in host materials such as calcium phosphate and halophosphate, calcium aluminate, tungstate, molybdate, and fluoride, and zinc and strontium sulfides. Europium has aroused great interest for its potential use in a superior color television tube phosphor promoting brilliant reds and requiring less voltage. Laser materials include crystals, glass rods, plastic, and liquids doped with rare-earth elements. Crystals of calcium tungstate doped with neodymium and of calcium fluoride doped with didymium emit continuous coherent infrared radiation. Neodymium oxide was used to dope sodium-calcium-silicate glass, europium chelates were used in plastic fiber, and terbium was used to dope a liquid laser material which emitted coherent green light for penetrating ocean depths. Control rods in some nuclear reactors contain rare-earth elements with high-thermal neutron absorption cross sections which have high resistance to radiation damage. The most promising in this application are gadolinium, samarium, and europium. Europium is particularly attractive because of its relatively high cross section and a five-membered chain of absorbing isotopes, permitting slower burnup. Neutron cross sections of the rare-earth elements are given in table 1.

Cerium and neodymium selenides and tellurides are of potential value as semiconductors in thermoelectric devices. Samarium 153 has been used as a radiographic source in a portable X-ray unit. Many other applications of rare-earth elements are noted in the literature, including those in therapeutic and cosmetic preparations, metal soaps, paint driers, refractories, and textile mildewproofing and waterproofing.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Monazite produced from beach sands and river gravel is a product of ilmenite, rutile, and zircon. Other minerals often found associated include gold, staurolite, sillimanite, tourmaline, kyanite, andalusite, spinel, and corundum. Domestically, the heavy-sands rougher concentrate usually contains less than 5 percent monazite; ilmenite and rutile are usually the major constituents and zircon next in quantity. Production from these deposits, therefore, depends primarily on the demand for the titanium minerals. In Malaysia, Indonesia, and Thailand monazite is recovered as a byproduct of alluvial tin mining. Copper was a coproduct in the ore formerly mined for monazite from the vein deposit in the Republic of South Africa.

Bastnaesite ores contain no accessory minerals of great value, although barite probably could be recovered from the Mountain Pass, Calif., deposit.

Processors of rare-earth ores and concentrates have a dfficult problem in byproduct relationship. There has always been a marked difference in demand for different rare-earth elements, yttrium, thorium, columbium, tantalum, and other elements contained in rare-earth minerals. Large stocks of certain rare-earth compounds have been accumulated by industry as a result of processing monazite for thorium formerly required by the AEC.

ALTERNATE MATERIALS

Substitutes are available for many of the applications of the rare-earth elements, and new processing techniques may be harmful to budding uses.

The rare-earth oxides, arsenic, and selenium are partly interchangeable for decolorizing glass. However, rare-earth compounds have no substitutes in the production of special glasses for absorption of the ultraviolet or yellow portions of the light spectrum. Rouge and possibly some alumina abrasive compounds are cheaper and can replace cerium and mixed rare-earth oxides for optical polishing but are less effective and not as clean to work with. The potential use of rare-earth elements in curtain windows (variable transmissibility glass) may be affected adversely by concurrent research on cheaper substitutes such as silver and certain organics. The new Pilkington float process, by which flat glass is deposited while molten on a bed of molten tin, may limit one of the most promising markets for cerium and rare-earth oxide abrasives.

In carbon-arc electrodes, rare-earth compounds are far superior to any other material. Iron and calcium fluorides were used by Germany in World War II, but the light from these materials is about 30 percent less intense than that from rare-earth fluorides. Furthermore, such substitute electrodes are unsatisfactory for color photography because the light emission does not have the proper color balance.

Lighter flints have been made of zirconium-impregnated lead, but they are more expensive and not as satisfactory. Additions of magnesium-rich nickel alloy and ferrosilicon are used to produce ductile nodular iron. In the unlikely absence of certain "subversive" elements, the magnesium treatment to produce ductile iron is more efficient and less expensive than that using cerium.

In thermal neutron absorbers for control rods boron is cheaper than rare-earth compounds and creates no secondary alpha-radiation for which additional shielding must be provided. Hafnium rod is less expensive than stainless-steel cermets containing europium oxide, but the europium oxide is said to be equivalent to massive hafnium at 20 volume-percent concentration.

RESOURCES AND RESERVES

Domestic rare-earth mineral deposits have been reported in 31 States (*19*). The recorded domestic occurrences of monazite are largely in recent southeastern beach placers, that is, in Florida where some production has taken place recently, and as fossil placers, largely in Idaho and Montana. Monazite resources have been depleted very little by production, and exploration in the Southeastern States indicates that beach deposits on the Sea Islands contain substantially more monazite than previously estimated. For example, beach deposits on one island alone were estimated to contain over 100,000 tons of monazite or about 60,000 tons of contained rare-earth oxides (*17*). Despite rising production, the large deposit of bastnaesite at Mountain Pass, San Bernardino County, Calif., still contains an estimated 5 million tons of rare-earth oxides, probably 80 to 90 percent of the U.S. total reserve.

There are extensive monazite placer deposits in India, Brazil, and Australia. Deposits along the southwestern coast of India are estimated to contain over 1.4 million tons of monazite. Other deposits are known on the eastern coast, but reserve figures are not available because of lack of data due to insufficient exploration. The reserve estimate also excludes large monazite placer deposits discovered in 1956–57 in Bihar and West Bengal. Some of these deposits were reported to contain about 35,000 tons of monazite per square mile.

In Brazil, monazite beach deposits extend along the coasts of the States of Espirito Santo, Bahia, and Rio de Janeiro. The total monazite reserve, including these beach deposits and extensive fluvial placer deposits, was estimated as over 300,000 tons (*1*).

Australian monazite is largely a byproduct of beach sand mining for ilmenite in the southwestern part of Western Australia. Other production in eastern Australia is the result of mining of beach sands for rutile in the contiguous coastal areas of southeastern Queensland and northeastern New South Wales. Original estimates, some of which were not considered too accurate, placed the eastern Australian reserves at nearly 50,000 tons of monazite (*6*). The average thoria content of the monazite was reported to be 6.6 percent (*23*). Using this figure as a base and applying it to Canadian figures on total thoria resources for Australia, it was estimated that beach sands contain approximately 800,000 tons of monazite (*7*).

In Africa, measured and indicated reserves in Malagasy Republic total about 130,000 tons of monazite found in beach sands in the southeastern part of the country (*18*). The vein monazite deposit in the Republic of South Africa is stated to contain reserves large enough to sustain 2 or 3 years of mine operation if there was a demand. Malawi has recoverable reserves of 13,000 tons monazite and, in North Africa, huge deposits of heavy minerals estimated to contain about 200,000 tons of monazite occur in

780-887 O—65——49

Egypt in the Nile delta. In Asia, placer deposits of lesser size are known in Malaysia and Indonesia, where monazite is a byproduct of tin mining, Ceylon, and the Republic of Korea. In South America, outside of Brazil, beach sands containing monazite are known in Uruguay and other deposits were recently discovered in Cordoba Province, Argentina.

Other sources of rare-earth materials, largely as byproducts, are available if needed. A typical example is the commercial production of rare-earth oxides from apatite, recently undertaken in Finland. In the United States substantial quantities of rare-earth-bearing apatite are known in tailings piles resulting from magnetic iron ore processing.

SOURCES OF STATISTICAL INFORMATION

The Bureau obtains annual data on production and shipments of rare-earth ores and concentrates by domestic producers and on production and consumption of rare-earth chemicals and their use by consumers. Mineral production is covered completely by the canvass. Complete information on consumption and usage is difficult to obtain because of confidentiality restrictions imposed by several major companies. From 1946 to July 1, 1955, thorium production was under security classification by AEC, and statistics on monazite could not be released. Prior to 1961 import data on monazite were not available because of agreements with foreign governments.

PRODUCTION, CONSUMPTION, AND TRADE

Through 1963, the world production of monazite has been about 270,000 short tons, of which almost 37 percent has been in Brazil, almost 24 percent in India, over 22 percent in the Republic of South Africa since 1952, about 6.5 percent in the United States, 5 percent in Australia, 2 percent in Malaysia (Federation of Malaya), and the rest in Indonesia, Ceylon, Korea, Thailand, the Congo (Leopoldville), Malagasy Republic, and Nigeria.

During World War II and until 1955 production figures were classified. Recent monazite data disclosing individual company operations cannot be divulged. Known disclosable domestic production of monazite concentrate from 1948 through 1963 was nearly 9,000 tons, but publishable data also showed shipments totaling over 3,500 tons. From 1960 to 1963 the known domestic monazite production by the one company processing Florida beach sands primarily for titanium minerals cannot be disclosed, but it has dropped significantly from the annual totals of the companies that produced in the 1950's. Similarly, figures on bastnaesite production continuing in California cannot be given. Stoppage of monazite export, because of its thorium content, by India and Brazil had been a factor in the resurrection of the domestic industry, but the close of the AEC thorium buying program, the availability of large tonnages of monazite from South Africa, the huge reserves of California bastnaesite, increased imports from other foreign producers, and high operating costs have created a prolonged lull in the domestic mining industry. The South African source was closed down in 1963 and henceforth domestic demand apparently will be more dependent upon Australian and other larger foreign producers as well as upon domestic bastnaesite.

Following the close of the AEC thorium buying program no monazite was imported by U.S. firms in 1960. From 1961 through 1963, however, chemical processors indicated they acquired nearly 17,000 tons of monazite of which 75 percent came from the Republic of South Africa, 15 percent from Australia, and the rest from Malaysia and Ceylon.

The apparent industrial consumption of REO in compounds, metals, and alloys in 1963 was about 2,350 short tons. From 1960 through 1963 average apparent consumption of REO, as derived from shipments, was about 2,000 tons per year. This was processed mostly from monazite, of which over 17,500 tons was consumed, and from bastnaesite. Production of bastnaesite concentrate dropped 25 percent from 1960 to 1963, but the grade increased. Shipments of bastnaesite concentrate in 1963 were over 1,200 percent greater than they were in 1960.

The quantity of imports of cerium compounds, metals, and alloys has decreased markedly since 1957, but the average unit cost (determinable by comparing ratio of weight to value) rose significantly in 1958 and has remained high. In 1963, a total of 22,835 pounds of compounds, metals, and alloys (including ferrocerium) worth $57,273 was imported. In the same period 168,712 pounds of cerium ore, metals, and alloys (including lighter flints) valued at $223,781 were exported.

Tariff changes on processed rare-earth materials became effective in 1963. Cerium metal was divided into two classes of rare-earth alloys, one consisting wholly or almost wholly of rare-earth metals (misch metal). Cerium alloy including ferrocerium became ferrocerium and other pyrophoric alloys. A new category was adopted for higher purity rare-earth metals.

STRATEGIC CONSIDERATIONS

Even if imports of monazite concentrate were halted, sufficient domestic supplies of rare-earth elements would be available from the California bastnaesite deposit. Any present requirements for light subgroup metals could be met from the mining and milling capacity of the Molybdenum Corp. of America plant at Mountain Pass.

From 1946 to 1950, when India, Australia, and Brazil decided to nationalize their production of monazite for their own use, the strategic situation for the rare-earth metals appeared critical, and they were placed on the Group 1 stockpiling list. For a time, many rare-earth compounds were placed under closed or restrictive export controls. Some of the first production of bastnaesite from Mountain Pass, Calif., was purchased for the stockpile under contract with Molybdenum Corp.

Although monazite stocks held by companies are large at this time, the closing of the South African vein monazite deposit will force the industry to depend upon byproduct monazite from Australia and Malaysia. There is a larger excess of rare-earth oxide in material held in the strategic stockpile, as shown by the new lower stockpile objective—3,000 short tons of REO—announced by the Office of Emergency Planning in the spring of 1964.

On June 30, 1964, government inventories totaled 15,800 tons, of which 10,000 tons was in the national (strategic) stockpile, and 5,800 tons was in the supplemental stockpile.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration (OME) provides financial assistance for exploration for monazite or other rare-earth minerals to qualified applicants.

The accelerated tax amortization program under the Defense Production Act was closed in August 1955 after $4,771,000 had been granted to processors and producers. No other programs are in effect or under consideration.

PRICES

For about a decade the nominal prices on imported monazite have been based on its rare-earth oxide and thorium oxide content. During this period the only changes in price have been on the 55-percent massive variety, which rose from 13 cents to 14 cents per pound in 1958, and for the 55-percent sand variety, which in mid-1960 changed from a rigid 15 cents to a range of 10 to 15 cents per pound. The monazite sands of 66 and 68 percent grades have remained at 18 cents and 20 cents per pound, respectively. Known prices of monazite produced and exported from six countries since 1960 ranged from 3 to 12 cents per pound of monazite concentrate. Company confidentiality prevents divulgence of prices paid for domestic monazite mined by a limited number of companies since 1959. A similar restriction exists on disclosure of the price of bastnaesite concentrate mined by one company in California.

Prices listed by one company on intermediate lot sizes of most commercial rare-earth compounds, referred to as production chemicals, were increased in 1963 over those in effect in 1960. For example, in 1963 and 1964 the price for rare-earth chloride in 50- to 99-pound lots was about 60 percent greater than that in 1960, and that for rare-earth oxide in the same size lots was about 35 percent more. Larger size lots of high-purity compounds were available from all companies. In many instances prices of high-purity compounds remained stable, but prices were increased moderately on others and substantially on several compounds of the scarcer rare-earth elements. In 1963, one company lowered prices on most of its high-purity oxides. Another company reduced prices on oxides twice in 1963, in some cases about 20 percent. Prices of other rare-earth salts are usually based on percentages of oxide prices.

Prices for misch metal in 1963 ranged between $2.60 and $3.50 per pound, depending upon grade, the quantity ordered, and whether it was in the form of ingots, donuts, pellets, or extruded pellets. Larger size lots of high-purity metals have become available recently. Quoted prices for small pound lots of high-purity metals from a major producer ranged from $123 per pound for cerium to $4,250 per pound for lutetium. Metal prices, generally on slightly smaller lots, from another company were increased slightly in early 1964 but ranged from $73 to slightly over $5,600 per pound. This company did not quote a pound price for lutetium metal. A third company cut prices on some metals by almost half in a period of 2 years and twice in 1963 reduced prices on some metals by several percent to over 25 percent.

TAXES

Rare-earth minerals, with the exception of monazite, are eligible for 15 percent depletion allowance on gross incomes from mining. Domestic monazite, because it is an ore mineral of thorium, is eligible for a 23-percent depletion allowance. A depletion of 15 percent is allowed on foreign production of monazite and other rare-earth minerals.

RESEARCH

Industry, educational and research institutions, private foundations, a number of Federal agencies, and foreign governments have spent and are continuing to spend large amounts of money on rare-earth research. The Lindsay Light Co., now the Rare Earth Division of American Potash & Chemical Corp., was an early industrial pioneer in developing uses for rare-earth materials. The advent of nuclear technology aroused increased interest in these elements, of which the AEC had a large share. Institutions working with or under the Commission are the Ames Laboratory at Iowa State University, Ames, Iowa, where ion-exchange techniques were developed (*26*, *27*) and distillation of metals has been investigated; Oak Ridge National Laboratory where effective solvent extraction methods have been devised; Los Alamos Scientific Laboratory where aqueous electrolytic extraction and phase studies have been investigated; and Argonne National Laboratory, where physical properties of metals have been determined. Other organizations working for the AEC on rare-earth projects include the General Electric Co. which has studied rare-earth compounds in neutron absorbers, and Battelle Memorial Institute, where semiconductor research has been underway. Sponsored by the Air Force Office of Scientific Research, scientists at RCA have investigated the use of rare-earth materials in lasers, and investigators at the University of Denver have made phase studies and determined thermochemical properties. Investigators at the Bureau of Ships, Department of the Navy, have conducted research on thermoelectric materials and the Bureau has sponsored investigations by Westinghouse Electric Corp. on semiconductors. The Office of Naval Research has helped finance laser research by General Telephone & Electronics Laboratories, Inc., and, with the National Science Foundation, has financed research by universities on the physical properties of the rare-earth elements. Scientists at the National Bureau of Standards have investigated physical properties and phase phenomena. Molybdenum Corp. of America and Pennsylvania State University have cooperated on a product-and-use study on bastnaesite.

All aspects of rare-earth research were discussed at four conferences held in the United States since the fall of 1960. At the most recent meeting, sponsored by Arizona State University and the U.S. Air Force Office of Scientific Research, there was increased emphasis on utilization of rare-earth materials in laser research and the gathering included a number of distinguished foreign contributors. New trends in the investigation and application of rare-earth elements were reported in a conference held in Moscow in March 1963 in which wider use of rare-earth elements in research and industry was recommended.

From 1948 to 1952, the Bureau of Mines cooperated with the AEC and the Geological Survey in extensive investigations of monazite resources (*5*, *11*, *14*). More recently the Bureau has compiled information on rare-earth metals and thorium deposits in several Western States (*12*), and currently studies are underway to evaluate tailings piles from magnetite iron ore processing as a potential source of rare-earth elements. The Bureau's metallurgical program has included intensive research on analytical procedures, thermodynamic studies, extraction from ores and concentrates, separation of the individual rare-earth elements from one another, their reduction to metals, and physical metallurgy of the metals and their alloys.

OUTLOOK

Rare-earth metals and compounds are expected to be consumed on a slightly increasing scale in the next few years in such conventional uses as metal and glass manufacturing and continued to be consumed at the same rate in the production of carbon-arc electrodes. Misch metal and newly developed rare-earth silicides will be used to deoxidize, reduce grain growth, and improve castability in certain types of steel and promote graphite nodularization in ductile cast iron. Consumption by the glass industry will be mostly as oxide polishing compounds used largely for grinding prescription eyeglasses and instrument lenses, as well as in the manufacture of mirrors. Fluorides and oxides will continue to be used in the cores of arc-light carbons.

The large increases in the consumption of rare-earth compounds, recently believed imminent because of anticipated greater long-range applications or expansions, probably will not develop because of new production methods or alternate materials. Large-scale flat glass polishing using rare-earth oxides probably will not develop as much as hoped for because of the recent development of the float glass process that produces plate glass that does not require the extensive polishing of glass produced by the old process. Furthermore, rare-earth chloride usage in fixed-bed petroleum cracking catalysts may not become as large a consumption factor as believed previously because of competition from the large-scale use of other types of fluid-bed cracking catalysts.

The long-range outlook, then, is for a steady but not explosive growth in consumption with any acceleration being contributed by uses now in their infancy or in the process of development. Many of these newer or potential uses will require separated extremely pure rare-earth compounds or metals. This is true especially in certain magnetic materials and for rare-earth compounds used in laser and television phosphor applications. A type of glass window, able to transmit and absorb sunlight rapidly, may depend upon absorption bands characteristic of rare-earth additives. Certain rare-earth sulfides may be useful in thermoelectric materials at elevated temperatures. Because of their superior neutron-absorption qualities, some rare-earth elements will be used increasingly in reactor control rods in commercial nuclear powerplants.

One of the least abundant of the rare-earth elements, europium, shows great possibilities as a television phosphor, laser, and control-rod material. Increased processing of rare-earth ores or reprocessing of residues might be required to meet a greater demand for this element. The likelihood exists that, by the last decades of this century, the processing of ores for the extraction of thorium required to generate nuclear energy also will provide by-product rare-earth metals. Other rare-earth elements may be extracted, as now done commercially in Finland, from apatite, a phosphate mineral often associated with magnetic iron ores and forming substantial parts of extensive mine tailings piles.

Generally, advances in technology will result in overall decreases in processing and refining costs. Prices for europium or other metals in great demand, however, probably will rise to offset the processing and storage costs of the excess rare-earth compounds.

PROBLEMS

Resource problems are created by the complex relationship of the rare-earth elements rather than by their scarcity. The occurrence of the suite of rare-earth elements in rare-earth deposits and as byproducts of varied significance in other ore deposits normally creates an inherent instability in rare-earth mineral supply economics. This problem is intensified from time to time by the accumulation of surplus rare-earth materials as byproducts of other commodities or of particular rare-earth elements in greater demand. The current situation is one of oversupply for most of the rare-earth elements; the main problem being to find markets. This problem probably will become more acute as the need for europium or other scarce rare-earth metals may lead to creation of excess quantities of the more abundant rare-earth elements. There probably will be the loss of a significant portion of the polishing compounds market due to the development of the float glass process. Producers often are handicapped by scanty knowledge of the extent and nature of some rare-earth resources, partly because certain rare-earth minerals are difficult to recognize. In addition to the influence of normal economic factors, instability also results from political and strategic policies in this and in foreign countries on exploitation of monazite because of the potential nuclear energy applications of its thorium content.

Limited knowledge of some of the unusual properties of extremely pure rare-earth metals and compounds continues to hamper development of new uses upon which the rare-earth industry depends for much of its expansion. The need for concentrated utilization research on mixed and pure materials probably is greater than scattered or unorganized basic research on physical and chemical properties of metals and compounds.

The difficulty of recognizing rare-earth minerals in the field handicaps the search for new deposits. Precise laboratory analyses for individual elements in rare-earth metals and compounds are difficult because of the low order of magnitude of impurities permitted for most new uses. This usually prevents use of ordinary chemical analyses necessitating methods involving emission and X-ray spectrography, neutron activation and atomic absorption, and advanced laser spectrography.

Typical placer mining problems are common to many rare-earth deposits. Sampling procedures are sometimes unreliable, mineral dressing methods (particularly in separation of fine-grained material) need improvement, and tailing disposal, land reclamation, and stream pollution create special problems of growing intensity. Improved quarrying or underground mining, crushing, and benefication methods are needed for disseminated rare-earth mineral deposits.

Technologic problems exist in all stages of rare-earth mineral processing. Mineral dressing and extractive processes used for rare-earth ores and other source materials are complex and time consuming. Natural raw materials vary in composition; similar materials from different sources vary in amenability to concentration and recovery. The separation of individual rare-earth elements from one another is difficult because of their chemical similarity. Clean-cut separation of elements of adjacent atomic numbers is particularly difficult, and it often

requires numerous processing stages or large quantities of expensive reactants to obtain pure compounds with reasonably high recovery. Problems encountered in metal production are those of incomplete reduction and the difficulty of collecting homogeneous metal nodules, the need for better construction materials for processing equipment to minimize contamination, the selection and development of suitable electrolytes, the lack of rapid continuous metal production processes, and the removal of certain impurities retained after ordinary refinement.

Distances between sources of supply and markets are usually large, with resulting high freight costs.

Statistical data accumulation and dissemination continue to be hampered by the restrictions companies place on the publication of production and consumption figures. Sometimes information on new uses is not readily available.

RHENIUM

By Richard F. Stevens, Jr.[1]

ALTHOUGH the existence of rhenium was predicted over 100 years ago, it was not isolated until 1925. Since that time, rhenium has been found in minute quantities in many minerals. It is obtained commercially only from the molybdenite concentrate of porphyry copper ores. Germany supplied the world's rhenium requirements until World War II. When U.S. imports from Germany were halted, domestic sources of rhenium were developed from the flue dust obtained during the roasting of Arizona molybdenite.

The University of Tennessee, the first domestic rhenium producer, roasted the molybdenite and processed the flue dust. Kennecott Copper Corp. later found rhenium in the molybdenite recovered from southwestern copper ores. During the roasting of molybdenite to form molybdenum oxide the rhenium oxide volatilizes. Chase Brass & Copper Co., Inc., a subsidiary of Kennecott Copper Corp., developed a method to recover rhenium from the flue gasses. In 1954, Chase began recovering rhenium and producing rod, wire, strip, foil, and other shapes of pure rhenium.

Prior to World War II the main use of rhenium was in thermocouples and pen points. However, in 1963, approximately 80 percent of the rhenium consumed was used in tungsten and molybdenum alloys. A minor amount of rhenium is used in electronics, thermocouples, electrical contacts, catalysts, and coatings. Research is being conducted to seek commercial applications of pure rhenium. Because of its high melting point rhenium is being studied for use in high-temperature and corrosion-resistant alloys.

In 1963 the domestic consumption of rhenium metal reported to the Buerau of Mines by five major consumers was almost 500 pounds which was believed to represent approximately 85 percent of the total domestic consumption. It is expected that the consumption will continue to increase significantly. Domestic resources of rhenium from molybdenite sources are estimated to be from 200 to 250 short tons.

In 1963 rhenium metal powder sold for $650 per pound up to 1 pound and prices decreased to $580 per pound for lots of 20 or more pounds. Wire, strip, foil, and other shapes are available at approximately $750 to $1,200 per pound. The principal problem associated with rhenium is its limited supply.

BACKGROUND

When the first periodic table of elements was published by Mendeleev in 1860 provisional names were given to several unknown and undiscovered elements; element 75 was named dvimanganese. In 1925 chemists in Germany, Great Britain, and Czechoslovakia (*3*) [2] almost simultaneously claimed the isolation of element 75, and Dr. Walter Noddack, Ida Tache, and O. Berg, of Germany were credited with discovering rhenium, naming it after the river Rhine. They identified rhenium in 5 of 30 complex mineral samples and produced 50 milligrams of residue containing 5 percent rhenium from a kilogram of columbite. In 1929 the discoverers produced 1 gram of rhenium from 660 kilograms of Norwegian molybdenite.

Before World War II, Germany supplied the world with rhenium. Potassium perrhenate was produced commercially in the middle 1930's from potash residues (brown salts), now exhausted, by Vereinigte Kaliwerke in Aschersleben, East Germany. Degussa processed the perrhenate and it has been reported that 200 kilograms of rhenium was extracted annually. Another source was the rhenium-bearing residues and dusts from the Mansfeld coppersmelter at Eisleben, East Germany.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

In 1942 Professors A. D. Malaven and J. A. Bacon, at the University of Tennessee, found a source of rhenium in molybdenite roaster flue dusts from the Miami Copper Co. smelter, Miami, Ariz., and developed a method for recovering the rhenium from this source. Subsequently, the University became the first domestic producer of rhenium. Kennecott Copper Corp. later found rhenium in molybdenite in its southwestern low-grade copper ores and began recovering the element in 1954 and shipping it in 1955.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Rhenium is produced in the United States by the chemistry department, University of Tennessee, Knoxville, Tenn., and by Chase Brass & Copper Co., a subsidiary of Kennecott Copper Corp., Waterbury, Conn.

DEFINITION OF TERMS AND GRADES

Rhenium melts at 3,180° C, has a density of 21 grams per cubic centimeter, and a modulus of elasticity of 67×10^6 pounds per square inch (*4, 5, 6*). In elemental form, only tungsten and carbon have higher melting points; only platinum, iridium, and osmium are denser, and only osmium and iridium have a higher modules of elasticity. The element retains its ductility after heating at high temperatures. The ultimate tensile strength of annealed rhenium sheet is about 168,000 pounds per square inch, and that for cold-rolled rhenium sheet reduced 30 percent is 322,000 pounds per square inch. The element has hexagonal close-packed crystal structure, and its elevated-temperature strength is higher than either tungsten or tantalum, which have body-centered cubic crystal structures. Rhenium oxidizes in air, and when heated to 1,000° C oxidizes at about the same rate as tungsten. Rhenium is the most refractory of the metals that can be electrodeposited from aqueous solution. The element resists corrosion by hydrochloric and hydrofluoric acid, is little affected by cold sulfuric acid, but is readily dissolved in nitric acid. Rhenium has valences −1, 1, 2, 3, 4, 5, 6, and 7.

Rhenium alloys with chromium, cobalt, columbium, iridium, iron, gold, mercury, molybdenum, palladium, platinum, nickel, osmium, rhodium, tantalum, tungsten, and vanadium but not with carbon, copper, silver, tin, or zinc. Some rhenium-molybdenum alloys have high-temperature strength and very high ductility. A 50-percent rhenium-molybdenum alloy has a melting point of more than 2,500° C and can be cold-rolled to more than 90 percent reduction without failure. At 800° C, the hardness of this alloy is about 200 Vickers Hardness Number (VHN) in annealed condition and 350 VHN in worked condition. Tungsten and molybdenum have hardnesses of 70 and 80 VHN, respectively. Tungsten alloys containing 30 percent rhenium and molybdenum alloys containing 50 percent rhenium are considerably more ductile than unalloyed tungsten or molybdenum.

Rhenium forms compounds with metals such as arsenic, germanium, selenium, silicon, titanium, zirconium, and with non-metals such as oxygen, phosphorus, sulfur, and halogens. Organic compounds containing rhenium also have been produced.

TECHNOLOGY

Geology

The average concentration of rhenium in the earth's crust is estimated at one part per billion, or about one fifteen-thousandths as much as molybdenum, the element with which it commonly occurs (*5*). It has been found in minute quantities in many minerals including alvite, chalcocite, chalcopyrite, columbite, gadolinite, molybdenite, orangite, pyrolusite, rutile, tantalite, thortveitite, wulfenite, and in rare-earth minerals and in ores of copper, manganese, molybdenum, platinum, uranium, and potash.

Metallurgy

Processes have been developed to extract rhenium from platinum ores, molybdenite-bearing flue dusts and gases, pig molybdenum, and residues from potash operations. During the milling of copper ores of Miami Copper Co., Miami, Ariz., and southwestern low-grade copper ores of Kennecott Copper Corps., rhenium-bearing molybdenite concentrate is produced as a byproduct. When the concentrate is roasted, rhenium oxide is volatilized, and it is recovered from flue gas and dust.

At the University of Tennessee, flue dust containing rhenium oxides and unconverted molybdenum sulfide, is leached with water and filtered. The filtrate, containing soluble rhenium heptoxide, is treated with solid potassium chloride and crude potassium perrhenate is precipitated. This precipitate is reduced to rhenium metal with hydrogen at 300° C under 3,000 pounds per square inch in a silver-lined bomb.

Kennecott Copper Corp. uses the following rhenium recovery process (*13*). Gas from the

roasting of molybdenite concentrate is cleaned of dust particles and scrubbed with water to dissolve the rhenium oxide. The solution is clarified, conditioned, and passed through ion-exchange equipment. Processing is continued until high-purity ammonium perrhenate is produced. To produce metal powder (*2*), finely ground, high-purity ammonium perrhenate is placed in 8-inch-long molybdenum containers (boats) to a depth of about five-eighths of an inch. The boats are loaded into an externally heated furnace of stainless steel pipe 2 inches in diameter by 12 feet long, and purified dry hydrogen is passed through the pipe to reduce the compound to rhenium powder.

Powder-metallurgy techniques are used to prepare metal shapes. Powdered metal compacts are pressed at 25 to 30 tons per square inch, vacuum presintered at 1,200° C for 2 hours, sintered with hydrogen at 2,850° C and shaped by alternate cold working and annealing. Products are rod, wire, strip, foil, and disks.

USES

Before World War II, rhenium was used commercially in pen points and thermocouples. Its major use now is as an alloying addition to tungsten and molybdenum. Tungsten-rhenium thermocouple elements have been developed which can measure and control temperatures up to 2,500° C. Rhenium also is used in other kinds of thermocouples; in filaments for mass spectrographs for analyzing gases; and in filaments for ion gages for measuring high vacuum (*2, 4, 10*). Most rhenium being produced in the United States is used in research on the properties and potential applications of the metal and its alloys. Some promising uses are as vacuum tube filaments, cathodes, and cathode supports and heaters; as lamp filaments; and in electrical contacts. Other uses developed for rhenium include filler rod for welding molybdenum and tungsten; heat-, wear-, and corrosion-resistant alloys; plating; and as a catalyst.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Rhenium is a byproduct of molybdenite derived from copper sulfide ores. Deposits mined principally for molybdenite usually contain little or no rhenium.

ALTERNATE MATERIALS

Technetium, which is recovered from the waste fission products of nuclear reactors and consequently has a potentially large supply, may be substituted for rhenium in alloying applications. Since rhenium and technetium have similar properties and structure they form the same type of alloys. The slight beta particle radioactivity of technetium is shielded by alloying. The use of technetium will be dependent upon the availability of waste isotope reprocessing facilities and the price of separating technetium from accompanying radioactive fission products.

Because technetium is radioactive, it is not a suitable substitute for rhenium in all of its uses.

RESOURCES

At present the only commercial source of rhenium is as a byproduct of molybdenite which itself is a byproduct of low-grade porphyry copper ores. In the United States the reserve of rhenium in copper ores is estimated at 200 to 250 short tons. Other countries which have copper ore deposits containing byproduct molybdenite include: Canada, Chile, Peru, and Mexico. Although rhenium may occur in these deposits, no production has been reported. The free world reserve of rhenium from byproduct molybdenite is estimated at about 400 to 600 short tons. At 50- to 80-percent recovery about 6 tons of rhenium could be produced annually if all presently recovered domestic byproduct molybdenite was treated. Additional rhenium resources may become available from other molybdenum, uranium, manganese, tungsten, zirconium, columbium, tantalum, and gadolinium ores.

Recovery of rhenium from reserves in molybdenum or porphyry copper deposits has been reported in Europe and the U.S.S.R.

PRODUCTION AND CONSUMPTION

The current consumption of rhenium in the United States has been estimated at 500 pounds per year. The potential production of rhenium from molybdenite sources in the United States has been estimated at 6 tons per year.

Rhenium production and consumption in Europe and U.S.S.R. are believed to be small.

TARIFF

Rhenium ore and concentrate enters the United States duty free. Under the "Tariff Schedules of the United States, Annotated (1963)," the duty on unwrought rhenium metal or compounds is 10.5 percent, ad valorem, and the duty on wrought rhenium metal is 18 percent, ad valorem. The corresponding Statutory Rates of Duty are 25 percent, ad valorem, and 45 percent, ad valorem.

PRICE

Rhenium powder was priced at $14 per gram in 1942, $10 in 1943, $6.50 in 1944, and $3.25 per gram in 1946. In 1963, Chase Brass & Copper Corp. quoted rhenium powder, Grade I, at $650 per pound ($1.43 per gram) in ½-pound lots. Prices for rhenium rod having diameters ranging from 0.2 to 0.025 inch were quoted at $900 to $1,260 per pound, respectively, and for rhenium strip having thicknesses ranging from 0.06 to 0.001 inch at $815 to $1,580 per pound, respectively. Rhenium sintered bar was quoted at $800 per pound up to 1 pound, $775 per pound for quantities between 1 and 5 pounds, and $750 per pound for quantities over 5 pounds. The base quotations for rhenium wire ranged from $65 per foot for wire of 0.100 inch diameter to $2.65 per foot for wire of 0.010 inch diameter.

RESEARCH

During World War II the University of Tennessee developed and patented a process to extract rhenium from molybdenum roaster flue dust. Since then, the University has occasionally announced research on preparation, isolation, physical properties, and uses of rhenium and its salts.

Kennecott Copper Corp. developed methods to extract rhenium incidental to the production of molybdenum oxide (*13*), and also developed methods to shape the metal (*2*).

Important contributions to rhenium technology have been made in the past few years as a result of work conducted by Battelle Memorial Institute and the National Aeronautics and Space Administration (NASA). Rhenium research, conducted primarily on alloying investigations, has been sponsored by the U.S. Air Force, Navy, and Atomic Energy Commission (AEC) (*7*).

The Buerau of Mines has conducted research on rhenium and published reports on its investigations (*1*, *8–9*, *12*). Current research by the Bureau on rhenium and tungsten-rhenium alloys is being conducted in cooperation with the AEC and Chase Brass & Copper Co. Research on vapor deposition of rhenium and tungsten-rhenium combinations from halide gasses is also being conducted by the Bureau.

OUTLOOK

The outlook for rhenium is for continued and increasing usage. The major consumption of rhenium will be as an alloying element with tungsten and molybdenum where rhenium additions lower the ductile-brittle transformation temperatures of the alloys and allow fabrication to be conducted at room temperature. Pure rhenium metal will continue to be used in electrical contacts, thermocouples, catalysts, and coatings. However, because of its high price and short supply the use of rhenium in these applications will represent a minor part of the total rhenium consumption.

Although the demand for rhenium as an alloying element will increase, its use will be limited by the limited supply. Development of a larger supply of rhenium would cause the applications to increase and the price to decrease. It appears unlikely that such a supply source will be found.

Unless rhenium recovery techniques are utilized by all processors of molybdenite obtained from porphyry copper ores, all the available rhenium will not be recovered.

PROBLEMS

The principal rhenium problems are its limited supply and high cost. As new sources of supply are found the price will decrease. Although the potential supply of rhenium is adequate for the immediate future, there is a current resource problem caused by the fact that approximately 50 percent of the rhenium occurring with molybdenum is not being recovered.

Although there is a need for continued research on rhenium and its alloys and compounds, to obtain more complete knowledge of these materials, the major need is for more intensive and extensive resource exploration to discover new sources of rhenium and for more research on methods of extracting rhenium from presently known submarginal resources. A partial solution to the problem of short supply might be that proposed by the Materials Advisory Board in its report (*6*), which recommended that rhenium be considered a strategic material and be purchased and stockpiled by the U.S. Government.

RUBIDIUM

By Donald E. Eilertsen [1]

RUBIDIUM, a highly reactive metal with air or water, was discovered in 1861. Numerous firms have processed raw materials to rubidium primary products during the last few years, but most of these operations discontinued. Currently most production of rubidium and its compounds is from accumulated stocks of alkali carbonates from operations that formerly processed lepidolite to lithium compounds. Some rubidium output has come from processing pollucite for cesium. Outputs of rubidium and its compounds are small but trends are upward. Very little is known about the resources of rubidium in commercial concentrations even though the element is more abundant than zinc in the earth's crust.

Rubidium has few commercial uses and among these are the use of rubidium in radio tubes and photocells, and the use of radioactive rubidium to trace the flow of blood. Rubidium has been studied somewhat intensely in recent years and a few important potential applications have been found. One of the major problems of rubidium is the lack of uses.

BACKGROUND

Rubidium was identified in 1861 and had almost no industrial applications until the 1920's when small amounts were developed for use in photoelectric cells. During World War II, Germany extracted rubidium and cesium from residues from lithium operations; the rubidium was used for medical purposes and cesium for photoelectric cells.

Prior to 1958, outputs of rubidium and its compounds in the United States were a few hundred pounds annually but during that year some new technical-grade rubidium compounds were prepared from alkali carbonate residues of lithium operations, and the production of rubidium and its compounds noticeably increased.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The rubidium-producing industry is small. Many firms have processed raw materials to rubidium primary products in the last few years, but most of this activity has stopped until the demand increases. During the period 1961–63, the producers of rubidium primary products were: Penn Rare Metals (subsidiary of Kawecki Chemical Co.), Revere, Pa., 1961–63; American Potash and Chemical Corp., Trona, Calif., 1961–63; MSA Research Corp., Callery, Pa., 1962; and Rocky Mountain Research Inc., Denver, Colo., 1962.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Rubidium (Rb) is soft, white, and the fourth lightest metal. It reacts violently with water and ice and ignites spontaneously when contacted with oxygen. Rubidium tarnishes rapidly in air and becomes coated with oxides. The molten metal ignites spontaneously in air. Some of its other properties are: Atomic number, 37; atomic weight, 85.48; density in solid form, 1.53 g./cm.^{3}; melting point, 38.5° C; boiling point, 688° C; and ionization potential of gaseous atoms, 4.16 volts.

ALKARB is a trade name given to a dry product formerly produced in San Antonio, Tex., from end liquor resulting from the extraction of lithium values from imported lepidolite. It consists of mixed alkali carbonates usually containing about 2 percent cesium and 20 to 25 percent rubidium carbonates. Lepidolite is no longer used to produce lithium compounds in the United States; consequently, ALKARB production ceased, but supplies are still available from accumulations.

TECHNOLOGY

Mineralogy, Geology, and Mining

Rubidium and cesium often occur together in nature. The earth's crust has been estimated to contain 310 parts per million of rubidium while sea water contains about 0.2 part per million (*5*). The element occurs as an impurity in various minerals including lepidolite, pollucite, microcline, and biotite from granites and pegmatites, and carnallite from saline deposits. A field test for cesium and rubidium was developed to help prospectors identify the elements (*2*). Usually rubidium is found associated with one or more of the other alkali metals and occurs in greatest abundance in granites, granite pegmatites, and greisen. Samples of brine have been analyzed that contain up to 600 parts per million of rubidium.

Currently the commercial source of rubidium is mostly from accumulated stocks of ALKARB but a little from pollucite. Lepidolite, valued for its lithium and cesium content, is mined usually with other valuable pegmatite minerals by conventional opencut methods, or in some instances from underground operations. Most pollucite is probably recovered by hand-sorting methods.

Metallurgy

The historical process used on both lepidolite and carnallite residues comprises extraction of mixed crystals of rubidium and cesium alum from alkali residues by means of a series of ammonium alum precipitations. About 30 fractional recrystallizations are required subsequently to separate the more soluble rubidium alum from the cesium alum. In recent years two less expensive extraction methods have been used (*6*).

The chlorostannate method requires a partial separation of the potassium contained in the starting solution by dispersing carbon dioxide flue gas through the mixed alkali solution to precipitate potassium acid carbonate ($KHCO_3$). The remaining dissolved carbonates are converted to chlorides by adding hydrochloric acid and treated with enough stannic chloride to precipitate cesium chlorostannate, which is less soluble than its rubidium counterpart. Then the cesium-free chloride solution is treated with an excess of stannic chloride to precipitate rubidium chlorostannate. To purify the rubidium chlorostannate precipitate, it is dissolved in HCl and reduced to the stannous state. Chlorine gas is injected into the solution, resulting in reprecipitation of pure rubidium chlorostannate. The chlorostannate may be decomposed to separate the rubidium and tin chlorides by pyrolysis, by electrolysis, or by reducing the chlorostannate with iron and then adding sodium perchlorate to precipitate rubidium perchlorate which is decomposed to the chloride by heating.

The ferrocyanide method is used if the ferrocyanide or carbonate form is the desired rubidium end product. The mixed alkali carbonate liquor from the lepidolite plant is treated with sufficient sodium zinc ferrocyanide to precipitate cesium zinc ferrocyanide selectively. Then sodium zinc ferrocyanide is added in excess to precipitate rubidium zinc ferrocyanide.

The rubidium zinc ferrocyanide is decomposed and carbonated by heating in air, rubidium carbonate is water-leached from the roasted material, and the solution evaporated to dryness.

The simplest method of preparing the metal is by high-temperature vacuum reduction of the carbonate, hydroxide, or chloride. Rubidium carbonate or other compounds can be reduced by heating in vacuum or hydrogen with any one of several metals. An alternate method, seldom used commercially, is electrolytic reduction in fused-salt systems, using a rubidium compound such as the hydroxide, cyanide, or one of the halides as starting material.

USES

Only a few commercial uses have developed for rubidium, among them are the use of its compounds in radio vacuum tubes and photocells and of radioactive rubidium in medical testing as a "tag" element to trace the flow of blood. The latter use is increasing (*7*).

Rubidium and its compounds are so similar chemically to those of cesium that choice between them depends largely on which gives superior performance. Quantities of rubidium metal and compounds have been utilized in

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

research and in the development of applications. Potential uses for rubidium under consideration include use as a heat-transfer fluid and additive to gas in thermionic converters to convert heat directly to electricity, use of rubidium compounds as catalyzers in organic reactions, and small additions of rubidium to make glass more stable and durable (7).

ALKARB, a commercial source of cesium and rubidium, also has uses in glass, ceramic glazes, and porcelain enamels.

BYPRODUCTS AND ALTERNATE MATERIALS

Rubidium currently is being obtained from stocks of ALKARB, a byproduct derived from processing lepidolite to lithium compounds and no longer produced in the United States. Some rubidium also has been produced as a byproduct of processing pollucite to cesium. Lepidolite and pollucite are recovered from pegmatites which often yield other valuable minerals.

Pollucite might be able to substitute for ALKARB as a commercial source of rubidium when stocks of ALKARB become exhausted, but it would be costly to process pollucite only for rubidium.

The properties of rubidium are similar to those of the other alkali metals, but it is rarely used as a substitute for them because of its relatively high price.

Cesium, germanium, tellurium, selenium, silicon, and several other elements and compounds are alternate photosensitive materials.

RESERVES

Rubidium is much more abundant than either lead, copper, or zinc in the earth's crust, but very little information is available on natural concentrations of rubidium in potentially commercial deposits.

One of the largest known resources of rubidium in North America is reported to be that in pollucite in lithium-bearing pegmatite deposits at Bernic Lake, Manitoba, Canada. Tentatively, these deposits have been estimated to have 350,000 tons of pollucite containing 20 percent cesium and substantial rubidium oxide.

The principal domestic source of rubidium is ALKARB, a mixture of alkali carbonates derived from waste liquors resulting from processing certain imported lepidolite for lithium. Lepidolite has been reported to contain up to 3.5 percent Rb_2O, the rubidium being considered an impurity.

Large quantities of rubidium are reported in lepidolite and pollucite deposits in Southern Rhodesia, South-West Africa, and Mozambique.

Rubidium also exists in certain feldspars, brines, and saline deposits.

PRODUCTION, CONSUMPTION, AND TRADE

Statistical data on domestic rubidium are obtained by the Bureau of Mines through canvassing. Most of the data obtained are withheld to avoid disclosing company confidential information. Output of rubidium metal and compounds have fluctuated, sometimes sharply, but the long term trend is upward.

Import data on rubidium metal have been available since September 1963. No rubidium was imported during the last 4 months of 1963 or during 1964. No data are available on imports of rubidium compounds and exports of rubidium metal and compounds.

Pollucite is imported duty free. Rubidium metal and rubidium compounds are each dutiable at 10.5 percent, ad valorem.

STRATEGIC CONSIDERATIONS AND GOVERNMENT PROGRAMS

Producers of rubidium metal and compounds have easily met the small demand for these materials.

The United States is self-sufficient in ALKARB as long as the privately owned stock lasts, but when this supply is exhausted, rubidium output will have to rely much more on imports of pollucite and/or other domestic or foreign raw materials for sources of rubidium.

Rubidium is not on the list of materials for stockpiling in the national (strategic) and supplemental stockpiles.

PRICES

Prices quoted for 99+ percent rubidium during 1963 and 1964 were $390 to $425 per pound.

TRANSPORTATION AND SAFETY MEASURES (7)

Major precautions should be taken in handling, transporting and storing rubidium because it is very reactive with water and air. Rubidium is available in Pyrex glass ampoules or returnable stainless steel cylinders and is normally packed under argon or in vacuum.

Rubidium compounds are not particularly reactive; consequently, no special precautions in packaging these materials are necessary.

RESEARCH

Rubidium has been studied somewhat intensely in recent years in connection with heat transfer fluid, additive to the gas in thermionic converters which convert heat to electricity, and other applications.

The Bureau of Mines research on cesium and rubidium in recent years has been concerned with the development of concentration methods for pollucite (*3*, *4*), extraction and separation of cesium and rubidium from pollucite (*1*), purification of cesium and rubidium salts, and recovery of rubidium and other valuable metals from saline water.

OUTLOOK

Only moderate growth of rubidium production is predicted, although unforeseen large uses could develop as a result of technological advances.

The major rubidium source material in the United States will continue to be from the limited stock of rubidium-rich alkali carbonates derived from that portion of the lithium industry which formerly processed lepidolite to lithium. Some rubidium will be obtained from pollucite, and if necessary, from other materials.

Research will continue to be moderately sustained in developing the technology of rubidium and on the development of uses.

Occasional reductions in the price of rubidium metal and some of its compounds may occur if firm and larger demand for these materials would allow large scale production on a regular basis.

PROBLEMS

Rubidium's numerous problems extend from discovery of deposits through extraction and uses.

Rubidium occurrences are numerous particularly in pegmatite, brines, and saline deposits, but information is lacking on the nature and extent of rubidium in deposits. Consequently, the rubidium discoveries currently of commercial worth may not be competitive with subsequent discoveries.

Practically all domestically produced rubidium is being produced from stocks of byproduct alkali carbonates derived from processing imported lepidolite to lithium. The lithium industry no longer processes lepidolite, consequently there is no rubidium byproduct raw material being produced from this source.

Costly multistage extraction techniques employed to extract rubidium are largely responsible for the high prices of rubidium and its compounds.

The lack of complete data on the physical and chemical properties of rubidium hinders the development of uses. In addition, the alloying characteristics of rubidium, especially the development of intermetallic compounds, have not been extensively investigated.

Special precautions must be taken in preparing, handling, storing, and transporting rubidium as rubidium is extremely reactive. It ignites spontaneously in air and reacts explosively in water, and mists containing certain rubidium compounds are caustic. These costs contribute to high prices of rubidium.

Rubidium's high prices, uncertain supply, and not fully developed technology discourage the development of uses.

SAND AND GRAVEL

By Perry G. Cotter [1]

THERE are more than 5,000 active producers of sand and gravel in the United States, and the output of sand and gravel, during the past two decades, has increased 250 percent. Total volume of production exceeds that of any other mineral commodity. Production is reported from every State, and latent or active deposits are located in almost all counties. Individual plants comprise small portable units, many of which produce less than 25,000 tons per year, and the multiunit operations of large corporations often associated with crushed stone plants, ready-mixed concrete plants, and slag processing, that individually produce in excess of 1 million tons annually. At the point of production, over 97 percent is valued at less than $1 per ton. Cost of transportation to markets may amount to much more than pit value and so markets are extremely confined. The volume and value of sand and gravel entering foreign trade is negligible.

The stability of the industry is evinced by its competence to produce increasing tonnages of this low-priced, bulky commodity to meet the various specifications of thousands of purchasers in all sections of the country. Few other producers of mineral commodities are faced with the number and complexity of the technical and economic problems inherent to the sand and gravel industry. However, the ingenuity of manufacturers of excavating, processing, and transportation equipment has assisted in keeping overall cost of production low, and research by various segments of the industry has developed profitable uses for materials formerly wasted. The upward trend of production is expected to continue, and yearly consumption by 1970 is estimated to be over 1 billion tons.

There are six factors to be considered in determining if a sand and gravel deposit can be profitably worked. (1) For what can the material be used? (2) Where are the potential markets, and what quantity can be sold? (3) What specifications as to particle size, shape, hardness, chemical composition, durability, texture, and freedom from impurities must be met? (4) For what price can it be sold? (5) What type of equipment is most efficient for mining and processing this sort of material? (6) What will it cost to prepare for market?

Some of the problems of the industry, low unit value, bulky nature of the product, and high transportation costs are universal. Others such as seasonality of operation, influence of day-to-day weather changes, stockpiling and reclamation, disposal of waste water and undersized material, changes in specifications and in market areas, together with restrictive zoning legislation may be more localized.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Nearly 6,000 sand and gravel operators reported production in 1963. As shown in figure 1, over 822 million tons was produced that year, outranking any other mineral product in output.

Firms in the industry range from one-man roadside operations to large corporations with 20 or more producing plants. The industry has become highly mechanized and produces about 65 tons a man-day. About 89 percent of the production enters the construction industry as fine or coarse aggregate.

Deposits of sand and gravel occur in every State in varying abundance. Local shortages of suitable material occur in many areas, such as in sections of Tennessee, Texas, and Loui-

[1] Commodity specialist.

780-887 O—65——50

siana where sand is practically nonexistent, too expensive, or unsuitable for construction. In Florida sand is abundant, but generally too fine for concrete sand, and gravel is virtually absent.

Due to the wide distribution, low cost, and bulkiness of sand and gravel, development has occurred near points of consumption where materials meeting the requirements are available. Some special grades, however, cannot be prepared from any ordinary sand deposit, and shipments are often made over considerable distances.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Sand and gravel are disintegration products of rocks. Although the term *sand* is commonly understood to refer to quartz sand, or silica, that predominates in natural deposits, it basically refers to size, and the term sand also is applied to other materials as black sands, zircon sands, slag sand, stone sand, and many others. Gravel that has not been subjected to all the abrasion and decomposition processes which produce sand may contain more of the original rock constituents such as mica, feldspar, olivine, shale, iron compounds, and calcareous minerals. Many of the size classification scales for sand and gravel are based upon that of Wentworth shown in table 1 (*15*).[2]

TABLE 1.—*Wentworth grading of sand and gravel*

Term	*Size (millimeters)*
Boulders	256+
Cobbles	64–256
Gravel	4–64
Granules	2–4
Sand	0.0625–2
Silt	0.0039–0.0625

The earliest recorded specification for sand is that of Vitruvius, (*14*) in the first century B.C., who stated that for testing masonry sand, "throw some sand upon a white garment and then shake it out; if the garment is not soiled and no dirt adheres to it, the sand it suitable." Since that time, because of the multitudinous uses of silica sand and gravel, the number and variety of tests and specifications have expanded greatly. Specifications now require tests for soundness, freedom from deleterious particles, resistance to freezing and thawing, adhesion of bitumens, size gradation, and many others. Specifications are written by users of foundry sand, (*3*) manufacturers of abrasives, glass, chemicals, ceramics, by building associations, governmental agencies, highway engineers, and the American Association for Testing and Materials.

For most glass products manufacturers prefer a sand with a minimum of iron oxide and chromium compounds. High percentages of alumina and calcium or magnesium oxides are also undesirable. It is generally agreed that all grains should pass a No. 20 sieve.

Sand for use in construction of bituminous and concrete roads must be clean, hard, and free from clay. For concrete pavements mixtures of coarse and fine sands are preferred, and the sand must be totally free from organic impurities. For bituminous paving and for wearing courses, the presence of small amounts of organic material is allowable. Specifications for paving sands are published in detail by Federal and State highway officials, industrial organizations, and contractor's associations (*2, 7–8, 12*).

Specifications for construction gravel are published by these groups along with standard test methods for grading (*5*).

Standards set for sand and gravel used in roadbuilding and concrete construction tend to become more specific and rigid as regards shape, physical properties, and screen sizing.

Sand used in filtration beds of municipal water plants must be of uniform grade, free from clay, loam, dust, or other foreign matter, and must possess good permeability.

For blast sands, used in cleaning castings, stone buildings, and for carving designs and lettering on stone, the ability to resist shattering and uniform grade are most important.

Glass sands for the manufacture of flat glass, table glass, and optical glass must contain 99 percent or more silica, and a minimum of coloring substances such as chromium or iron, and be of uniform grade. Specifications for common colored-glass bottles are less rigid, and these sands may contain as much as 1 percent of coloring materials. For high-grade chemical and optical equipment, either pure quartz or vitreous silica are used. Standard methods for the chemical analysis of glass sands are described under ASTM designations C–146–43 (*6*).

TECHNOLOGY

Geology

Most of the commercial sand and gravel deposits in the Northern and Eastern United States are the results of glacial disintegration and abrasion of bed rock. Upon recession of the glaciers, the transported material was deposited in the form of moraines, drumlins, eskers, and kames and further abraded, transported, and segregated by the action of running

[2] Italicized numbers in parantheses refer to items in the list of references at the end of this chapter.

water. Specific understanding of the processes which entered into the formation of particular deposits of sand and gravel is fundamental in attempts to locate such deposits, particularly as they are frequently hidden by overburden. If a deposit consists largely of hard, well-rounded pebbles, the inference is that the material has been transported for a long distance; the obverse may be assumed if the gravel is angular and poorly classified. Material deposited directly from glaciers with little working over by water, as in mountainous areas, may exhibit large irregularities in quality and size. Material from such deposits requires considerable processing to remove unwanted fines and must be crushed to meet size specifications. Fluvioglacial deposits, on the other hand, generally contain less clay, are better classified or sorted, and resemble stream deposits, although alluvial fans may contain highly segregated material along with clay and silt because the glacial streams, which deposited the fans frequently shifted channels and were subject to wide variations in the volume of water received. In the Central and Far Western States stream deposits, often replenished by periodical floods, are an important source of sand and gravel. Marine and lake deposits consist of well-rounded pebbles and fine sand, but are commonly contaminated by particles of calcareous shells and organic matter. Dune sands, formed by wind action, and occurring at various places along the Atlantic and Pacific coasts, the southern end of Lake Michigan, and in central Colorado have, so far, been of little economic value. In a few areas there are deposits of sand and gravel of exceptional depth and extent. Mined for many years, these sands and gravels have been named from the localities in which they were first developed, as Ottawa sand, Portage sand, Albany sand, or from the geological horizons in which they occurred as St. Peter sand, Tertiary gravel, and Quaternary sands and gravel.

To summarize, most commercial sands and gravels are obtained from thickly bedded deposits covered by little or no overburden and they must be worked economically where they are found.

Mining

Excavation of sand and gravel deposits is accomplished by means of a wide assortment of equipment; power shovels, bulldozers, front-end loaders, digging wheels, draglines, dredges, hydraulic monitors, and many others. Most large producers use combinations of digging equipment.

Hydraulic dredges, designed for excavating from river, lake, and ocean deposits, may wash, screen, and otherwise process the material upon the dredge, and then transport it to stockpiles. Others may pump the unprocessed material to shore installations. Fine sands, used for fill, are frequently excavated by dredges and pumped for several miles. Unconsolidated glass sand deposits may be excavated by hydraulicking. This involves pumping water, under high pressure, against a bank and then removing the slurry by a solids pump to a stationary plant for screening and sizing. Portable plants, designed to combine crushing, screening and conveying equipment, and operated by a few men, produce sand and gravel from deposits of limited extent, and usually for local use.

Processing

Although small amounts of unprocessed bank run sand and gravel are used for fill the larger part of U.S. production is partially or totally processed. Early methods simply screened the material to separate sand and loam from the coarser gravels. Present methods demand washing with water during the screening process, followed by crushing of the larger aggregate in cone or gyratory crushers, or in some cases, jaw or impact crushers when cubical aggregate is specified. Secondary crushing is usually done by cone crushers, although many self-contained portable plants use roll crushers. Screening is done, in most plants, by horizontal or sloped vibratory screens or multidecked screens frequently heated to prevent clogging. For some river deposits, contaminated by coal refuse or other deleterious materials, heavy-media separation or jigging equipment is used. Sand, for use in construction, is freed from clay by log washers or by rotary scrubbers. The scrubbing is followed by classifiers, separatory cones, hydroseparators to remove water, and fine screens for grading. Removal of processed sand and gravel from the processing plant to stockpiles or bins is accomplished by flexible combinations of conveyor belts, bucket elevators, and screw conveyors (*4*, *10*).

Most natural sands are deficient in the small grain sizes now demanded by the building trades, and such sands may be further reduced in size by ball mills.

USES

Extensive utilization of sand and gravel in concrete for construction of buildings and for concrete and bituminous paving accounts for 96 percent of total production. Of the total Government-and-contractor production, 97 percent is used for roads.

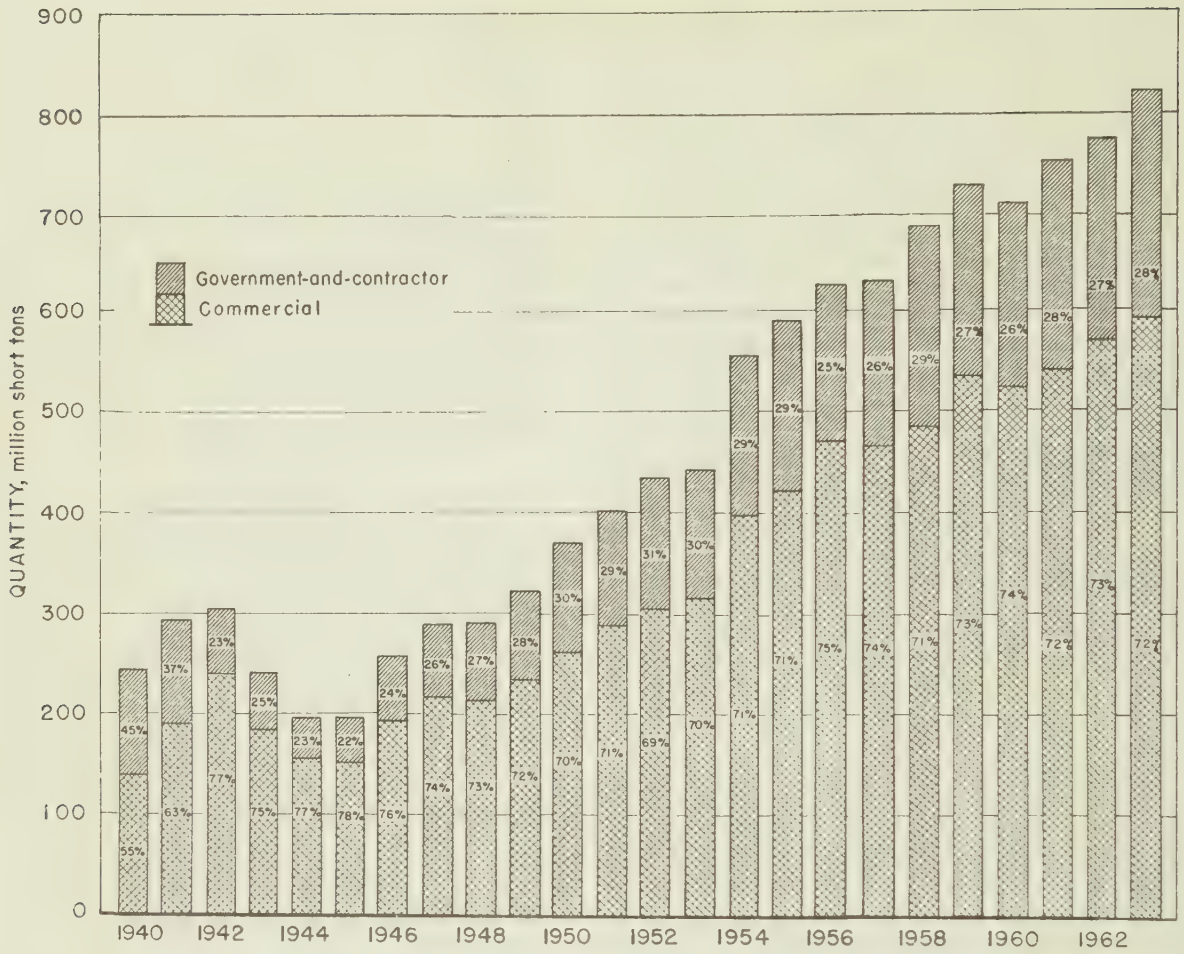

FIGURE 1.—Sand and Gravel Sold or Used in the United States, by Producers.

The glass industry is one of the most important users of the higher priced industrial sands. Sands used for glassmaking must meet definite specifications for both grain size and chemical composition.

Large tonnages are used in iron and steel foundries to make molds for castings. Natural molding sands, usually containing 8 to 20 percent clay, are a distinct product of the industry as are many other types used for steel castings, for the casting of nonferrous alloys, and for mold facings.

Smaller amounts are used for ceramics, in stone sawing, sandblasting, glass grinding, stone polishing, as fillers in paints, plasters, cements, and as abrasive material in soaps and polishing compounds. The chemical industry uses silica in the manufacture of sodium silicate, silica gels, calcium silicate, silicon tetrachloride, and in a wide variety of silicones.

Filter sands, used in municipal water plants, must be of uniform grain size within limits designed to allow maximum pore space for rapid filtration. They must also be free from mineral constituents which could react with chemicals used in water treatment.

Table 4 shows U.S. production of sand and gravel by end use.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

In metropolitan areas the sale of top soil, produced in the course of removing overburden from sand and gravel deposits, is an important factor in making sand and gravel operations profitable. Many producers have installed plants for manufacturing concrete blocks, facing panels, ready-mixed concrete, facing aggregate, and other construction materials.

ALTERNATE MATERIALS

Crushed stone, iron-blast-furnace slag, and fly ash are used to implement or replace sand and

gravel in some types of construction. As these alternates are sold at prices comparable to those received for sand and gravel and transportation costs may be lower, competition for markets is keen, although many producers of building materials stock all types of aggregates.

Stone sand produced by marble and granite processors is frequently used to replace natural sand in masonry work, and larger sized chips from the same processors find a ready market for exposed aggregate panels.

Chemical stabilization of clay subsoils with lime and cement is of growing importance and decreases demand for sand in some areas.

Lightweight aggregates, produced by bloating clays or shales, are in greater demand for use in the manufacture of concrete blocks to be used where load-bearing properties are of minor importance.

RESERVES

Because of the relatively low unit value of sand and gravel, deposits are seldom surveyed in depth to determine reserves. However, as a generality, it may be stated that resources of sand and gravel are sufficient to meet the demand created by any foreseeable expansion in the national economy. This does not mean that good construction sand and gravel is available in quantity in every area nor that all marginal deposits can be processed to supply satisfactory aggregate. The yearly production of nearly 1 billion tons of sand and gravel, most of which is used in metropolitan areas, has reduced supplies near some large cities to the point where these commodities must be secured from greater distances with accompanying higher costs. Rapid and undirected surburban growth has eliminated many potential reserves, not only by restrictive zoning ordinances, but by overspreading deposits with roads, houses, apartments, and business districts. Reserves of higher priced industrial sands, purchased for future development, are menaced by the rapid expansion of rural zoning restrictions.

CONSERVATION

Because of the assumed abundance of sand and gravel, few definite measures have been taken toward conservation, as the supply generally has been considered adequate except in deposits near large cities. To utilize available supplies in such areas, increasing depths of overburden are being removed and lower grade deposits are being worked.

Indirectly, a measure of conservation can be considered as a result of using portable plants that are able to mine small, scattered deposits, near points of application. These deposits that formerly were of no economic value supplement larger deposits and increase reserves.

Little or no regard has been given to the various ideas advanced for multiple land use in which sand and gravel deposits are removed prior to construction of schools, housing developments, and shopping centers.

SOURCES OF STATISTICAL INFORMATION

Statistical data published by the Bureau of Mines on production, value, uses, employment, and technical aspects of operations are acquired from the individual producer on a voluntary basis and from the Governmental agencies for which material was produced.

PRODUCTION, CONSUMPTION, AND TRADE

The continued increase in population with resulting demands for homes, industrial buildings, highways, defense, public works, and industrial uses has given impetus to the sand and gravel industry. The national road building program offers opportunities for even greater utilization of sand and gravel.

The construction industry utilizes most sand and gravel produced and is mainly responsible for the doubled annual tonnage and dollar volume over the past decade.

Sand and gravel production is divisible into two main classes; commercial production which consists of a particular plant's output with at least part of the material sold on the open market, and Government-and-contractor production which is produced exclusively for use on Federal, State, county, or municipal projects. If part of the production from a particular plant is sold commercially, the entire output is placed in the commercial category.

Table 5 presents general data on production by size of plant. Statistical data are given each year in the Minerals Yearbook chapter on sand and gravel. The terms "consumption" and "production" are used interchangeably, as stocks are relatively small and constant.

Sand and gravel are not major commodities in foreign trade. Glass sand is sometimes imported, as well as certain types of molding sand, which is still preferred by some users. Some ballast sand enters the country, and there is some movement across borders of ordinary sand and gravel for local use.

Over 1 million tons of sand and gravel was exported to Canada, in 1963, having an average value of $2.67 per ton.

Crude sand and gravel enter the United States duty free. Glass sand with less than 0.06 percent Fe_2O_3 is dutiable at 50 cents per ton. The quantity imported is small and usually consists of specialized sands such as the Belgium glass sand imported for making optical glass.

[1] Classification reads, "Sand containing 95 percent or more silica and not more than 0.6 percent oxide of iron and suitable for manufacturing glass."
[2] Consists mainly of synthetically prepared silica from West Germany for specialized uses and is not comparable in value to ordinary glass sand.
[3] Data known not to be comparable with other years.
[4] Sand, n.s.p.f., crude or manufactured and gravel no longer separately classified.

Source: Bureau of the Census.

STRATEGIC CONSIDERATIONS

Although sand and gravel are of vital importance to the construction and other industries, including building of landing strips for aircraft, for missile bases, shelters, and other defense facilities, the industry is not concentrated in any one locality. In case of attack, transportation of sand and gravel to point of use would be a major problem.

PRICES

Except for minor amounts of bank-run sand and gravel produced by Government-and-contractor operators for road fill, all construction sand and gravel is now processed to meet exacting specifications.

The average value for commercially produced sand and gravel in 1963 was $1.12 per ton, the same as in 1962; that for Government-and-contractor production was $0.81, an increase of $0.05 per ton. Representative prices per ton for construction sand in various metropolitan centers were as follows: Birmingham, $1.30; Boston, $3.00; Chicago, $4.13; Denver, $1.42; Minneapolis, $1.70; New York, $2.45; and San Francisco, $2.35.

TAXES

Depletion allowances applicable to the sand and gravel industry, based on gross income and apportioned according to the quantity sold in each category, are 5 percent for sand and gravel used for construction purposes and 15 percent for industrial sand and gravel.

TRANSPORTATION

Sand and gravel has a relatively low value per ton; therefore, transportation factors loom large in the economics of the industry and sometimes make up more than two-thirds of the selling price. There has been a marked trend toward increased truck transportation for many years. It is conceivable that the railroads might win back some of their lost haulage as plants are removed farther from metropolitan centers. On the other hand, the tendency toward utilization of portable plants has shortened the distance of transport. The imposed restrictions on the wheel-load that are permitted over highways forbid the use of trucks on the road that are required in some pits.

In order to lower transportation rates for the sand and gravel industry and allow haulage to market from greater distances, some railroads are installing unitized train systems.

RESEARCH

Research is conducted by the National Sand & Gravel Association on methods for prospecting for sand and gravel deposits, processing, and rehabilitation of worked-out areas. Others actively engaged in research to develop new uses or to improve specifications are the Portland Cement Association, the National Lime Association, Asphalt Institute, Bureau of Public Roads, U.S. Army Corps of Engineers, Bureau of Reclamation, National Ready Mixed Concrete Association, Bureau of Mines, various State universities, highway departments, and many others. Manufacturers of excavating and processing machinery conduct research to develop more efficient machinery and reduce wear on crushers and screens.

OUTLOOK

In spite of the marked trend toward increased use of lightweight aggregate and aerated concrete, to construct lighter buildings, and in the use of glass, metals, and plastics for ornamentation, major construction programs will continue to be essentially dependent upon supplies of large amounts of low-priced raw materials such as sand and gravel. Moreover, demand for the higher priced specialty sands used in glassmaking, in refractories, in metallurgy, and by the chemical industry may be expected to increase. Continuation of the Federal highway program, originally scheduled to be completed in 1972, may be expected, with expansion of programs for interstate and primary systems and modernization of many ABC roads. Increased production of aggregate will be required to supply this demand as well as for construction of new schools, industrial plants, sewage and water treatment plants, homes and apartments. Based upon forecasts of increases in national income, population, and demand for various types of housing, production of sand and gravel in 1980 may be expected to be about 1.8 billion tons. However, it should be noted that the unit price may continue to be low, that specifications will tend to become more stringent, that operations in many areas will be dependent upon the seasonal activity of the construction industry, and that

suburban growth, although supplying new marketing areas, may also curtail some operations through restrictive zoning legislation.

The trend toward firmer specifications will require better product control, including stricter attention to sizing, blending, and removal of deleterious substances.

No new uses are foreseen for the great volume of sand and gravel used in construction, but new applications for chemical products derived from silica, and expansion of use in paints, silicone rubber, plastics, paper, pharmaceuticals, and as dehydrating agents, will increase markets for high-grade silica.

PROBLEMS

The production of large quantities of sand and gravel from sources very near markets, at a price low enough to compete with alternate building materials such as crushed stone, slag, and lightweight aggregate, is a major problem for operators. Most sand and gravel is used within 25 miles of the point of production and in metropolitan centers where zoning regulations and transportation problems are complicated. Operative deposits are rapidly depleted in these areas, and development of new deposits is restricted by construction of buildings which submerges them.

Few other sectors of the mineral industry are so subject to seasonal influences or to the daily changes in production schedules caused by the construction industry's dependence upon the weather.

Sand and gravel occur in the same deposits, but the relative proportions of each vary over a wide range, from cobblestones to silt. Consequently the problem of producing aggregate to rigid specifications is difficult and involves combinations of many types of equipment; crushers, screens, washers, classifiers, and grinding mills. Many operators are unaware of methods by which much of this processing equipment may be most efficiently used. In addition, the wide range of specifications for construction sand and gravel set by Federal, State, and other government agencies, multiplies the difficulties faced by operators who attempt to furnish aggregates of a specified size distribution.

With increased demand for washed aggregate, the problem of securing adequate supplies of wash water has been intensified with the accompanying problem of waste water disposal (*9*).

The elimination of dust and noise from sand and gravel operations has been the subject of much research, but results of this research are not widely disseminated, although application of such control methods might assist in reducing the growing demand for restrictive zoning legislation.

The problems of land-use planning to allow extraction of sand and gravel before such deposits are lost forever by covering them with buildings are receiving some consideration (*1*, *13*), and research is continuing on methods for rehabilitating worked out sand and gravel pits (*11*).

SCANDIUM

By Donald E. Eilertsen [1]

SCANDIUM is one of the few elements that is still a laboratory curiosity. Recovery of a full pound of scandium, the largest amount ever to exist in one place at one time, made scientific news in January 1960.

At present very few uses have been developed for scandium. In recent years, three firms have produced scandium and its compounds; sales of scandium oxide in 1962 were less than 30 pounds. Scandium prices are high; the demand is small. The resource of scandium in uranium ores and phosphate deposits is very large. The most acute problem of scandium is the almost complete lack of uses.

BACKGROUND

The element scandium was predicted in 1871 and separated from gadolinite in 1879. Little attention was given to the element for many years. In the late 1950's the U.S. Air Force sponsored research to gain a better understanding of its physical and mechanical properties for possible usage. The scandium for study was produced at The Metals Research Laboratories of Union Carbide Metals Co. from scandium fluoride purchased from Heavy Minerals Co. (*2*).[2] Meanwhile the Bureau of Mines began studies on sources and recovery of scandium from uranium mill solutions. Some of this work was in cooperation with Vitro Chemical Co. and led to experimental production of scandium as a byproduct in processing uranium ores.

SIZE AND ORGANIZATION OF THE INDUSTRY

The scandium-producing industry is relatively small. The major producers in recent years are American Scandium Corp., Newtown, Ohio (metal and oxide); Research Chemicals Division, Nuclear Corporation of America, Phoenix, Ariz. (oxide); and Michigan Chemical Corp., St. Louis, Mich. (oxide).

PROPERTIES (*1*)

Scandium (Sc) has properties similar to yttrium and lanthanum. The chemical and physical properties of scandium are gradually becoming known as a result of recent research.

Scandium, silvery white but slightly yellow after exposure to air, has the following properties: Atomic number, 21; atomic weight, 44.96; melting point, 1,539° C; boiling point, 2,727° C; density, 2.99 grams per cubic centimeter; heat capacity (25° C), 6.01 calories per mole per °C; heat of fusion, 3.85 kilocalories per mole; heat of vaporization at 1,630° C, 78.6 ± 0.7 kilocalories per mole; linear coefficient of expansion (0 to 900° C), 12×10^{-6} per degree; crystal structure to 1,335° C, hexagonal close packed; atomic volume, 15.0 cubic centimeters per mole; and metallic radius, 1.64 A.

Scandium does not tarnish quickly in air, nor is it attacked quickly by water, but it reacts quickly with acids. Scandium has been successfully rolled, swaged, and welded.

TECHNOLOGY

Mineralogy and Geology

The earth's crust contains an estimated 5 parts per million (ppm) of scandium, the same as for arsenic. Sea water contains about 0.00004 ppm of scandium. Thortveitite, $(Sc,Y)_2 \cdot Si_2O_7$, the only known mineral that is usually rich in scandium, can contain almost 35 percent of the element. For many years a Norwegian firm produced thortveitite concentrate containing approximately 20 percent scandium.

In a survey of scandium occurrences (*5*), samples of pegmatites contained 5 to 20 ppm of scandium; coal ash and zinc plant residues,

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

10 to 30 ppm and monazite, euxenite, zircon-bearing sandstones, thorite ores, ferberite tungsten ores, and laterite nickel ores, 30 to 100 ppm. Certain samples of wolframite tungsten mineral concentrate contained 500 to 800 ppm of scandium, while phosphoric acid solutions contained 6 to 20 ppm. Solutions from uranium mills that used acid-leach processes contained 0.2 to 1 ppm of scandium. Iron sludge from intermediate material of uranium mills using an organophosphate solvent extraction procedures contained 1,000 to 1,800 ppm of scandium.

Extraction (*3*)

In uranium recovery operations of Vitro Chemical Co., scandium was found to follow uranium in solvent extraction operations using a dodecyl phosphoric acid in kerosine as the organic solvent. Scandium did not strip with the uranium but remained in the solvent, thus increasing the concentration of scandium in the organic phase with recycling. After this was discovered, provisions were made to recover a scandium-bearing concentrate.

Ore was crushed, ground, and leached with dilute sulfuric acid. Addition of an oxidant assured conversion of uranium minerals to soluble form for undergoing solvent extraction. For scandium concentrate recovery, part of the stripped solvent was fed to the hydrofluoric strip section of the plant. The scandium content was less than 0.1 gram of scandium sesquioxide (Sc_2O_3) per liter in the organic. A two-stage countercurrent solvent extraction system with acid fluoride solution was used to treat the solvent, the main aqueous stream of which was filtered to remove a scandium-thorium fluoride cake containing about 10 percent Sc_2O_3 and 20 percent thorium oxide (ThO_2) for further treatment.

This crude fluoride cake was digested in a weak solution of sodium hydroxide for conversion to scandium hydroxide and was filtered to remove soluble sodium fluoride and other impurities. The hydroxide cake was digested with hydrochloric acid, and the pH was adjusted to precipitate thorium, titanium, zirconium, iron, and silica by hydrolysis. Filtration removed the contaminants, leaving a filtrate containing scandium and some iron and uranium, which was treated with oxalic acid to precipitate scandium oxalate. Iron and uranium were removed by filtration. The scandium oxalate precipitate was calcined to form scandium oxide and then dissolved in HCl for subsequent solvent extraction and stripping operations. Ammonia was used to precipitate scandium hydroxide and the hydroxide was calcined to 99.5+ percent scandium oxide.

Methods to extract scandium from thortveitite have been described (*4*, *7*). Dissolution with concentrated hydrochloric or sulfuric acids yields a gelatinous residue of silica which occludes appreciable scandium. To avoid this, one method is to roast the finely ground mineral with charcoal at 1,800° C to form scandium carbide, which can be decomposed by dilute hydrochloric acid. Another method consists of chlorinating in the presence of carbon at 850° C to produce soluble scandium chloride which is extracted by leaching. Scandium chloride does not sublime below about 970° C.

Ammonium oxalate or tartrate is added to the acid solution obtained after separation from silica by either of the above methods, precipitating the scandium, yttrium, and rare-earth elements as oxalates or tartrates. The filtered and washed precipitate is decomposed by igniting at 900° C and forms an impure scandium oxide, which is again dissolved in hydrochloric acid. Further purification of the scandium is by ion exchange or solvent extraction.

Scandium metal may be prepared from the oxide by converting it to scandium fluoride, heating it in a stream of hydrogen fluoride gas, and reducing scandium fluoride with calcium (*1*).

Very little data are available on the alloying of scandium with other metals.

USES

Scandium and its compounds have been used in research and development to obtain better understanding of the properties of these materials. Very few commercial applications have developed, the principal use for scandium being in radioisotope tracers for applications in oil well drilling and in analytical work.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS AND ALTERNATE MATERIALS

Scandium is currently a byproduct in uranium-processing.

For all uses for scandium thus far developed,

there are other cheaper and more abundant materials available.

RESERVES

Reserves of scandium are not known, but recent research points to the existence of relatively large quantities of scandium in uranium ores and even larger quantities in phosphate rock deposits.

Uranium ores usually contain less than 0.0005 percent scandium, but in view of the large reserve of uranium ore, 60 million tons in the United States and perhaps 600 million tons in the free world, the scandium content is quite large.

Recent studies on recovering scandium from fertilizer plant phosphoric acids revealed them to contain up to 0.002 percent scandium. Based on the resources of 16 billion tons of P_2O_5 in the United States and 48 billion tons in the world, phosphate deposits conceivably contain hundreds of thousands of tons of scandium.

Recovery of scandium from uranium ore or phosphate rock would be limited by the rate at which these ores were mined, and percentage recovery would be low because of the very low scandium content.

SOURCES OF STATISTICAL INFORMATION

Statistical data on scandium metal and compounds are obtained by the Bureau of Mines through annual canvassing, but most of the data are withheld to avoid disclosing company confidential information.

PRODUCTION, CONSUMPTION, AND TRADE

A pound of scandium produced in 1959 for research purposes was probably the largest quantity of scandium ever to exist in one place.

Sales of scandium oxide in 1962 were less than 30 pounds.

Data on imports and exports of scandium and its compounds are not available.

PRICES

The following prices for scandium and scandium oxide were quoted in 1964:

Item	1–99 grams, per gram	100 to 453 grams, per gram	1 to 2 pounds, per pound
Scandium metal:			
99 percent	$15.70	$13.50	$5,123
99.9 percent	16.60	14.25	5,393
Scandium oxide:			
99 percent	5.35	4.37	1,520
99.9 percent	5.63	4.60	1,600

Source: Research Chemicals, Division of Nuclear Corporation of America, Phoenix, Ariz.

RESEARCH

Government and industry have studied scandium in recent years, concentrating on extraction, determination of properties, fabrication, and development of uses.

Bureau of Mines research on scandium in recent years has consisted of studies of scandium resources and recovery methods (*5*, *6*), and thermodynamic properties.

OUTLOOK

Scandium probably will continue to be produced commercially for research and development purposes from uranium mill wastes. Once the pattern of uses develops, the supply may come from cheaper source materials such as the phosphate fertilizer industry.

Research and development of scandium will be continued on a small scale, and most of the expense will be borne by private concerns interested in the development of scandium.

Uses for scandium will probably develop slowly.

PROBLEMS

Problems confronting scandium extend from ore discovery through extraction, fabrication, high prices, and uses, the most acute problem being the almost complete absence of applications.

Though scandium is known to be widely dispersed in deposits of uranium, phosphate, and other minerals, information is lacking on the nature and extent of scandium in specific deposits for economical extraction. Therefore, all scandium concentrations discovered in ores, minerals, and residues from mills, smelter, and chemical operations become potential commercial sources.

Cheap and simple methods are needed for recovering scandium from uranium plant raffinates and residues as well as from phosphate ores and other source materials, because high

extraction costs cause high prices and discourage the development of uses.

More complete data on the physical, chemical, and metallurgical properties of scandium alloys and compounds are needed, because the special properties may determine new or potential uses. New alloy systems particularly need to be developed.

SELENIUM

By Arnold M. Lansche [1]

SELENIUM production is centered at the electrolytic copper refineries in the industrialized nations. The element is widely distributed in the earth's crust but in small quantities, similar to gold. Native occurrences are rare, and there are no known areas of concentration that can be mined profitably for selenium alone under present technology.

The five selenium-producing companies in the United States accounted for 44 percent (928,000 pounds) of the free world's output in 1963. Canada, Japan, and the United States are the three major producers of selenium; the United States consumes about half of the free world's supply.

The most serious problem confronting the selenium industry is its dependence on electrolytic copper refinery production. This byproduct source is too inflexible to permit adjustment to shifting demand.

BACKGROUND

Selenium was discovered by Berzelius in 1817. He named the element after Selene, Greek goddess of the moon. Although useful applications of some of its properties were recognized as early as 1873, there were no large-scale uses for the element until about World War I.

Commercial production of selenium in the United States began in 1910 with the production of 10,000 pounds. Between World War I and World War II, the limited requirements for selenium could not absorb the quantity of selenium-bearing anode slimes generated at electrolytic copper refineries, and large quantities of slimes were stockpiled. About 1949, increased demand overtook the supply and stocks of anode slimes which had accumulated over many years were rapidly used.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Selenium is produced as a byproduct from the electrolytic copper refineries. U.S. companies reporting selenium production during 1963 were American Metal Climax, Inc., Carteret, N.J.; American Smelting & Refining Co., Baltimore, Md.; International Smelting & Refining Co., Perth Amboy, N.J.; Kawecki Chemical Co., Boyertown, Pa.; and Kennecott Copper Corp., Magna, Utah.

[1] Commodity specialist.

Primary production of selenium accounts for over 99 percent of the total domestic output. Although selenium is about equally abundant in the sulfide minerals of several metals, copper sulfide is the principal source; lesser quantities are recovered from lead smelter flue dusts treated at copper refineries and from selenium-bearing sulfur residues from chemical plants.

The geographic distribution of the free world selenium industry closely follows the pattern of the world's electrolytic copper refineries. Selenium is also a byproduct of lead smelting. Canada, Japan, and the United States are the three major producers of selenium, producing about 82 percent of the 1963 output. Other producers are Australia, Belgium-Luxembourg, Finland, Mexico, Northern Rhodesia, Peru, and Sweden, as well as U.S.S.R. and possibly other Communist nations.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Selenium may behave as either a metal or a nonmetal and occurs in several allotropic forms. It may be amorphous or crystalline. It can conduct electricity or act as an insulator and displays unipolar conductance of electricity.

High-purity selenium for electronic applications is marketed as pellets, sticks, and rectifier shot and contains from 99.95 to 99.99+ percent selenium. Material with 99,999+ percent selenium is available in pellets. Commercial-grade

selenium usually is marketed as a powder containing from 97.00 to 99.94 percent selenium. Government specifications for selenium for the strategic stockpile require that the commercial-grade selenium be not less than 99.0 percent selenium in the form of a black powder that will pass through a standard 200-mesh screen. Ferroselenium is used in the steel industry and contains 50 to 58 percent selenium. Selenium dioxide contains approximately 71 percent selenium and is sold in chemically pure and commercially pure qualities.

The poisonous characteristics of selenium compounds require careful handling. The maximum allowable concentration in air is about 0.10 parts per million (ppm). Contact dermatitis is caused by selenium salts. Selenium and the vapors of selenium, whether taken orally, inhaled as vapors, or absorbed through the skin, produce gastrointestinal disturbances and have deleterious effects upon the lungs, liver, and other organs. In acute stages the breath acquires a garlic odor. Contact with metallic or amorphous selenium has not been reported as a source of skin injury.

Selenium is required for the growth of some plants, is tolerated by others, and is deleterious to many. Animals native to seleniferous areas instinctively avoid forage containing large quantities of the element. Grazing animals not native to the seleniferous areas may eat the vegetation and sicken and die. Many times in the past when sheep, cattle, horses, or mules were driven or used in areas of selenium vegetation they would mysteriously become ill and die. It was not until about 1930 that the selenium content of plants was found to be the poisonous agent.

TECHNOLOGY

Selenium is widely but sparsely disseminated throughout the earth's crust, averaging approximately 0.09 ppm, and is 40th in abundance among the elements. It is rarely native and is not known to occur in sufficient quantities to make its extraction alone profitable. There is a wide range of selenium-bearing minerals that may become important as new exploitation techniques are developed. Selenium is associated with iron, copper, uranium, and other metals, and the most common sources are pyrite, chalcopyrite, bornite, and other sulfide minerals. After weathering, much of the selenium is released from these minerals; it may be redeposited as ferric selenite with secondary iron minerals such as limonite, or it may remain as native selenium. Small quantities find their way into the soil and, being soluble, are absorbed by certain plants.

In smelting copper ores, part of the contained selenium reports with the blister copper and part is carried through the flues as fumes and dust and is collected and returned to the reverberatory furnaces. To this circulating load of flue dust returning to the furnaces is added dust from lead smelters. Blister copper averages only about 0.05 percent selenium.

Selenium may be precipitated from a solution of selenosulfates by sulfur dioxide or from selenides by aeration of the solution. These properties are fundamental to the methods used to obtain selenium from its chief source—anode slimes from copper refineries. The copper and lead ores that contribute selenium to the anode slimes also contain tellurium and other impurities. As a consequence, each producer bases his extractive process on his experience, the raw material he must treat, and the product he sells.

All commercial processes may be considered as modifications or combinations of three fundamental methods: Smelting with soda ash, roasting with soda ash, and roasting with sulfuric acid. In the first two methods the selenium in the anode slimes is converted to sodium selenate which is soluble in water. Tellurium is precipitated from the solution by neutralization with acid and recovered by filtration, and then elemental selenium is precipitated with sulfur dioxide. In the third process, the anode slimes are roasted with sulfuric acid. Selenium dioxide volatilizes and is recovered in a wet Cottrell precipitator, leaving copper and other metals behind as sulfates.

High-purity selenium is made by several methods, such as fractional distillation, zone refining, dissolving as selenious acid followed by purification with subsequent reduction to selenium, and catalytic oxidation to high-purity selenium dioxide followed by either gaseous or wet reduction.

USES

Selenium has a wide range of applications, but most require only small quantities of metal. Nearly all of selenium consumption is in the electronic, chemical, glass, and metallurgical industries.

The electronic and electrical industries have become the major users of selenium during recent years. Of the selenium employed in these fields, over 90 percent is applied in manufacturing dry plate metal rectifiers, while most of the remainder is used in photoelectric cells. Selenium rectifiers have been known since 1884, and have been used commercially since about 1930. Selenium rectifiers change alternating to direct current and are extensively used in electroplat-

ing, welding, direct-current motor operation, battery chargers, magnet coils, arc lamps, induction braking, and voltage regulators.

Selenium photoelectric cells are used in photographic exposure meters, detectors, electric eyes, colorimeters, and pyrometers. Selenium is used in thermoelectric devices and other electronic applications using semiconductor materials.

The chemical industry consumes nearly one-third of the total selenium, principally in pigment manufacture. Selenium is compounded with cadmium sulfide in manufacturing the orange-red-maroon range of cadmium-selenium pigments. These give strong, bright colors with good light stability and resistance to heat and chemical attack. Selenium pigments are used to color many products, including plastics, paints, enamels, inks, and rubber. Selenium is used as a catalyst in the pharmaceutical industry. It has been applied in producing cortisone and niacin. Selenium is also used as a fungicide for control of dandruff and dermatitis and in manufacture of deodorant pharmaceuticals. The rubber industry uses selenium, mostly in the form of selenium diethyldithiocarbonate. The selenium acts as an accelerator and vulcanizing agent. It also promotes resistance to heat, oxidation, and abrasion and increases the resilience of the rubber. Selenium and its compounds are widely employed in industrial and research chemistry. Selenium dioxide oxidizes organic compounds and can be either a hydrogenating or a dehydrogenating agent. Selenium is a hydrogenation and cracking catalyst in crude oil and coal distillations. Soaps, waxes, edible fats, and plastics are produced by fat hardening with a selenium catalyst. Selenium imparts exceptional antioxidant properties to printing ink, mineral oils, transformer oils, and vegetable oils. Nondrying properties of linseed, oiticica, and tung oils are due to selenium. Selenium also retards gelation in tung oil. The antioxidant and antigalling properties of selenium compounds find application in lubricating oils and in extreme-pressure lubricants. Selenium compounds are finding application as insecticides, parasiticides, bactericides, and herbicides. Photographic photosensitizers and toning baths contain selenium compounds such as sodium selenosulfate. Mercury vapor detectors, fireproofing agents, insect repellants, phosphorescents, and luminescents have been made from selenium compounds.

Selenium is important to the glass industry to eliminate the greenish tinge in glass caused by iron impurities. From 0.02 to 0.3 pound of elemental selenium, sodium selenate, barium selenite, or sodium selenite per ton of glass is required; the exact quantity is determined by the iron content to be neutralized. Excess selenium causes a pink tinge, which is desirable in milk bottles and a few other food containers. From 1 to 50 pounds of selenium per ton of glass yields a desirable ruby-red glass, which is used in tableware, vehicular taillights, traffic and other signal lenses, light filters, and infrared equipment.

Selenium is used to control porosity in stainless-steel castings and to improve the machinability without reducing corrosion resistance or the hot-forging and cold-working properties. Selenious acid is used in the steel industry as an etchant. The addition of selenium improves the machinability of copper and copper-base alloys.

Xerography, a dry photographic process, employs selenium-coated metal disks from which the photographic image is transferred by static electricity. Radioactive selenium has been utilized in radiography. The oxychloride is a powerful solvent; it may be used as a paint and varnish remover and as a solvent for rubber resins, glue, and other organic substances.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Selenium is primarily a byproduct of the electrolytic refining of copper. The electrolytic slime from which selenium is extracted also contains gold, lead, silver, and tellurium as recoverable coproducts. Selenium is a byproduct of lead smelting and occurs in some sulfur residues generated at chemical plants.

ALTERNATE MATERIALS

There are satisfactory substitutes for selenium in many of its applications. The chief substitutes are germanium and silicon in electronic applications, and sulfur and tellurium in the chemical, rubber, and steel industries.

The high price and shortage during 1950–57 encouraged selenium consumers to find substitutes. Substitutes subsequently made competitive inroads into the major consuming segments of the selenium industry.

SECONDARY SOURCES AND RECOVERY

Secondary selenium is reclaimed from factory scrap generated during manufacture of selenium rectifiers, from burned-out rectifiers, and from spent catalysts. Selenium in the chemical industry is mostly expendable. There was no reported recovery of selenium from secondary sources in 1962 and 1963.

780-887 O—65——51

RESERVES

Selenium reserves are primarily a function of copper and, to a lesser extent, lead reserves. The recoverable reserve of selenium in domestic copper ores is about 25 million pounds, based on the present recovery rate of three-fourths pound of selenium per ton of copper treated. About 4 million pounds of selenium is contained in lead ore reserves. Large tonnages of selenium are contained in the rock strata and soils of the Western United States.

SOURCES OF STATISTICAL INFORMATION

Statistics on selenium production, shipments, and stocks are received quarterly and annually by the Bureau of Mines from producers of selenium and selenium compounds. These data are received on a company confidential basis, and individual company data are combined to make up the published totals. Five companies supplied statistics in 1963. World production data also are compiled by the Bureau. Imports of selenium are available from records of the Bureau of the Census, U.S. Department of Commerce.

PRODUCTION, CONSUMPTION, AND TRADE

Production and consumption of selenium in the United States were about the same during 1959–63. In 1959 and 1960 consumption exceeded production plus imports, but in 1961–63 the opposite was true. Producer stocks were adequate to supply the deficit in 1959 and 1960. Output was 728,000 pounds in 1959 compared with 928,000 pounds in 1963, and reached the high level of 1,022,000 pounds in 1961.

Canada was the source of most of the selenium imported by the United States in 1959–63. In 1963 Canada supplied about 250,000 pounds, or 74 percent of the total selenium imports. Selenium comes sporadically from Belgium-Luxembourg, Japan, Norway, Peru, Sweden, the United Kingdom, and West Germany. Selenium-bearing residues have been received occasionally from Northern Rhodesia. Imports from Mexico are reported as "lead flue dust—selenium content." Ultimately, the selenium content of the lead flue dusts is included and reported as domestic selenium production.

Tariff rates of 20 and 25 percent, respectively, were levied on selenium and selenium salts in 1909 and removed in 1913. Since that time all selenium has remained free of tariff.

STRATEGIC CONSIDERATIONS

The United States has an adequate supply of domestic selenium. A stable domestic copper industry, plus substantial quantities of selenium available from Canada and Mexico, should eliminate any possibilities of a serious selenium shortage under foreseeable conditions. While a stable copper production assures selenium self-sufficiency, at the current rate of consumption this tie-in to copper production precludes rapid expansion if an unexpected increase in demand or strategic use should develop.

From the standpoint of strategic consideration, the major part of the selenium recovery industry is vulnerably concentrated in a relatively small area in Maryland, New Jersey, and eastern Pennsylvania. One producer is in Utah.

The Office of Emergency Planning raised the selenium stockpile objective to 475,000 pounds on April 17, 1964. On June 30, 1964, the inventory of Government-owned selenium metal totaled 439,800 pounds, 92.6 percent of the maximum stockpile objective. Of the total stocks, 97,100 pounds was in the national (strategic) stockpile, 110,500 in Commodity Credit Corporation stocks, and 232,200 in the supplemental stockpile.

Selenium was placed in group B of the "Strategic and Critical Materials List" in September 1948, and in May 1953 it was transferred to group I.

The Office of Defense Mobilization established an expansion goal (No. 178) on October 9, 1952, for a total supply of 1.1 million pounds of selenium in 1955, including scrap recovery and imports. This goal was revised on September 29, 1955, to a supply of 1.2 million pounds annually from domestic primary sources, exclusive of scrap recovery and imports. The expansion goal was closed on February 28, 1957.

GOVERNMENT PROGRAMS

A critical supply shortage for selenium began during 1950. On December 10, 1951, the National Production Authority issued Order M–91 placing both imported and domestically produced selenium under complete allocation. The order became effective in February 1952 and was revoked in February 1953.

Exportation of selenium was under Government control and limited to approximately 24,000 pounds annually from 1953 through 1956. This was changed May 2, 1957, to allow industry to export unlimited quantities of material to friendly countries. However, exporters were required to obtain a license through the U.S. Department of Commerce for all shipments.

Selenium was designated by the President as eligible for acquisition under the 1959 and 1960 barter program of the U.S. Department of Agriculture, Commodity Credit Corporation (CCC). In 1961 and 1962 it was left out of the barter program. On February 13, 1963, the Department of Agriculture revised the program and U.S. firms were invited to submit offers for commercial-grade selenium produced from raw materials originating in friendly foreign countries, in exchange for CCC-owned agricultural commodities for export to CCC-approved destinations.

Selenium is eligible for financial assistance of up to 50 percent of the cost of exploration projects approved by the Office of Minerals Exploration (OME).

PRICES

In 1959–63 the price of selenium declined steadily. The high for the commercial-grade powder was $7 per pound in 1959; other prices were $6.50 to $7 in 1960, $5.75 to $6.25 in 1961, and $5.75 to $6.25 in 1962. In 1963 the range was $4.50 to $5.75, with the price at $4.50 for most of the year. The high-purity grade was $9.50 per pound in 1959, and at the end of 1963 the price was $6. In 1963 99.999 percent selenium sold for $13 to $20 per pound.

Selenium is not paid for by the custom copper refiner.

TAXES

There are no special taxes on selenium. Producers are granted a depletion allowance of 15 percent on domestic and foreign production.

TRANSPORTATION

Commercial-grade and high-purity selenium are shipped in polyethylene bags, 30 pounds to a carton, with four cartons stacked within a larger carton to make a 120-pound unit. Ferroselenium usually is packed in wood barrels of 500 pounds each; smaller quantities are shipped in wood boxes. There are no shipping regulations for selenium metal or its compounds.

RESEARCH

Selenium purification research was reported by the Royal Radar Establishment, Great Malvern, England (*6*).[2] Reports on biological applications of selenium compounds were made by government agricultural agencies in New Zealand (*2*, *3*, *5*).

Industry continued to do research on the use of selenium in alloy steels to improve their machineability (*4*). Metal selenides were studied in industry laboratories for their applicability as lubricants (*1*).

OUTLOOK

The variety of properties displayed by selenium assure its continued use in many areas of industry and for the protection of animal life. A steady growth can be expected in conventional uses, especially in the steel, chemical, glass, ceramic, drug, and electrical industries.

The short-term outlook indicates, however, that the selenium industry cannot grow beyond the limit imposed on it by the copper and lead industries unless alternate sources of selenium on an economic and commercial scale are found. The inducement of a higher price was not successful in efforts to find these alternate sources of supply, and it is unlikely that supply, other than as a byproduct, will be developed.

PROBLEMS

The major problem facing selenium producers is the inability to maintain a supply-demand balance. The principal reason for the failure to establish market stability stems from the metal's byproduct relationship with the copper-refining industry. This relationship creates a problem of inflexible procurement because production cannot be adjusted to requirements.

Although the chemical and physical properties of selenium have been extensively studied and fully covered in the literature, there remain numerous unsolved problems of application to potential new uses. Problems resulting from the increased use of the high-purity selenium and its handling and storage are especially significant.

SILICON

By John L. Morning [1]

SILICON is featured by its unlimited supply position and its diversity of forms and uses. A recent development of substantial importance has been its use in achieving miniaturization of electronic circuits and devices. Silicon metal and silicon alloy's largest industrial use is as an alloying agent in iron and steel products and in aluminum alloys.

Silicon as covered by this chapter includes high-purity silicon for semiconductors, silicon metal and silicon alloys for chemical and metallurgical applications, and specialty silicon products such as silicon carbide and silicon nitride. Additional information on silicon alloys will be found in the Ferroalloy chapter in this bulletin.

The growth in demand for silicon alloys as an addition agent to steel has paralleled that of the steel industry since 1889 when R. A. Hadfield discovered silicon steels. Since the turn of the century, advancing technology has introduced metallurgical-grade silicon metal, special grades of silicon alloys, silicone products, and high-purity silicon.

High-purity silicon is used in electronic applications and is produced by six firms. Metallurgical-grade silicon metal and silicon alloys are made by 13 metallurgical firms for use as addition agents in ferrous and nonferrous industries along with some use in chemical applications.

High-purity silicon is produced to customers' specifications in polycrystalline or single crystal form. Silicon metal is manufactured in numerous grades according to chemical specifications for the metallurgical and chemical industries.

Silicon in its various forms is used in chemical, metallurgical, electrical, electronic, refractory, optical, and abrasive applications. Semiconductor devices made from silicon are being used where high reliability is required. Ferrosilicon is the most important deoxidizer of steel and is also an important alloying agent. Metallurgical silicon metal is the starting material for making silicone products and is used as an alloying agent in aluminum, copper, and nickel alloys.

Shipments of high-purity silicon to the electronics industry in 1963 was 24,539 kilograms of polycrystal and 5,917 kilograms of single crystal. Consumption of silicon metal, ferrosilicon, and other silicon alloys totaled 651,628 short tons.

High-purity silicon is priced according to customer's specifications as to doping, resistivity, and size. Polycrystalline silicon, without dopant, is priced at $123 per kilogram in quantity lots. Silicon metal for metallurgical and chemical use ranges from 16.75 to 21.50 cents per pound.

Application research is being sponsored by the U.S. Government, but most research is being performed by private industry. Integrated circuitry and miniaturization of devices have evolved from these efforts.

The outlook is good for the continued growth of semiconductor silicon for electronic applications. With the trend to miniaturization in devices it is probable that primary production of high-purity silicon will not rise markedly.

A major problem for the high-purity silicon producer is the changing technology which may outdate his process or product as a result of new developments.

BACKGROUND

Progress in producing and using silicon and its compounds was slow until well into the 20th century. Berzelius, in 1824, prepared the first relatively pure silicon by passing silicon tetrachloride over heated potassium. The first crystalline silicon was made by Deville in 1854. A major advance in technology was made in 1889

[1] Commodity specialist.

when R. A. Hadfield published the results of his comprehensive investigation of the effects of silicon in steel and the discovery of silicon steels.

Once the demand for silicon was created, production of ferrosilicon in the newly developed electric furnace was initiated in the 1890's by J. T. Moorehead and du Chalmot of the Willson Aluminum Co., at Spray, N.C., and later at Holcomb Rock, Va., and Glen Ferris, W. Va. In 1891, E. G. Acheson discovered how to make the abrasive, silicon carbide, and the same year founded the Carborundum Co. Patents for making metallurgical-grade silicon metal were first issued to H. N. Potter in 1907. F. M. Becket patented in 1921 an acid purification means for preparing silicon that was more than 99 percent pure. In 1949, technologists for E. I. du Pont de Nemours & Co., Inc., headed by D. W. Lyon produced the first grade of silicon suitable for transistors and other semiconductor devices by reducing the tetrachloride with zinc. During the first half of the 20th century silicon was being introduced into alloys of aluminum and nickel, and as a starting material for manufacture of silicones.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Primary producers of high-purity silicon at the close of 1963 were:

Company:	*Location*
Allegheny Electronic Chemicals Co.	Lewis Run, Pa.
Dow Corning Corp.	Hemlock, Mich.
Linde Co. (Div. of Union Carbide Corp.).	Cleveland, Ohio
Mallinckrodt Chemical Works	St. Louis, Mo.
Monsanto Chemical Corp.	St. Charles, Mo.
Texas Instruments, Inc.	Dallas, Tex.

Since 1960, six firms have ceased production of high-purity silicon due to changing technology and declining profit in a saturated market.

In 1963, 13 firms made silicon metal, ferrosilicon (including silvery iron) or other silicon alloys in 27 plants. A list of producers of silicon metal and silicon alloys is included in table 1 of the Ferroalloy chapter in this bulletin. Production of silicon metal and silicon alloys for metallurgical use in 1963 was 696,000 tons.

DEFINITION OF TERMS, GRADES, SPECIFICATIONS, AND PROPERTIES

Elemental silicon is a light, brittle substance, dark gray in color with a metallic luster. Structurally, silicon has the same cubic symmetry as diamond and four valance electrons. Its atomic weight of 28.09 and density of 2.33 g/cm^3 are less than half those of germanium. Currently accepted electronic, mechanical, and thermal properties comparing silicon and germanium have been published (*8*).[2]

In high-purity silicon technology, the term "semiconductor" is used to designate a class of material. It is a material that has an electrical conductivity intermediate between a conductor and an insulator. Silicon is a monatomic semiconductor along with germanium, gray tin, and diamond. Actually silicon is an imperfect insulator and will not serve satisfactorily as a semiconductor until it has been purified and then had precise amounts of specific impurities added. This technique is called doping.

High-purity silicon is produced in polycrystalline form and converted to single crystal by float-zone or crystal-pull (Czochralski) methods of refining. High-purity silicon is marketed in polycrystalline form either as rods or chunks for customers to process, or as single-crystal rods, slices or wafers depending on customer requirements. Producers supply high-purity silicon to a resistivity specification as measured in ohm-centimeters and conductivity type, positive or negative (p or n).

Silicon metal is marketed to the metallurgical and chemical industries in numerous grades depending principally on iron, aluminum, or calcium specifications. Five typical grades of metallurigcal silicon metal are shown in table 1. Most grades can be purchased with 0.03 percent maximum calcium specification.

TABLE 1.—*Grades of silicon metal of metallurgical quality*

[Percent]

Grade	Silicon minimum	Iron maximum	Calcium maximum	Aluminum maximum
Maximum 0.35 percent iron	98.40	0.35	0.07	----------
Maximum 1.00 percent iron	98.00	1.00	.07	----------
Low calcium	98.00	1.00	.03	----------
High calcium	97.50	1.00	.40	----------
Low aluminum	98.50	1.00	.03	0.10

Silicon alloys include ferrosilicon, silvery pig iron, silicomanganese, ferroaluminum-silicon, magnesium-ferrosilicon, ferrochrome-silicon, ferromanganese-silicon, calcium-silicon, calcium-manganese-silicon, barium-silicon, ferrozirconium-silicon, and zirconium-silicon, all of which are principally used in metallurgical industries. Ferrosilicon accounts for the largest tonnage of the silicon alloys produced. The

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

American Society for Testing and Materials (ASTM) lists tentative standards for five of these products (*2*).

Silica (SiO_2) for metallurgical use in producing silicon metal, ferrosilicon, and other silicon alloys is usually quartz, quartzite, or well-cemented sandstone with at least 98 percent silica content. Size requirement ranges between 1 and 6 inches depending on the type of reduction furnace used in the manufacturing process. Impurities such as lime, magnesium, and aluminum are kept low to reduce the slag volume to a minimum. Arsenic and phosphorus are objectionable because unstable compounds are formed which cause deterioration and disintegration of the finished product.

Silicon carbide manufacture uses a high-grade glass sand with a silica content of at least 99 percent. Like silica for silicon metal products, impurities such as lime, magnesium, phosphorus, and arsenic must be low. The sand should be dust free and between 35 mesh and 150 mesh.

Silica ores are used in metallurgical processes as a fluxing material in nonferrous metal and phosphorus smelting. Individual companies use their own specifications for this material as price is more of a factor than quality.

TECHNOLOGY

The technology of making and fabricating high-purity silicon has changed rapidly since Du Pont developed a process for making hyperpure silicon by the reduction of silicon tetrachloride ($SiCl_4$) with zinc (*14*). The first commercial production by this process was in 1951. From 1951 to 1960, producers were concerned in making improvements in starting materials and in their intermediate and final products, while device makers were making improvements in the fabrication and application of these materials. Boron was the main obstacle in this period, since no method of purifying silicon could remove this element including zone refining, which is the standard method of reducing boron in germanium. By 1960, due to change in processes boron had ceased to be a problem.

The starting materials for high-purity silicon are metallurgical-grade silicon metal and chlorine which are reacted in a shaft or fluidized bed reactor to form liquid silicon tetrachloride, or by the addition of hydrogen to the reactor to form trichlorosilane ($SiHCl_3$). These products are generally purified by the use of cold traps, absorption techniques, or distillation in quartz columns.

In 1959, device manufacturers experimented with crystal growth by vapor phase deposition techniques called thin film or epitaxial deposition. Most producers and all device makers are now using some form of this method either for supplying material to device makers for assembly or in creating devices. The common feature in depositing silicon epitaxially from the vapor phase is a hot-silicon single crystal wafer or substrate exposed to an atmosphere charged with a silicon compound such as silicon tetrachloride or trichlorosilane. The substrate is heated to between 1,000° and 1,300° C depending upon the silicon compound being used. The substrate should have a smooth, clean, structureless surface prior to deposition of the thin film. One method to achieve this is to etch the substrate while at temperature with hydrogen chloride gas. The growth rates of thin films deposited on substrates range from 0.1 to 3 microns per minute (*4*, *5*, *13*, *18*, *19*).

An advancement in technology was made by the introduction of semiconductor silicon that has low oxygen and low etch pit density made by a new undisclosed process. Low oxygen is typical of single crystal material produced by float zoning and low etch pit density is typical of single crystal rod made by the crystal-pull or Czochralski process. This new method of manufacture combines the best characteristics of both older techniques. In addition, this new type of silicon has a minority carrier lifetime of up to 8,000 microseconds, compared with normal specifications of 100 microseconds for conventional single crystal (*6*).

Domestic production of high-purity silicon is believed to be made by the hydrogen reduction of trichlorosilane or silicon tetrachloride using modified processes of Siemens or van Arkel. Producers that used processes such as decomposition of silicon tetraiodide (SiI_4), thermal cracking of Silane (SiH_4), and zinc reduction of silicon tetrachloride have dropped out of the market. Most producers keep their methods of manufacture secret, as proprietary, in this highly competitive business.

Japanese producers list reduction of silane and silicon tetrachloride, thermal decomposition of silane and trichloresilane, and hydrogen reduction of trichlorosilane and silicon tetrachloride as their methods of production of polycrystalline silicon (*11*).

Silicon solar electric cells have been made by diffusing thin layers of selected elements into silicon, usually boron and phosphorus. Device manufacturers continue to improve performance of these devices by switching from phosphorus and boron to aluminum for doping. The currently produced solar cells are more efficient than formerly with higher power outputs and resistance to radiation damage (*7*).

Recovery of silicon in the production of metallurgical silicon metal in the electric-arc furance has increased from 70 to about 90 percent with improved operations. At one time it was considered good furnace practice to hold production to a 2-percent iron specification. Today, large tonnages are produced to a maximum of 0.3 percent iron content. To meet customers requirements, low-aluminum or low-calcium grades have been developed. Methods of refining impure silicon metal to lower the content of these elements include treatment with oxidizing agents such as air, oxygen, carbon dioxide and chlorine. These refining agents vary in their ability to selectively remove calcium or aluminum and affect the yield of silicon in the refining operation (*12*).

The manufacturing processes for silicon metal and ferrosilicon are the same except for introduction of iron for the latter. Ferrosilicon is made by reducing quartz gravel, crushed quartzite, or well-cemented sandstone with coke, low-volatile coal or charcoal together with iron such as steel turnings, mill scale, or iron sinter in an electric arc furnace. To produce the various grades of ferrosilicons and silicon metals the charge is varied to give the desired product.

Substantial research has been done with 3 percent silicon-iron sheet on the orientation of the crystals in two directions for use in the cores of transformers and the armatures and stators of electric motors and generators. By orienting the crystals so that the magnetic flux flows along the edges of the cubic crystal, the cores are easier to magnetize and have the lowest energy loss. For many years transformer sheet has been grain-oriented in one direction, now with proper selection of processing cycles, silicon iron sheet with improved magnetic properties can be produced with cube orientation (*17*).

Silicon carbide (SiC) is manufactured in electric-resistance furnaces by the reaction of silica and carbon ($SiO_2+3C=SiC+2CO$) at a temperature above 1,500° C. Sawdust and salt are added to the charge, sawdust to promote porosity for the circulation of hot vapors, salt to react with iron and other impurities to produce volatile chlorides. The reduced product is cleaned, crushed, and ground to a particular size prior to making finished products such as heating elements, abrasives, high temperature refractories, and corrosion resistance hardware (*3*).

The British Admiralty has developed a new production process for silicon nitride (Si_3N_4) in which specially graded silicon powders are shaped into parts and sintered at 2,600° F in a nitrogen atmosphere. The process can be interrupted when the material is partially hardened, additional fabrication can be performed and the material given a final nitriding to complete the conversion. Silicon nitride produced by this process will withstand temperatures of 2,200° F in air or 3,000° F in inert atmospheres. Resistance to attack by molten metals up to 2,000° F and to extreme thermal shock are features of this material (*15*).

USES

High-purity silicon is used mainly where performance and reliability are more important than price. Silicon and germanium, the elements most commonly used in semiconductor devices, transistors, diodes, and rectifiers, perform the functions that a decade ago were done by vacuum tubes, or by selenium, copper oxide, or similar rectifiers. Silicon maintains its electronic characteristics to an operating temperature of 250° C, compared with 75° C for germanium.

Present development in miniaturization of devices is called "integrated circuitry." A small chip of silicon approximately one-eighth of an inch square can contain 2 electronic circuits with 15 transistors and 13 resistors. By combining such components together in one package, a reduction in lead wires, soldered joints, and number of containers eliminates many weak points of conventional circuitry.

Optical silicon, which is polycrystalline, is manufactured by several producers in shapes for covering infrared sensing devices used in aerospace instruments. Silicon will transmit more radiation from 1.2 to 6.7 microns at a higher temperature (350° C) and thicker sections than most materials.

Silicone manufacturers have become heavy users of silicon metal in the last decade. This industry is one of the chief users of the silicon metal made in electric furnaces by ferroalloy producers. It is crushed and ground to a powder, reacted with methyl chloride in the presence of copper and copper-oxide catalysts to produce a mixture of silanes which are separated by fractional distillation. From these are separated the chemicals, methyltrichlorosilane, dimethyldichlorosilane, and trimethylchlorosilane, from which some 450 silicone resins, lubricants, elastomers, antifoaming agents, and water-repellent compounds are made (*9*).

A minor use of silicon is as a drier, the familiar silica gel. Silica gel can be regenerated by heating for repeated use as a moisture absorbent.

Silicon nitride is used as a high-temperature oxidation-resistant coating for metals, as laboratory ware such as protection tubes and supports

subjected to extreme thermal shock and as furnace linings for some molten metals.

Silicon metal is used chiefly in the metallurgical industry for alloying with aluminum, copper, and nickel. Aluminum is alloyed with 2 to 25 percent silicon to improve casting fluidity, and at the higher percentages to improve both fluidity and wear resistance. Several elements including phosphorus are added in minor amounts to refine the silicon particle to improve the wear resistance and machinability of the higher alloys of silicon in aluminum. Copper alloys with silicon are strong, weldable, and have good resistance to corrosion and galling. Nickel with silicon possesses excellent tensile properties, and corrosion resistance to sulfuric acid.

Some ferrosilicon is used in the silicothermic process for making magnesium wherein the silicon constituent reduces magnesium oxide. Ferronickel is manufactured by the Ugine Process in electric arc furnaces using ferrosilicon as a reductant.

Ferrosilicon, including silvery pig iron, is primarily used in the iron and steel industry for the deoxidation of molten metal, as an alloying agent to meet chemical specifications, and in some instances for reduction of metalloids in the slag. The ferrosilicon most commonly used for these purposes contains 50 percent silicon and 50 percent iron; however, high-silicon specification steels such as electrical grades generally are made with higher percentage silicon content ferrosilicons.

Ferrosilicon is added to the furnace or ladle and occasionally to the ingot mold for deoxidation. More ferrosilicon is used as a deoxidizer than all other deoxidizing agents combined. Ferromanganese, which is used in larger tonnage than ferrosilicon, can act as a deoxidizer but is added to steel primarily for control of sulfur and to enhance certain physical properties.

Most ferrosilicon consumed to form an alloy with iron is used in electrical sheet steels of 0.5 to 5 percent silicon content. Smaller quantities are used in spring and high-temperature alloy steels. In cast irons, however, as much as 17 percent silicon is employed to resist growth and scaling at elevated temperatures, and corrosion of certain mineral acids, free chlorine and copper salt solutions (*1*, p. 518). In combination with magnesium, silicon gives a "plunging alloy" for making ductile, nodular iron.

Silicon imparts high strength to steel at moderately elevated temperatures. Shih, Averbach, and Cohen (*16*) show that silicon additions up to 1.5 percent in standard ternary alloy steels beneficially affect the mechanical properties by increasing the tensile and yield strengths and yet maintain the same ductility properties of the standard compositions. A comparison of mechanical properties of AISI (American Iron and Steel Institute) 4340 and 4340+(1.5 percent Si) steels hardened and tempered at 500° F for 1 hour are given in table 2 (*16*).

Another use of silicon is as a diffused case for steel parts for protection against corrosion, heat, and wear. The case is produced at 1,700° to 1,850° F in the presence of silicon and chlorine. The usual applications of siliconized parts are as automotive water pump shafts, and valve guides, valves and fittings in the chemical industry, and as furnace parts and fittings (*1*, pp. 708–709).

TABLE 2.—*Influence of silicon on an alloy steel*

Property	4340	4340 (1.5 percent silicon)
Hardness, Rockwell C	51	54.5
Tensile strength, pounds per square inch	260,000	300,000
Yield stress, do	230,000	256,000
Elongation, percent	6.7	6.3
Reduction of area, do	40	40
Room temperature Charpy impact strength, V-notch, foot-pounds	14.3	15.9

ALTERNATE MATERIALS

The principal alternate material for silicon in semiconductor applications is germanium. Germanium, however, breaks down electronically above 75° C while silicon can be used to 250° C. Newly developed semiconductor materials such as gallium arsenide and cadmium sulfide may replace high-purity silicon in certain applications.

Metals such as aluminum, manganese, and vanadium, nonmentals and compounds, can be substituted for ferrosilicon as deoxidizers but only at higher cost.

SOURCES OF STATISTICAL INFORMATION

The Bureau collects production and shipment information quarterly from producers of metallurgical silicon metal and silicon alloys, and consumption canvasses since January 1, 1959, have been conducted monthly combined with other ferroalloy commodities. High-purity silicon production and shipment information formerly obtained and published quarterly, are now obtained and published annually. The Bureau's statistics for single-crystal silicon do not include data for companies that do not produce polycrystal material. The data on imports and exports of silicon metal and silicon alloys are supplied to the Bureau of Mines by the Bureau of Census.

PRODUCTION, CONSUMPTION, AND TRADE

High-purity silicon production in 1963, as shown in table 3, was 41,247 kilograms, of which 34,582 kilograms was in the form of polycrystal. Shipments of 24,539 kilograms of polycrystal and 5,917 kilograms of single crystal had a combined estimated value of $11 million.

The high-purity silicon shipments went primarily to the electronics industry for fabrication into rectifiers, transistors, diode and complex electronic devices. Increase in the number of such fabricated siilcon products, in the face of lower production of high-purity silicon for 1963, reflected increased efficiency in fabrication of devices and changes in technology.

Salient statistics for 1963 for metallurgical silicon metal and principal silicon alloys are shown in tables 4 through 7. Silvery pig iron is used primarily in gray and malleable iron castings, the true ferrosilicons mainly in iron and steel production and metallurgical silicon metal primarily as an addition agent to aluminum base alloys but with substantial amounts being used by the growing silicone industry.

A change in classification of imports was effective August 31, 1963. Classifications of ferrosilicon grades are now over 8 percent but not over 60 percent silicon, over 60 percent but not over 80 percent silicon, over 80 percent but not over 90 percent silicon, and over 90 percent silicon. Classification of metallurgical silicon metal was specified as being not over 99.7 percent silicon; high-purity silicon, formerly lost in a blanket classification, will now be reported as silicon metal containing over 99.7 percent silicon.

Tariffs for most nations effective in 1964 were as follows: Silicon containing by weight not over 99.7 percent of silicon was 4 cents per pound contained silicon. Silicon containing by weight over 99.7 percent of silicon was 10.5 percent ad valorem. Duty rates for Communist nations were as follows: silicon containing by weight not over 99.7 percent of silicon—8 cents per pound contained silicon and silicon containing by weight over 99.7 percent silicon—25 percent ad valorem.

Tariffs for ferrosilicon products are listed in table 8 of the Ferroalloy chapter in this bulletin.

TABLE 3.—*Production, shipments, and value of high-purity silicon in the United States*

Type	1962			1963		
	Production (kilograms)	Shipments		Production (kilograms)	Shipments	
		Quantity (kilograms)	Value (thousands)		Quantity (kilograms)	Value (thousands)

PRICES

Prices of high-purity silicon are highly competitive and are generally quoted to customer's exact specifications as to doping, resistivity, and dimensions. Producers supply polycrystalline silicon in rods or pieces with or without dopants. Examples of 1964 nominal prices for 20 kilogram lots are as follows:

Polycrystalline up to 3 inches in diameter, n-type, 100 ohm-centimers without dopant.. $123.00/kg
Polycrystalline up to 3 inches in diameter, n-type, 200 ohm-centimers with dopant..... $139.00/kg
Float zoned refined single crystal in diameters of 30–33 mm, n-type..... $1.20/g
Special high resistivity single crystal over 2,000 ohm-centimers:
p-type..... $2.20/g
n-type..... $6.50/g
Source: Dow Corning Corp., Hemlock, Mich.

Prices of metallurgical silicon metal and silicon alloys vary with the quantity ordered, size required, method of packing, f.o.b. shipping point or delivered, and whether purchased on a contract or on the spot basis. Some alloys such as ferrosilicon are sold on a per pound contained silicon basis, others such as silicomanganese are priced on an alloy unit basis. Table 8 lists products and prices for 15-ton carlot bulk shipments.

TABLE 8.—*Prices of silicon metal, ferrosilicon and silicon alloys, October 1964* [1]

Type and grade	Percent silicon	Cents per pound gross weight
Silicon metal (0.35 percent max. iron)	98.40	19.00
Silicon metal (1.00 percent max. iron)	98.00	17.00
Silicon metal (0.3 percent max. calcium)	97.50	16.75
Silicon metal (low aluminum)	98.50	21.50
Ferrosilicon	50	[2] 13.60
Ferrosilicon (low aluminum)	75	[2] 16.50
Silicomanganese (1.50 percent max. carbon)	18–20	8.30
Ferrochrome-silicon (39–41 percent chromium)	42–45	11.40
Zirconium alloy (12–15 percent zirconium)	39–43	10.50

[2] Per pound contained silicon.

RESEARCH

The Department of Defense sponsors applied research on high-purity silicon and other semiconductor materials. Research in the field of solid state microelectronics technology and other related research is conducted by the Air Force Avionics Laboratory, Wright Patterson AFB, Dayton, Ohio, and Electronics Research Directorate of the Air Force Cambridge Research Center, Bedford, Mass.

While the various services of the Department of Defense contribute considerably to the expanding technology, private industry has a large and very extensive research and development program. Most device manufacturers, as a result of research, introduced integrated circuitry (miniaturization) during 1964. An indication of the magnitude of current research was the introduction at a trade show of 125 new semiconductor products by one manufacturer.

OUTLOOK

The outlook is good for continued increase in the number of silicon electronic devices used. However, due to the trend to miniaturization, it is possible that the total quantity of high-quality silicon produced and used to make these electronic devices will not rise markedly. Continued growth should be experienced in the demand for silicones and other organo-silicons, with continued increase in new applications.

Consumption of ferrosilicon and other silicon alloys will grow with the demand for steel, and consumption of silicon metal should grow with the demand for aluminum.

The Nation's supply of raw material for the silicon industry is unlimited.

PROBLEMS

The problems of the high-purity silicon producer are serious ones. Profitability is dependent on large volume, and the producer is continually faced with the threat that his process or product will be quickly outdated as the result of a new development in technology—either the technology of silicon or that of a competing material. The rapidity, frequency, and magnitude of these changes can have serious adverse economic effects for a producing company. Further, the advances in utilization of the product are pointed toward miniaturization, so that quantity drops with improvement. Competition among the producers of high-purity silicon, foreign competition, and the competition from other materials are advantageous to the user but intensify the problems of the producer.

The problems of the silicon ferroalloy and metallurgical silicon metal producer are essentially the same as those of the other ferroalloy producers and are set forth in that chapter.

SILVER

By J. Patrick Ryan [1]

SILVER has been mined through the ages in many parts of the world. Total world production of silver from 1493 to 1963 is estimated at 22 billion troy ounces, of which the United States contributed about 21 percent. Maximum annual production of the United States was nearly 75 million ounces in 1915. Mexico has been the leading silver-producing country since 1900; the United States ranks second. World output of silver for 1963 was estimated at 250 million ounces, of which the United States supplied about 35 million ounces, or about 15 percent. A substantial quantity of silver also is recovered from secondary sources in the United States.

For many years domestic output of primary silver has been obtained chiefly as a byproduct of base-metal and gold mining, and production has been determined chiefly by the output of base metals and gold.

Domestic consumption of silver in the arts and industry, and for coinage greatly exceeds domestic production. Most of the shortfall in industrial supply has been balanced by imports; coinage requirements have been furnished from the Treasury stock of nonmonetary silver. Similarly, in recent years world consumption of silver has exceeded world production by substantial amounts.

Most of the world's silver production in recent years has been used in various industries and the arts, but substantial quantities also are used in coinage in several countries. The principal nonmonetary uses are in the photographic and electrical industries, in manufacturing silver solders and brazing alloys, for sterling and plated silverware, and for jewelry and novelties. Large quantities of silver are also used in coinage and as monetary reserves.

The New York price of silver reached the monetary value of $1.293 per ounce in June 1963 after a more or less steady advance since November 1961 when Treasury sales at the fixed price of $0.91 per ounce were discontinued. The monetary price, at which silver is available for commercial use, provides an effective ceiling as long as Treasury policy regarding the conversion of silver certificates remains unchanged.

The expansion of domestic industrial and coinage requirements for silver in the past few years has increased the deficit in supply and brought heavy drafts on U.S. Treasury stocks. These stocks had been reduced at the end of 1964 to a point where continued withdrawal at the 1964 rate would result in exhaustion in 3 or 4 years; the drain during the last quarter of 1964 would cause depletion in 2 years.

Solution of the silver problem involves ways and means of increasing supply by increasing mine production and secondary recovery or reducing demand whether for the arts, industries, or coinage.

Resource development and research programs to develop new sources and more efficient use of silver are essentially long-range and results cannot be expected in the near future. Furthermore, production of silver is not normally responsive to increases in the price of silver because of the byproduct nature of most of the silver output and to limitations posed by the geological occurrence of silver deposits.

After long study and debate the Congress passed the Coinage Act of 1965, signed by the President on July 28, 1965, which authorized for silver-free 10-cent and 25-cent coins, 50-cent coins of 40 percent silver content and certain other silver economizing provisions. Development of substitutes for industrial use does not appear promising for reducing consumption.

Measured and indicated reserves of domestic silver-bearing base-metal ores are equivalent to a 17-year supply at the current production rate, and no doubt new ore will be developed as presently known ore is mined. However, the indicated productive rate, based on projections of base-metal output, is inadequate to supply projected domestic needs.

[1] Commodity specialist.

BACKGROUND

Silver, one of the earliest known metals, was first used by primitive man by shaping into ornaments. Evidence of the use of silver as early as the period 3000–2500 B.C. was disclosed by the discovery in Asia Minor of silver ornaments and utensils. This early silver probably was found as native metal, or as silver chloride which could be converted easily into bullion in a charcoal fire.

Silver was adopted by the Romans as the basis of their monetary system. The silver of Laurium, Greece, the most famous of the ancient silver districts, provided much of the wealth that won for Athens leadership among the Greek city-states. The mines at Laurium were worked for several centuries in the first millennium B.C. and had a total output of more than 250 million ounces. After discovery of America, most of the world's silver came from deposits in the Western Hemisphere. Bolivia, with a total production of more than 1 billion ounces, was the leading silver-producing country to 1700; the United States was the largest producer, except for a few years, from 1871 to 1900; Mexico has been the leading producer during most years since then.

The first monetary standard established in America was based on the value of silver. The first financial law passed by the Continental Congress in 1776 made the silver dollar the unit of value. The dollar was defined by Congress in 1792 as 371.25 grains of fine silver (412.5 grains of silver 0.900 fine). Except for minor variation with respect to alloy, that definition has not been changed.

Until the discovery of the Comstock Lode in Nevada in 1859, U.S. production of silver was insignificant (*4*).[2] Development of this great deposit and many others in the Western States placed the United States first in silver production for many years.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

In 1963, domestic mine production of silver was 35.2 million ounces of which one-third was recovered from precious metal ores and two-thirds as a byproduct of base-metal ores (fig. 2). Of the 25 leading domestic silver-producing mines, only four were worked principally for the silver value of the ore, 9 were copper mines, and the remainder were lead, lead-zinc or copper-zinc mines. The 25 mines supplied about 84 percent of the domestic output valued at $45.1 million. About 1,500 men were employed in mining and milling ores in which silver is the predominant metal recovered.

In 1963, the largest domestic silver mine was the Sunshine mine in the Coeur d'Alene region of Idaho. About 133,000 tons of ore was treated and 5.0 million ounces of silver was produced as well as substantial quantities of base metals as coproducts and byproducts. About 500 men were employed.

Silver has been found in most countries of the world and has been mined in recent years in more than 60 countries in all continents. In the United States, silver has been mined in 27 States. The principal silver-producing States in order of total output are: Montana, Utah, Colorado, Idaho, and Nevada; these five States contributed about 84 percent of the total domestic production. In order of recent output (1963) the five leading States are Idaho, Arizona, Utah, Montana, and Colorado.

Mexico has been the leading silver-producing country for many years, followed by the United States and Canada. The value of world production of silver in 1963 was about $250 million. The geographical distribution was as follows:

Country	*Production, million ounces*	*Percent of total*
Mexico	42.8	17
Peru	36.4	15
United States	35.0	14
Canada	30.7	12
U.S.S.R. (estimate)	27.0	11
Australia	18.9	7
Other	58.7	24
Total	249.5	100

About 99 percent of the domestic silver production in 1963 was recovered in the smelting of ores and concentrates; the remainder was recovered by amalgamation, cyanidation, and placer mining. In the United States, smelting and refining plants recovering silver and associated base metals are situated in several parts of the country near mines, centers of trade and commerce, and sources of low-cost fuel.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The classification of silver ores is based on smelter terminology, smelter settlement contracts, and metal recovery originally adopted in 1905, except for modification necessitated by improvements in metallurgy and lowering of the grade of complex ore treated.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

The proportion of silver in bullion, coin or jewelry is usually expressed by its *fineness*, or parts a thousand. Fine silver is pure silver, 1000 parts fine or 100 percent silver. Sterling silver is 925 fine or 925 parts (92.5 percent) silver and 75 parts (7.5 percent) copper. Coin silver is 900 fine silver and the balance copper; and commercial silver bullion is 999 fine or higher. The troy system of weights is used in measuring silver as well as other precious metals and is based on the troy ounce of 480 grains or 20 pennyweight. There are 14.583 troy ounces in an avoirdupois pound.

TECHNOLOGY

Geology

Silver is commonly associated with base metals, chiefly lead, copper, and zinc, and most gold deposits contain silver. In deposits of these metals silver commonly occurs as a minor constituent of byproduct importance. Silver ores have been deposited in rocks of several geological ages, notably Tertiary, Cretaceous, and pre-Cambrian. Most of the world's silver has been mined from fissure veins or closely related deposits. The principal silver minerals of economic importance are argentite (Ag_2S), polybasite (Ag_9SbS_3), proustite (AG_3AsS_3), stephanite (AG_5S_4Sb), pyrargyrite (AG_3SbS_3), cerargyrite (AgCl), and native silver.

The Comstock Lode at Virginia City, Nev., from which silver valued at $225 million was produced from 1859 to 1911 is a fault fissure in tertiary andesite 2½ miles long and in places several hundred feet wide. The ore consists of argentite, polybasite and gold associated with pyrite and other sulfide minerals in quartz and calcite. Most of the minable ore was less than 2,000 feet in depth.

In the Cobalt district of Canada native silver deposits occur in narrow fissure veins in pre-Cambrian rocks associated with cobalt sulfides and arsenides. The veins are relatively small; however the deposits yielded around 375 million ounces in three decades following discovery in the early 1900's.

The silver ores of the Silver Belt in the Coeur d'Alene mining district of Idaho, which currently is the major silver-producing area of the United States, occur in veins in fault fissures and shear zones in pre-Cambrian quartzites and argillites in proximity to intrusive monzonite. The chief ore mineral is argentiferous tetrahedrite associated with sulfides of lead, copper, iron, and zinc in a gangue of quartz and siderite. Vein widths range from a few inches to 8 feet with mineralized zones as much as 30 feet wide. There are all gradations to the metal content of deposits in which the chief values are in silver.

Although the silver content of base metal ores may be extremely low, it can be recovered relatively economically by currently used refining methods. The porphyry copper deposits have a very low content of silver (0.02 to 0.11 ounce recovered per ton of ore), yet so great a tonnage of ore is mined and processed annually from these deposits that they are a major source of silver. In other ores silver is an especially valuable byproduct and may determine whether certain deposits can be worked profitably.

Mining

Methods of mining silver ore are similar to those used in mining several other metal ores and vary considerably from one mine to another, depending on such factors as size and shape of the ore bodies, physical and mineralogical character of the ore and surrounding rock, and depth of mining.

The Sunshine mine, the largest domestic silver mine, is serviced essentially by one main shaft 4,000 feet deep and five winzes. A sixth winze, the No. 10, has been completed to 125 feet below the 4,600 foot level. Development drifts are driven on the veins at level intervals of 150 and 200 feet and raises are driven between levels at approximately 100-foot intervals depending upon the characteristics of the ore. Stope blocks thus are about 100 feet long. The ore is mined by a hydraulic cut and fill method utilizing sand fill, an occasional rock bolt, but little timber. Ore is broken by breasting down using jackleg drills with carbide tipped rods and ammonium nitrate-fuel oil explosive. Broken ore in stopes is scraped to a chute in the timbered raise, loaded from the chute into 40-cubic foot cars, and transported by battery locomotives to the shaft pockets and hoisted to surface. In 1963 the ore averaged 38 ounces of silver a ton, 0.58 percent lead, and 0.71 percent copper.

Metallurgy

The argentiferous ores of the ancient mines at Laurium were treated by washing on stone tables and smelting the resulting concentrate, or by direct smelting, depending on the quality of the ore. The silver-bearing lead bullion produced by smelting was refined by cupellation to recover the silver. The amalgamation process by which metallic silver is wetted and becomes alloyed with mercury was first used in 1540. About 1850, the Augustin process was developed, in which the ore was roasted with common salt to convert the silver minerals to chlorides, followed by leaching with hot brine

780-887 O—65——52

and precipitation with metallic copper to recover the silver.

The Patio process which came into use in 1557 for the treatment of silver ores at Pachuca, Mexico, utilized a chloridizing roast, brine leaching, and amalgamation. The Washoe process, or pan amalgamation, was developed at the Comstock mines, Washoe County, Nev. In this process the crushed silver ore was ground in large cast-iron pans, mercury and salt were added to the steam-heated pulp, and the silver subsequently was recovered from the resulting amalgam by retorting. The Patera process which followed the Augustin and Patio processes was first applied to the ores of the Joachimsthal district, Bohemia. This process utilizes the solubility of silver chloride in a solution of sodium hyposulfite, and subsequent precipitation of the silver as silver sulfide (Ag_2S) by sodium sulfide (Na_2S).

Chlorination and hyposulfite leaching were superseded by cyanidation by 1900 and later by flotation combined with smelting. Cyanidation of silver ores, however, is still practiced in some districts in Mexico and Central America.

Byproduct silver from base-metal mines follows the ores produced through all stages of mining, direct shipping or concentration and shipping, smelting, and is ultimately recovered in the precious metal units of base-metal refineries. Losses of silver in the concentration processes are about the same as those for base metals. Average unit recoveries of silver in ounces per ton from base-metal ores of various classes in the United States in 1963 were copper ore, 0.08; lead ore, 1.09; zinc ore, 1.01; other base-metal ores, 1.41.

Silver ore from the Sunshine mine is crushed in gyratory and cone crushers and ground in ball mills in closed circuit with Akins classifiers to 60 percent through 200 mesh. The ore pulp is treated in Fagergren flotation cells, and a bulk concentrate containing 90 to 95 percent of the silver-bearing tetrahedrite and 75 percent of the silver-bearing galena is recovered. A tetrahedrite concentrate is floated in a retreatment circuit and sent to the antimony plant where antimony and arsenic are removed by caustic Na_2S leach; the high-grade silver-copper residue is washed and filtered and shipped to a copper smelter for recovery of silver and copper. The galena depressed in the retreatment flotation circuit is collected in settling cones filtered and shipped to a lead smelter for recovery of silver and lead. Mill recovery is about 97 percent of the silver and copper and 93 percent of the lead.

Silver in lead ores is carried down with the lead in smelting and is recovered by the Parkes process. This process consists of stirring zinc into the molten lead bath heated to above the melting point of zinc and allowing the mixture to cool slowly. A zinc crust containing the silver separates and can be skimmed from the lead, the zinc is driven off by distillation, and the residue is cupelled to dore silver. The silver in copper ore follows the copper in smelting processes, and in the electrolytic refining of copper, the silver remains in the anode slime from which it is recovered as silver bullion by smelting. The silver produced with gold in gold-placer mining or lode gold mining is recovered in the electrolytic refining of gold bullion.

Crude silver bullion, contains gold and sometimes small quantities of other metals, and is refined by electrolysis, using an electrolyte of silver nitrate and nitric acid. The refined silver is cast into ingots that have a purity of over 99.9 percent.

USES

Although silver has been used for centuries for coinage and the arts, it also has many essential uses in industry. Silver bullion also serves as backing for paper currency.

Some of the properties that make silver valuable in the arts and industries are attractive color and ability to take a fine finish; high malleability and ductility; high electrical and heat conductivity; resistance to corrosion and the sensitivity to light of some silver salts.

The principal industrial uses of silver are in the manufacture of photographic materials, in the fabrication of sterling silverware and electroplate and in silver solders and brazing alloys. Large quantities of silver are used for jewelry, optical goods, and novelties. Silver is also used in the manufacture of various chemical products for the laboratory, and for caustic, astringent and antiseptic purposes in medicine. Dental amalgams and alloys also consume important quantities of silver. Silver solders and brazing alloys made by alloying silver with varying proportions of base metals such as copper, zinc, and cadmium are widely used in the electric-appliance, air-conditioning, and automotive fields for joining pipes, making electrical connections, and forming mechanical assemblies. These alloys are being employed to an increasing extent for high-temperature applications in jet aircraft and in cooling rocket nozzles.

Substantial quantities of silver are used for electrical contacts in such regulating equipment as light-duty relays in telephone and aviation equipment, fluorescent-lamp controls, electromagnetic counters, and in protective devices for motors, and thermostats. Other growing industrial uses for silver include decorative finishes on ceramic materials, high-efficiency silver-

zinc and silver-cadmium batteries in jet aircraft and guided missiles, portable television cameras and scientific instruments that require high power output with minimum size and weight.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Gold is usually associated with silver in nature and is recovered as a byproduct or coproduct of some silver ores. Lead is commonly recovered as a byproduct or coproduct of silver-lead ores, and copper, zinc, antimony, bismuth, and arsenic are also byproducts in some silver ores. Tin is a coproduct of silver in some ores in Bolivia, and cobalt, uranium, and radium are coproducts of silver in some ores in Canada and Africa.

ALTERNATE MATERIALS

Silver in coatings on light-sensitive photographic paper for office copy work has been largely replaced by Xerography, an electrostatic duplicating process. Stainless steel is an alternate material for silver flatware, particularly in commercial use, and constitutes a large part of the market for tableware.

Aluminum and rhodium are substituted for silver for reflectors and amalgam in dental fillings; and tantalum can be used in place of silver for plates, sutures, and pins in surgery. The total substitution of other materials for silver is small, however, in comparison to the total consumption.

Cupro-nickel, nickel and other base metals have replaced or are replacing silver coins in some countries including the United States where subsidiary silver coinage is to be replaced by copper coins clad with cupro-nickel or 80-percent silver alloy as provided in the Coinage Act of 1965.

SECONDARY SOURCES AND RECOVERY

A constant flow of new scrap generated in manufacturing processes but not consumed in end products is returned to refiners for reuse. This material includes waste from metal stampings and coin manufacturing, turnings and anode butts. Silver is also recovered from used products such as batteries, mirrors, photographic film and plates, silverware, alloys, jewelry, and silver-plating and photographic solutions. According to the Bureau of the Mint, in the United States an average of approximately 60 million ounces of silver was returned from industrial use annually during the period 1959–63.

RESERVES

United States

Most of the United States reserve is in the Western States, but small amounts of silver are recovered as a byproduct of other metals in the Central and Eastern States. Measured and indicated reserves of silver, minable at or near current metal prices, total 590 million ounces (table 1), equivalent to a 17-year supply at the 1963 rate of production. About 90 percent of the reserve is contained in base metal deposits, compared with only 9 percent in deposits mined chiefly for silver. The exploration and development of inferred reserves will augment measured and indicated reserves and extend the productive life of currently operating mines. In addition new discoveries are almost certain to be made which will further augment known reserves. However, as most of the reserves are in base metal deposits, output of silver will be closely related to base metal production. Thus, domestic reserves of silver in silver-bearing deposits are adequate to supply silver for several years at, or moderately above, the current annual rate of output, but, because of limitations on annual output, the reserves are not adequate in terms of supplying silver at a high enough rate to meet domestic demand.

TABLE 1.—*Silver reserves of the United States, classified by type of ore*

Type of ore	In measured and indicated ore		In inferred ore	
	Million troy ounces	Percent of total	Million troy ounces	Percent of total
Straight silver	52.7	9.0	85.0	10.0
Lead-zinc-copper	236.0	40.0	570.0	67.0
Copper-zinc	.4		8.2	1.0
Copper	295.0	50.0	170.0	20.0
Gold	5.3	1.0	4.0	2.0
Tungsten or iron	.7		.6	
Total (rounded)	590.0	100.0	840.0	100.0

Foreign

Reliable data on reserves of silver in most foreign countries are scarce or entirely lacking. Estimates of reserves of the principal silver-producing countries of the free world shown in table 2 are based on reserves of silver-bearing base metal ores and the average ratio of the output of silver to the output of base metals. Like domestic reserves, the free world silver reserve, totaling 2.7 billion ounces, is adequate to supply silver for many years at, or moderately above, the annual rate, but because most of the output of silver is limited by the output

of associated base metals, the reserve is not adequate in terms of supplying silver to meet demand at the current level.

Discoveries of silver-bearing ore in the past few years, now being explored and developed in several countries, especially in Canada, Australia, and the United States, have not been fully evaluated but will add substantially to the total world reserve in the foreseeable future. Furthermore, intensive exploration prompted by substantial increases in the price of silver and associated metals, lead, zinc, and copper, is expected to result in new ore discoveries and ultimately increased production of silver.

TABLE 2.—*Estimated silver reserves and production of the principal free world countries*

Country	Production in 1963 (million troy ounces)	Reserves (measured and indicated) (million troy ounces)	Years supply at 1963 output rate
Canada	30.7	640	21
United States	35.2	590	17
Mexico	42.8	734	17
Peru	36.4	528	14
Australia	18.9	259	14
Total	164.0	2,751	17

Monetary stocks of silver in the U.S. Treasury at the end of 1963, comprising bullion and coin, totaled 1,584.3 million ounces. Silver held outside the Treasury in coins aggregated 1,716.3 million ounces.

Substantial quantities of silver as coinage in circulation are held in several countries, but data on world monetary stocks are incomplete.

SOURCES OF STATISTICAL INFORMATION

Statistics on mine production of silver in the United States are gathered, analyzed and compiled by the Federal Bureau of Mines in cooperation with the Geological Surveys of some States. The data compiled permit monthly and annual reports on mine production including information on sources and types of ore, methods of treatment, and recoveries.

Data on refinery production and on domestic and foreign consumption of silver are compiled by the Bureau of the Mint (*2*) and data on foreign trade in silver are supplied by the Department of Commerce. Monthly bulletins of the U.S. Treasury Department publish detailed data on monetary silver stocks, and silver in circulation as coinage. Daily statements show changes in the Treasury stocks and the relation of monetary reserves to nonmonetary reserves. Transaction Statements of the Bureau of the Mint also give detailed information on stocks, acquisitions, sales, and withdrawals for coinage and commercial use.

Silver production statistics are published by some foreign countries, especially those of the British Commonwealth, but corresponding data from other countries are not complete. The Bureau of Mines publishes a report on world production of silver based on information obtained from questionnaires sent to each country, consular reports, official publications, and company reports. Reliable data from Soviet-bloc countries are significantly lacking.

PRODUCTION, CONSUMPTION, AND TRADE

Since World War II, world output of silver has increased steadily reaching an average of about 234 million ounces annually for the period 1954–63. Domestic production has been moderately stable in the post-war period, averaging about 36 million ounces annually since 1950. Thus, in recent years U.S. mines produced about 15 percent of the total world silver output.

It has been estimated that about one-third of the total world output of silver is in circulation as coinage or held by governments for monetary purposes; one-third is privately owned; and one-third has been lost or dissipated.

World production of silver from the discovery of America to 1963 was approximately 22 billion troy ounces or nearly 763,000 tons. About four-fifths of this total was produced in the Western Hemisphere with North America contributing about 60 percent and South America 20. Mexico produced about 35 percent of the world total, the United States 21, Peru 9, and Bolivia 9.

World production of silver reached a peak of 278 million ounces (9,530 tons) in 1937; U.S. maximum annual production was nearly 75 million ounces (2,570 tons) in 1915. In 1963 world output of silver was estimated at 250 million ounces, and output of United States was approximately 35 million ounces (fig. 1).

The domestic supply of silver for industrial needs is obtained normally from mine production, secondary returns, and imports.

U.S. consumption of silver in the arts and industries, and for coinage greatly exceeds production. In recent years free world consumption in the arts and industries for coinage also has exceeded total production. For the period 1959–63 estimated free world consumption of silver averaged nearly 302 million ounces annually, of which nearly 60 percent was consumed by the United States. Summarized data on silver consumption in the arts and industries of the United States are given in table 3. No

current breakdown by end uses is available, however, photographic supplies, sterling and plated silverware, electrical products, and brazing alloys constitute the principal use of silver in the arts and industries. In 1963 it was estimated that the manufacture of photographic materials accounted for about 30 percent of the total silver used; electrical and electronic equipment, 24 percent; silverware and jewelry, 20 percent; brazing alloys and solders, 12 percent; space and defense applications, about 9 percent; and the remainder in miscellaneous uses. Imports and mine production furnished about three-fourths of the total industrial and defense silver requirements; the remainder was supplied from Treasury stocks.

The quantity of silver used in minting subsidiary coins averaging slightly more than 50 million ounces in the preceding 5 years rose to 111.5 million ounces in 1963. U.S. coinage requirements normally constitute about one-half of total silver used in free world coinage; however, in 1963 U.S. coinage requirements constituted nearly two-thirds of total silver used in free world coinage. Rising domestic coinage requirements in recent years was attributed to the growth in the use of coin-operated vending and metering machines and withdrawals of coins from circulation by collectors and speculators.

In 1963 the United States imported silver ore, base bullion, refined bullion, and silver coins valued at $71 million from some 28 countries. In the same year it exported the same items valued at $42 million to 17 countries. Foreign trade of the United States in silver for the period 1954–63 is shown in table 4.

The United States imposes no duties on imports of silver in ores, bullion, or coins, but does levy duties on products ranging from 10–10.5 percent on silver compounds to 55 percent on semimanufactured silver.

STRATEGIC CONSIDERATIONS

Most of the silver mined in the United States is a byproduct or coproduct of base-metal or gold ore. In some silver-bearing base-metal ores, the value of the recoverable silver may be an important factor in economic feasibility of mining and production of base metals needed for peacetime industrial uses and for vitally essential purposes in wartime.

Silver had incalculable value to the United States and its allies in World War I in obtaining supplies from far eastern countries where silver traditionally has been the principal monetary metal. A somewhat similar situation developed in World War II when large quantities of silver from Treasury stocks were loaned to our European allies. In addition a large quantity of silver was sold to industry by the Treasury for purposes approved by the War Production Board. During World War II, silver was first used for plating bearings of aircraft engines and for mechanized equipment where high-duty service and long life were essential. A large quantity of silver from Treasury stocks was loaned to the Defense Plant Corporation during World War II for use as electrical busbars, thus releasing copper for other needs. The total silver utilized in World War II exceeded 1,480 million ounces or about 40 times the total domestic production in 1963. U.S. Treasury stocks of silver bullion securing silver certificates are large, and large quantities of silver are in circulation as coinage. Total Treasury silver, both inside and outside the Treasury, represent a stockpile of over 3 billion ounces and, in an emergency, legislation could be enacted to release silver for military purposes from this vast stock.

Domestic consumption in recent years has been about three times production with the supply deficit being balanced by imports and withdrawals from the Treasury stock. Estimates and projections of silver supply and requirements indicate that consumption probably will continue to exceed available new supply by progressively increasing quantities in the short-term future. At the projected rate of withdrawal, the Treasury stock is not adequate to balance the deficit in supply for both industrial and coinage requirements after 1967 and the stock could be virtually depleted by 1968. The impending depletion of the Treasury stock would require that a strategic stockpile for silver be established to provide for emergency demand.

GOVERNMENT PROGRAMS

The Silver Purchase Act of 1934 and subsequent amendments of 1939 and 1946 significantly affected domestic price, production, and consumption of silver for many years. Large quantities of silver were purchased under the Government's buying program, and substantial sales were made to domestic consumers from Treasury free stocks until sales were discontinued late in 1961.

Consumption and use of silver in industry and the arts was controlled by War Production Board regulations during World War II. Treasury silver, in effect, was eligible for essential industrial and military uses; domestic silver was permitted in silverware, jewelry, watchcases, church articles, and other items classed as nonessential; and foreign silver was limited to use in photography, electrical appliances, dental and medical supplies and other items with preference ratings.

The Bank of Mexico acquires large quantities of silver from mining companies in Mexico, maintains substantial stocks to cover foreign commitments, and exercises some control on trading through the issuance of export licenses to producers.

The repeal in June 1963 of the Silver Purchase Act, and the tax on transfers of silver bullion, combined with redemption of silver certificates, largely freed silver from government control. However, the availability of silver from the Treasury continued to be the principal stabilizing factor in the world market.

Silver became eligible for government financial assistance under the program administered by the Office of Minerals Exploration in June 1961. The percentage of Government participation in the exploration of silver deposits was raised in October 1964 from 50 to 75 percent to provide greater incentive to search for and explore new silver deposits that might lead to increased production and help to alleviate the domestic supply shortage.

The Geological Survey initiated a reconnaissance program in 1964 designed to outline favorable areas for the occurrence of near-surface silver deposits. The work includes geological mapping and geochemical studies and utilizes as ore guides the distinctive hydrothermal alteration halos and geochemical anomalies associated with epithermal deposits. New tools and geophysical techniques applicable to silver exploration also are being tested.

PRICES

In 1933 the Treasury was authorized, under Presidential Proclamation 2067, and by Congress (31 U.S.C., secs. 316c and 316d), to acquire for coinage newly mined domestic silver with seigniorage deduction of 50 percent. Based on the monetary value of the silver dollar of $1.2929 per fine troy ounce, the Treasury buying price was thus fixed at $0.6464 per ounce. The monetary value of the silver dollar is based on the fine silver content of the standard silver (371.25 grains or 0.7734 fine ounces).

The Treasury price subsequently decreased to $0.5001 in August 1934; increased to $0.7757 in April 1935; decreased to $0.6464 in January 1938; and increased to $0.7111 in July 1939. The latest change in the Treasury price to $0.905+ per fine troy ounce, was effected by act of Congress (60 Stat. 750, 31 U.S.C., sec. 316d) on July 31, 1946, when the seigniorage deduction of 30 percent was set for services performed by the Treasury relative to the coinage and delivery of silver dollars.

Under authority of the act of July 31, 1946, Treasury silver became available to domestic consumers from its nonmonetary or free stocks at a selling price of $0.91 per fine ounce for delivery at the San Francisco Mint; and $0.91 plus the equivalent of railway express charges from San Francisco, or effectively $0.9225, at the New York Assay Office.

The New York price as quoted daily by Handy & Harman represents the actual price at which refined silver, in commercial bar form of acceptable brand and quality, was offered to Handy & Harman for New York delivery in quantities sufficient to meet daily requirements.

The buying and selling activities of the U.S. Treasury, which had been the chief factor stabilizing the price of silver in world markets for several years, became essentially inoperative following the Presidential order terminating Treasury sales in November 1961. Following cessation of Treasury sales the New York price began a general rise from the equivalent Treasury selling price of approximately 92 cents at New York to $1.293 an ounce, the monetary value of silver, in September 1963, after which it remained unchanged through 1964.

Repeal of the Silver Purchase Acts and the silver transactions tax in June 1963 permitted resumption of trading in silver futures on the New York Commodity Exchange for the first time since 1934. Prices for forward delivery exceeded the New York spot price by a considerable margin ranging up to 9 cents an ounce premium in September 1964 for delivery in August 1965. Amendment of the Federal Reserve Act permitting the replacement of $1 and $2 silver certificates by Federal Reserve notes effectively established a ceiling on the market price of silver at its monetary value of $1.293 per ounce since silver became available for commercial use through redemption of silver certificates.

Prior to cessation of Treasury sales and repeal of the Silver Purchase Laws, the average price of silver in the London market remained relatively stable, fluctuating in a narrow range near the fixed buying and selling prices of the U.S. Treasury. In 1963 spot prices in London did not vary much from the equivalent New York price, reflecting the cost at New York plus transportation to London and sterling-dollar exchange.

After long study in the executive departments and extended hearings before congressional committees, the Congress passed the Coinage Act of 1965 which the President signed on July 28. The Act provided for the elimination of silver from 10-cent and 25-cent coins substituting coins with a copper core clad with cupronickel alloy adn the reduction of silver in the 50-cent coin from 90 to 40 percent by the introduction of a copper core coin clad with an 80 percent silver alloy; other provisions give the President considerable authority in effecting a smooth transition to the new coinage system.

The average New York price for silver for the period 1910–63, and the U.S. Treasury price from 1933 to 1961 are shown in figure 2.

TAXES

Silver mining, refining, and manufacturing industries are taxed the same as other industries. The 10 percent excise tax levied on the

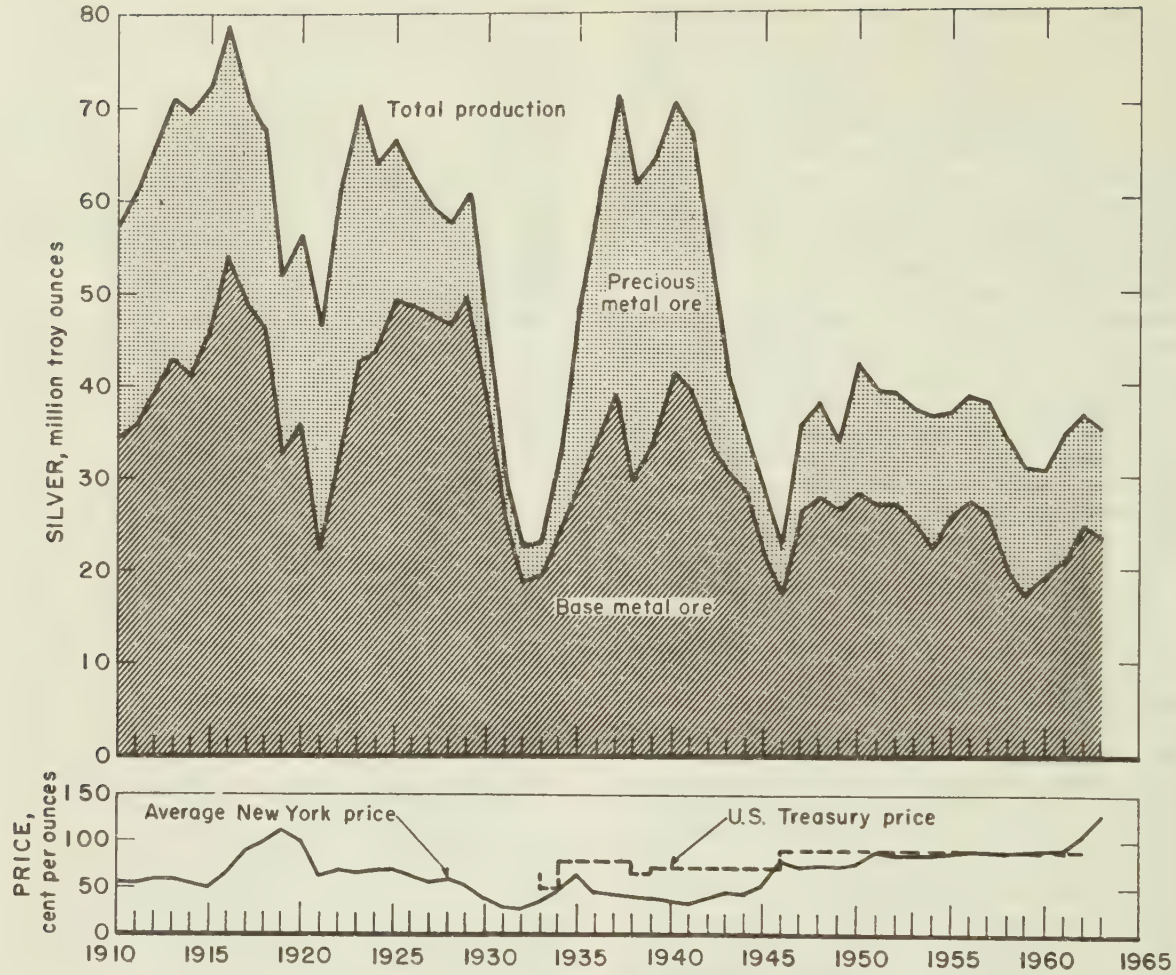

FIGURE 2.—Silver Production in the United States and Price Per Ounce.

sale of luxury items made of silver was repealed June 22, 1965.

The depletion allowance for silver is 15 percent of the gross income both domestic and foreign.

RESEARCH

Metallurgical research to adapt basic processes to the recovery of silver and other metals from refractory ores is conducted by various mining companies and ore-testing laboratories. Also, extensive research to develop new uses leading to increased consumption of silver was carried out in the 1930's by the American Silver Research Project, an organization of the principal silver producers and dealers. Areas of research investigation by this organization, included: Properties and technology of silver, binary and ternary alloys of silver, low and high-temperature bonding, silver in bearings, coatings, stationary and moving electrical contacts, corrosion resistance of silver and silver alloys, and silver as a catalyst and as a fungicide. The investigations pointed up areas where use of silver could be expanded, such as corrosion-resistant coatings on containers, catalysts in chemical process industries, and electrical contacts.

Bureau of Mines research in mining and metallurgy yields information contributing to greater efficiency and safety in mining, better evaluation of mineral resources, increased recovery of silver from ores and wastes, and more effective utilization of silver.

The Bureau recently began investigations to determine if recovery of silver from large low-grade deposits is economically feasible by the application of newer hydrometallurgical techniques of extraction. These studies include the use of ion-exchange resins and solvent-extraction tehniques to concentrate silver-bearing solutions, nitric acid leaching procedures, and a thorough evaluation of combined flotation-leaching-electrolytic recovery methods.

The Bureau also is surveying possible use of substitutes for silver in industrial applications such as transpiration-cooled rocket nozzles, high-temperature solders and brazing materials, and dental amalgams. Major industrial losses of silver are being studied by Bureau engineers to determine if current collection methods for scrap and waste silver-bearing materials can be improved and if current secondary silver reclamation technology is adequate.

Research on developing improved methods of sampling ores and evaluating mineral deposits and in applying new scientific techniques in mine planning and operation has yielded information useful to silver as well as other metal mining. Studies were begun by the Bureau in 1964 of low-grade deposits which could not be mined during earlier days, but which might be economically recoverable through the application of improved evaluation techniques and the use of modern low cost surface or underground mining methods. New mining techniques which provide for the prevention or control of rockbursts are currently being studied. This problem may become a serious handicap to production in deep mines.

OUTLOOK

The outlook for consumption of silver in the United States and in the world was profoundly affected by the signing of the Coinage Act of 1965 on July 28. The replacement of most of the silver in United States subsidiary coinage with base metals should go far toward righting the serious imbalance in silver supply and demand that has been growing in recent years. The output of silver from mines in which silver constitutes more than 50 percent of the value of the ore probably will continue to yield about one-third of the domestic production. The recovery of silver from secondary sources is expected to increase slightly in the next 4 or 5 years as primary consumption grows. Net imports probably will constitute a much smaller part of domestic supply in the next few years than in past years, as surplus stocks in foreign countries appear to be largely depleted.

Net industrial consumption is expected to increase about 1.5 to 2.0 percent annually in the foreseeable future. The use of silver probably will continue to grow in industrial or defense-oriented products, while its use in other consumer materials may level off or decline. The sharp rise in the quantity of silver used in coinage since 1961 may continue in the next few years, assuming no change in the present coinage policy.

As long as the Treasury continues to redeem silver certificates at the monetary price of $1.293 an ounce, this price establishes an effective ceiling on the New York market price.

As most of the world production of silver is recovered as a byproduct or coproduct of copper, lead, and zinc ores, any substantial increase in new supply will be dependent largely on the output of associated base metals. Hence, prices and other factors affecting production of base metals will, to a large extent, continue to determine the output of silver.

In recent years, intensive exploration using new and improved scientific techniques has resulted in the discovery of substantial deposits of silver-bearing ores in various countries of the free world.

Current and planned development of the new silver-bearing ores, and expansion of production facilities at established mines particularly in Canada, Peru, and Mexico, and to some extent in the United States, will eventually lead to greater silver output and thereby aid in reducing the overall supply deficit. Unless some unforeseen industrial or defense applications requiring substantial quantities of silver are developed, free world mine production may ultimately approach a balance with industrial consumption.

Silver will continue to find new uses in industry where its superior electrical and thermal conductivity, excellent reflectivity, malleability and ductility, and good corrosion resistance justify its high cost.

The rapid expansion of the electronics industry has created increased demand for silver contacts, conductors, and other silver-bearing components in fabricating various electrical and electronic equipment.

New applications of silver in military and consumer products continue to be developed. The use of silver-zinc and silver-cadmium batteries continues to increase in response to demand for a compact, dependable power source of high capacity not only for space and military equipment, but for industrial and consumer applications as well. High-energy silver chloride-magnesium batteries were developed to power torpedoes, sonar equipment and other equipment used in submarine warfare. The use of high-silver alloys in brazed honeycomb assemblies capable of withstanding high-temperature service conditions may be expected to

increase as the production of advanced aircraft and space vehicles expands. In addition to rocket motor applications, silver-infiltrated tungsten is being used as electrical contacts and for rotating bearings. The use of silver alloy contacts in electrical relays to control circuits in computers and tabulators continues to expand as demand for these machines grows. The recent development of photochromic glass containing silver halide for protection from solar light and heat has large potential use and may ultimately require a substantial quantity of silver.

The continued growth in the quantity of photographic materials used in amateur, professional and commercial photography will probably offset any reduction in the silver content of such materials and photographic materials likely will continue to be the leading silver-consuming industry.

The expanding use of coin-operated, merchandise-vending machines and meters will probably continue to absorb increased quantities of silver coins. The withdrawal of large quantities of silver coins from circulation by collectors and speculators is likely to continue at least in the near future.

PROBLEMS

Consumption of silver in the arts and industries and for coinage has exceeded new production since the early part of World War II, and the supply deficit has accelerated since 1958 as increased demand continues to outrun new production. The status of silver in the world economy has thus reversed from one of overproduction and correspondingly low world market prices, prior to World War II, to one of underproduction, in spite of price increases in postwar years. Thus, the paramount long-term silver problem is to find and develop new supply sources that can meet growing demand before world stocks are depleted.

Silver mining has many economic and technologic problems common to other deep level underground mining operations. Basically they are cost problems connected with breaking rock underground, ground control, ventilation, and transporting ore to central hoisting stations, and to concentrating and smelting plants to recover the relatively small quantities of silver and other metals it contains.

Many of the fundamental physical factors relating to the environment and extraction of ore from mineral deposits are not well understood and, although advances in mining technology have been notable in recent years, much of the technique of mining continues to be based on empirical methods rather than scientific principles. This deficiency in fundamental knowledge of the physical and mechanical properties of rock associated with mineral deposits has been a contributing factor in preventing maximum efficiency in mineral extraction and reduction of the cost of mining. Solution of problems restricting mineral extraction would result ultimately in greater production of silver and associated metals at some mines. Although offset to some extent since 1960 by higher world market prices, operating costs have continued to increase and some mines, where silver is the principal metal recovered in terms of value, have been forced to mine higher grade ore and abandon reserves that have become submarginal.

Problems relating to the exploration of small and widely distributed silver-bearing ores are chiefly economic. The high capital costs of mining and milling facilities in some remote areas and the relatively high operating costs of small-scale operations are deterrents to the development of new mines. Production capacity at most silver mines is limited or determined largely by the shape, size, and depth of the orebodies. Most of the deposits at silver mines are narrow veins or replacement masses lying deep in the ground. The orebodies are commonly irregular, discontinuous, and enclosed by fractured and altered wall rocks, making it difficult and expensive to extend and support mine openings. These physical conditions and high cost of exploration and development are factors restricting the scale of mining and fixing the capacity of reduction facilities. Hence, production capacity is relatively inflexible and not readily responsive to increases in demand for silver.

Serious deficiencies exist in consumption statistics on silver, needed by producing and consuming industries and government agencies, because of incomplete data on quantities used in various industries. This lack of reliable data on the end use pattern is a serious handicap in assessing trends and estimating future demand and in connection with developing a comprehensive program for silver.

Up-to-date information is lacking on the economic relationship of the production of silver to that of associated base metals and on the extent that price changes of associated base metals af-

fect silver output, and conversely, the effect of price changes of silver on the output of associated base metals.

Basic data on the preparation and properties of some silver alloys, such as silver-palladium, are needed to fully assess their current and potential use. Better knowledge of properties would aid in developing new and improved products and more efficient utilization of silver in industrial processes.

Substantial quantities of silver are consumed in fabricating silver infiltrated tungsten nozzles for rocket motors. The silver used in silver infiltrated tungsten is vaporized at the very high temperatures created by solid rocket fuels and is nonrecoverable.

SODIUM

By William H. Kerns [1]

SODIUM and chlorine, supplied primarily by salt, are as essential to man as air, water, and food. Sodium compounds play a part directly or indirectly in the preparation, processing, or production of virtually everything he eats, drinks, touches, and sees.

The commodities covered in this chapter are sodium chloride, sodium carbonate, sodium sulfate, and metallic sodium. Sodium chloride, common salt, is a plentiful mineral commodity. Exclusive of the oceans and salt lakes, which contain inconceivably large quantities of dissolved salt, vast amounts are found in underground deposits scattered throughout the world. The United States has virtually an inexhaustible reserve of salt despite an annual consumption exceeding 31 million tons.

More than one-half of the salt output each year is produced as salt brine from underground deposits and used as such, more than one-quarter as rock salt by underground mining, and the remainder as evaporated salt by solar, vacuum pan or open pan evaporation of natural or artificial brines. Salt is produced by 57 companies at 95 plants located in 17 States. Imports account for 4 percent of the U.S. apparent consumption and exports are about one-half of the imports. The annual salt production rate of increase has correlated closely with the growth rate of gross national product (GNP). Using this as a base, production should double by 1980 and quadruple by the year 2000.

The largest consumer of salt is the chemical industry, which uses two-thirds of the annual output. The production of chlorine-caustic alone consumes one-third of the total domestic salt output, while that of soda ash consumed one-fifth of the total. The trend of an increasing proportion of the salt output being used each year for chlorine production accompanied by a decreasing amount consumed in manufacturing soda ash is expected to continue. Quantities of salt used for road stabilization, highway snow and ice removal, and for regeneration of water softeners using the ion-exchange principle are expected to increase each year.

Problems of the salt industry are chiefly those of maintaining the same or lowering production and marketing costs so that salt may continue as a high-volume low-unit-cost commodity. Quoted prices for salt have remained steady since 1958, average reported selling price or value at place of production has decreased slightly, and packaged-salt prices have remained virtually stable. As an example, a 26-ounce box of salt costing 10 cents in 1925 costs 11 cents today. Prices are maintained through constant improvements in mining, producing, processing, handling, and marketing methods. Other problems relate to the corrosive nature of salt solution on plant equipment and on vehicles and roads when salt is used for snow and ice removal.

Sodium carbonate (soda ash) requirements of nearly 6 million tons per year are supplied by manufactured soda ash from 11 ammonia-soda (Solvay) process plants in the East and Midwest and from natural sources of trona mined at 2 operations in Wyoming and from brines at 3 operations in California; 81 percent of the total is manufactured and 19 percent is natural. The growth in the soda ash industry is expected to continue to be largely from natural soda ash rather than ammonia soda production because new ammonia soda plants are too expensive compared with natural soda ash production installations. This has resulted in new and expanded natural soda operations and exploration and development work on other prospective operations. U.S. soda ash imports for consumption are negligible, but exports are 3 percent of the U.S. production and have increased each year for the last decade.

Reserves of trona alone would supply the total U.S. soda ash needs for 100 years at the present consumption rate. In addition, the reserves of brine in California from which sodium carbonate, sodium sulfate, and other minerals are recovered are known to be large.

[1] Commodity specialist.

Nearly one-half of the sodium carbonate produced is required in manufacturing glass; one-quarter for chemicals; and the remainder in producing pulp, paper, soap, and detergents, in producing aluminum, for treating water, and for other miscellaneous uses. The total U.S. production of manufactured and natural soda ash is expected to increase at the anticipated growth rate of GNP or quadruple by the close of this century. The expected growth in chlorine consumption may cause an overproduction of the coproduct, caustic soda, which is a substitute for soda ash, and thus depress the demand for soda ash. However, new uses for caustic soda have absorbed and should continue to absorb the extra production of caustic.

Two-thirds of the more than 1-million-ton demand for sodium sulfate (salt cake) in the United States is supplied as a byproduct of chemical processes at 40 plants located in 16 States (12 Eastern and Southern, 3 Central, and 1 Western) that produce rayon, cellophane, hydrochloric acid, and other chemicals. The remainder comes from natural sources at three operations in California and one each in Texas and Wyoming. Four percent of the U.S. production of sodium sulfate was exported. However, imports were equivalent to 13 percent of domestic production.

The reserves of natural sodium sulfate in the Western United States and Canada exceed several hundred million tons, sufficient to supply our needs for several hundred years. In addition to the natural and byproduct sources, the raw materials from which sodium sulfate could be produced are sufficient to meet all future expanding needs. The kraft paper industry consumes more than two-thirds of the total U.S. sodium sulfate production. It is also used in making glass, ceramic glazers, detergents, stock feeds, dyes, textiles, and miscellaneous chemicals.

An anticipated increase in the demand for sodium sulfate and decline in byproduct salt cake output are expected to be supplied by natural sodium sulfate production. Consequently, a greater proportion of the total requirements should be supplied each year from natural sources.

Sodium metal is recovered by electrolysis of a fused mixture of calcium and sodium chlorides in Downs cells. Because sodium metal is extremely reactive and ignites spontaneously when exposed to air or moisture, handling, controlling reactions, and maintaining it in the required state of purity present difficulties.

Sodium metal is produced by three companies at five plants in five States. The annual output of 110,000 to 125,000 tons is used chiefly in producing tetraethyl and tetramethyl lead—two compounds added to fuels to increase their antiknock rating. This use is affected by the demand for high-test fuel, which is not required by economy cars. An increasing use of jet aircraft and gas turbines will depress this use. Metallic sodium also is used in metal descaling, ore reduction, manufacturing sodium peroxide and other chemicals, and in cooling or transferring heat in certain types of atomic reactors. New and expanded uses for metallic sodium are expected to take the places of any declining uses.

BACKGROUND

The elements sodium and chlorine are essential to animal life, and, as sodium chloride meets this requirement most readily, salt has been a dietary essential since earliest times. Early mankind depended upon the flesh of animals and the occasional outcroppings of salt or salt licks frequented by animals to satisfy his salt requirements. As civilization progressed, mankind learned to evaporate sea water and brines of saline lakes and springs to obtain salt; uses and demand for salt grew enormously; huge underground deposits now are mined on a large scale to supply most of the ever-increasing salt requirements of modern civilization.

The importance of salt in the minds of early men may be seen from the many allusions to salt found in the Bible and other historical writings. Expressions such as "not worth his salt," "the salt of the earth," and other sayings have become idiomatic in the English language. Salt has symbolized friendship, fidelity, purity, and hospitality. It has been used as a currency, has had religious significance, caused wars, and has been a favorite commodity for taxation.

Today salt retains its importance to the physical well-being of mankind, and in addition, it has thousands of other uses. Of each 100 pounds of salt produced in the United States, less than 3 pounds is for table use. The other 97 pounds is for chemical, industrial, and agricultural uses.

The history of sodium carbonate also goes back into antiquity. It was recovered by the early Egyptians from incrustations around playa lakes. Until near the end of the 18th century, seaweeds and marine plants were

burned and sodium carbonate recovered from the ashes for use in soap, cleaning compounds, and glass. From these early sources the common term of sodium carbonate became soda ash. About 1791 Le Blanc in France developed a commercial process for the production of sodium carbonate, using salt, limestone, and coal. This process was widely used in Europe. In the 1860's the Solvay brothers of Belgium developed a process for manufacturing sodium carbonate from salt, limestone, and ammonia. The Solvay process, also called the ammonia-soda process, now is used in making most of the world's sodium carbonate.

During World War I, when imports of potash and other salts were curtailed, increased attention was focused on domestic deposits of these salts, such as those at Searles and Owens Lakes in California. Besides salt, these deposits are rich in sodium carbonate and sodium sulfate, as well as compounds of potash, borax, lithium, and other minerals. The chemistry involved in separating the various products was complex; however, as the technology for exploiting these and other saline deposits improved, the production of sodium carbonate and sodium sulfate from natural sources gradually increased. The byproduct salt produced in these operations is usually wasted.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

With an annual production of nearly 31 million tons, the U.S. salt industry ranks among the largest in the nonmetals field. Salt is foremost of the mineral commodities consumed by the chemical industry. In fact, chemical concerns are among the largest producers of salt.

Salt was produced by a total of 57 companies at 95 plants in the United States in 1963. Six of the leading salt-producing companies, operating a total of 26 plants, produced 65 percent of the total output. Ten companies each produced in excess of 1 million tons. The leading 24 companies, each producing more than 100,000 tons, operating a total of 62 plants, accounted for 96 percent of the total salt output. The remaining 4 percent of the total output was produced by 33 companies at 33 plants. About two-thirds of the salt produced in the United States was recovered as salt in brine and sold or used as such.

Louisiana was the leading salt-producing State in 1963 with 20 percent of the total output; Texas was second with 19 percent; and New York was third with 16 percent. Michigan and Ohio each produced about 14 percent of the total and California 6 percent. These 6 States supplied 89 percent of the total U.S. output. The remaining 11 percent came from 12 other States.

Although domestic salt-producing areas are widely distributed, several areas are without known salt deposits or facilities that can be developed at competitive costs. Notable examples are New England and most of the East Coast States. The Pacific Northwest is an important salt-consuming industrial area lacking in local salt-producing facilities.

Canada and Mexico are the chief source of U.S. salt imports, furnishing nearly three-fourths of the total in 1963; major quantities also came from the Bahamas, Jamaica, Spain, Tunisia, and Egypt.

The United States leads the world in production of sodium carbonate with an annual output of nearly 6 million tons in 1963. By far the greatest proportion, 81 percent, is produced from sodium chloride by the ammonia-soda (Solvay) process. Eleven eastern and midwestern plants strategically situated in regard to salt and limestone deposits and nearby chemical markets provided the bulk of the Nation's soda ash requirements. The remaining soda ash output was supplied from natural sources of sodium carbonate, such as brines of Searles and Owens Lakes in California and underground deposits in Wyoming.

The growth of the sodium carbonate industry since 1960 has been largely from natural soda rather than ammonia-soda production. The high cost of new ammonia-soda plants compared with natural soda producing and refining operations probably caused the stalemate in new ammonia soda plant construction and increased interest in natural soda output. In 1962, the cost of a new 1,000-ton-per-day ammonia soda plant, the smallest that can be built and operated profitably, was estimated at $40 million.

Production of sodium carbonate and sulfate from natural sources comes from three States—California, Wyoming, and Texas. In California, both commodities are produced from the brines of Searles Lake by American Potash & Chemical Co. and Stauffer Chemical Co., West End Division. Pittsburgh Plate Glass Co. recovers sodium carbonate from brines of Owens Lake. U.S. Borax & Chemical Corp., Pacific Coast Borax Division, produces sodium sulfate as a coproduct in making boric acid from borax.

In Wyoming, FMC Corp., Inorganic Chemicals Division, and Stauffer Chemical Co. of Wyoming, West End Chemical Co. Division, operate underground trona mines near Green River and were two of the major producers of natural sodium carbonate in 1963. Plans were

made for expanding mining and processing capacities at these operations, and other firms were conducting exploration work on trona deposits in the area or contemplating installations. William E. Pratt produces sodium sulfate from semidry lakebeds near Casper, Wyo.

In Texas, the Ozark-Mahoning Co. produces sodium sulfate from brines at two operations, Monahans and Brownsville.

Production of manufactured sodium carbonate is mainly in the East and Midwest. The 11 plants are distributed in the United States as follows: 2 each in Louisiana, Michigan, Ohio, and Texas, and 1 each in New Jersey, New York, and Virginia.

Sodium sulfate output in the United States was 1.2 million tons in 1963. About 64 percent was produced as byproducts or coproducts of chemical processes that produced rayon, cellophane, hydrochloric acid, sodium bichromate, boric acid, phenols, and other chemicals; and 36 percent was produced from natural sources in California, Wyoming, and Texas.

Manufactured sodium sulfate was produced as a byproduct or coproduct at 40 plants in 16 States—12 Eastern and Southern, 3 Central, and 1 Western—in 1963.

Sodium metal is produced as a coproduct, along with chlorine, by three companies by electrolysis of molten salt at five plants in five States. E. I. du Pont de Nemours & Co., Inc., has plants at Niagara Falls, N.Y., and Memphis, Tenn.; Ethyl Corp. at Baton Rouge, La., and Houston, Tex.; and National Distillers & Chemical Corp. at Ashtabula, Ohio. The output in 1963, 125,566 tons, was used chiefly in making tetraethyl and tetramethyl lead, a gasoline additive.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Brine is a term applied to solutions of salts in water. The brines of the seas and other natural brines were formed by fresh-water leaching of rocks and soil containing soluble minerals. Natural brines usually have been concentrated by evaporation.

Artificial brines are produced by injecting fresh water into salt formations and allowing the salt concentration to build up to a point near saturation. Artificial brines used by the salt-producing industry are approximately 25 percent sodium chloride.

Evaporated salt is a term applied to fine crystals of sodium chloride produced by evaporating brines in large covered, steam-heated kettles or pans under vacuum conditions.

Solar salt is the term applied to salt crystallized in shallow ponds by exposing brines to evaporation by sun and wind. In some Bureau of Mines tabulations, solar salt is included with evaporated salt. Bittern is the concentrated solution of various salts remaining after most of the salt (sodium chloride), has been crystallized from natural brines by solar evaporation.

Highly pure evaporated salt produced in open pans either by the Alberger or Grainer process is called flake salt. It is characterized by an agglomerated crystal of flakes and cubes.

Grainer salt consists of relatively large, pure, hopper-shaped crystals and is produced primarily for the food industries' use in butter, cheese, crackers, pretzels, and other products. The crystals are caused to grow in the shape of inverted pyramids or hoppers by allowing slow evaporation at the undisturbed surface of the brine. As the brine flows slowly through long, shallow, steam-heated troughs, known as open pans or grainers, floating seed crystals grow circumferentially, gradually sinking deeper as they grow heavier, until they sink to the bottom and are collected.

Rock salt is a term applied to salt produced by drilling and blasting natural salt deposits. Salt domes are large masses or plugs of salt formed by pressure deformation of natural salt deposits.

Soda ash is the term used in the industry for sodium carbonate (Na_2CO_3). When crystallized with 10 water molecules it is washing soda. Baking soda ($NaHCO_3$) contains a greater proportion of CO_2 than soda ash. Trona or sodium sesquicarbonate ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$) is a commercially important sodium carbonate mineral. Caustic soda, sodium hydroxide (NaOH), commercially known as caustic alkali, lye, or simply caustic, is recovered as a coproduct of chlorine from salt.

Solvay soda or ammonia soda are terms used interchangeably for sodium carbonate produced from salt by the Solvay process.

Light ash is soda ash having a bulk density of 32 to 35 pounds per cubic foot. Dense ash is the same material having a density about 60 to 66 pounds per cubic foot.

Salt cake is the term used for sodium sulfate (Na_2SO_4). Glaubers salt is a common hydrated form of sodium sulfate ($Na_2SO_4 \cdot 10H_2O$).

In the salt industry the quality of the product of one manufacturer usually is the same, grade for grade, as that of another. Grades usually refer to size distribution rather than quality.

Four grades of commercial salt produced at a rock salt mine operated by one of the leading salt-producing companies are as follows:

Size:	Through—	Retained on—
No. 2	0.500 inch	0.420 inch.
No. 1	0.420 inch	0.301 inch.
Coarse C	0.301 inch	10-mesh.
Fine C	10-mesh	None.

Rock salt produced in the United States usually has a sodium chloride content above 98 percent. Impurities are chiefly calcium and magnesium sulfates and chlorides. Evaporated salt from vacuum pans usually contains less than 0.5 percent impurity; flake and grainer salt usually contain less than 0.2 percent impurity.

Many specialty salt products contain special additives. Caking due to moisture absorption in table salt is retarded by adding 0.5 to 2.0 percent of an additive such as magnesium carbonate, calcium carbonate, hydrated calcium silicate, or tricalcium phosphate. These additives often are referred to as fillers or driers. To be effective they must coat each salt crystal and not become dusty.

Iodized salt contains 0.01 percent potassium iodide and a stabilizer consisting of 0.1 percent sodium carbonate and 0.1 percent sodium thiosulfate or other suitable nontoxic stabilizing agents. Iodized table salt is an effective means of preventing certain diseases attributed to iodine deficiency in the diet.

For salting livestock, fine particles of either evaporated or rock salt are compressed into 50-pound blocks, 4-pound bricks, or 3-ounce pellets. In addition to plain salt the blocks are made with the following additives: (1) 2 to 4 percent sulfur; (2) 0.01 percent potassium iodide; (3) trace minerals including compounds of manganese, iron, cobalt, copper, iodine, and zinc; and (4) minerals such as carbonates and phosphates.

"Federal Specification SS–S–31h, June 25, 1964, Salt: Table," approved by the Federal Supply Service, General Services Administration, covers specifications for table salt, plain or iodized, for use by the agencies of the Federal Government and are not otherwise binding on industry. However, the products marketed by the industry for use in food meet or exceed these specifications for table salt, which are set forth as follows: Table salt shall be of edible grade, clean, sound, wholesome, and free from extraneous matter. Plain table salt shall be free flowing and shall be derived from fine granulated salt (rock salt) or evaporated salt, with one or more effective anticaking agents. The plain table salt shall contain not less than 97.5 percent sodium chloride on a moisture-free basis and not more than 0.1 percent moisture. When fine granulated salt is used, table salt shall be of such size that not less than 95 percent shall pass through a U.S. Standard No. 25 sieve and not more than 10 percent shall pass through a No. 70 sieve. When evaporated salt is used, table salt shall be of such size that 100 percent shall pass through No. 16 sieve, and not more than 20 percent shall pass through a No. 100 sieve. If iodized salt is specified, the iodized salt shall conform to the finished product requirements of plain salt. In addition, the iodized salt shall contain potassium iodide not less than 0.009 and not more than 0.01 percent or other nontoxic iodine compounds with a stabilizer consisting of sodium carbonate or sodium thiosulfate or other suitable stabilizing agents which are equally effective in preventing the loss of iodine.

"Federal Specification SS–S–550, July 5, 1957, Sodium Chloride, Technical, for Water Softening Units," covers salt for use in regeneration of water-softening units by the agencies of the Federal Government. Type I rock salt shall pass through a ⅜-inch sieve and at least 95 percent shall be retained on a No. 60 sieve. Minimum sodium chloride shall be 97 percent, maximum moisture 0.50 percent. Type II, grade A, evaporated salt shall pass through a ⅜-inch sieve and not more than 5 percent shall pass through a No. 100 sieve. Sodium chloride shall be at least 98 percent, and moist shall not exceed 0.50 percent.

TECHNOLOGY

Salt

The technology of salt production, properties, and uses have been described in a comprehensive publication (*19*).[2] Papers presented in five principal areas of salt technology—geology of salt formations, mining rock salt, evaporated salt, solution mining, and underground storage—were published in a major source book on both salt technology and North American salt deposits (*1*).

Sodium chloride has a molecular weight of 58.454 and contains by weight 39.34 percent sodium and 60.66 percent chlorine. It has a hardness of 2.5 and a specific gravity ranging from 2.1 to 2.6 for rock salt and 2.165 for the pure crystal. Salt is transparent or translucent and highly diathermic. When pure it ranges from white in the finely divided state to gray in large masses. Salt has a vitreous luster.

Traces of iron oxides in salt produce various shades of yellow, orange, brown, pink, or red. The peculiar shade of red sometimes found in salt produced by solar evaporation of sea water has been attributed to tiny organisms. Blue mottlings sometimes seen in halite crystals have been attributed to colloidal sodium.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Salt is soluble in water to the extent of 35.7 parts per 100 parts of water at 0° C and 39.8 parts per 100 of water at 100° C. The small difference in solubility due to temperature changes is an important factor in the economics of producing salt by evaporating brine. Salt has a negative heat of solution, which is 1,281 kilogram-calories per mole at 18° C in 200 moles of water. This energy value is an important factor in the cost of freshening salt water.

Under great pressure, rock salt is plastic and will flow slowly as a viscous fluid. The viscosity of rock salt is 10^{18} poises at 18° C and 10^{17} poises at 80° C. For comparison, the viscosity of asphalt is 10^{7} poises at 20° C. The ability of rock salt to flow under pressure enables it to seal cracks and fissures in the surrounding rock, helping to keep the interior of salt mines dry. This property also permits the formation of salt domes.

Salt is found in two forms—solid, as rock salt, and in solution, as brines. The salt content of the seas is attributed largely to leaching of soluble salts from rocks and soil by water resulting from precipitation. Some of this water flowing through streams eventually reaches the sea. Many rivers have an appreciable salt content and because of their volume pour large quantities of salt into the oceans (*23*). For example, it is estimated that the Rio Grande deposits 5 tons of salt in the Gulf of Mexico each minute. As water evaporates from the sea surface the salts remain in the brines. The average concentration of salts in sea water is about 35 grams per liter. More than 40 different molecular and ionic substances have been detected in sea water, but three-quarters of the total dissolved solids is sodium chloride (*7, 34*).

As evaporation of sea water approaches completion, the brine becomes saturated with respect to the various salts at different stages. Knowledge of the order of precipitation of salts from sea water helps to explain how relatively pure sodium chloride may be deposited from sea water containing many different salts.

The following order of deposition of salts from sea water occurs: (1) Fe_2O_3 and $CaCO_3$ were precipitated as the brine was evaporated to 53 percent of its original volume; most of the $CaSO_4$ and the remainder of the $CaCO_3$ were precipitated as the volume was reduced further to 19 percent. Sodium chloride began to precipitate when the volume reached 9.5 percent and the density 1.21 and continued until the solution was dry. Small quantities of $CaSO_4$, $MgSO_4$, and $MgCl_2$ were deposited along with the salt until the volume was reduced to 3.90 percent, at which point some NaBr was also precipitated until the density reached 1.32 and the volume was 1.66 percent of the original. From this point on further evaporation precipitated potassium chloride and a series of complex salts, the composition of which depended on the temperature and the relative concentration of the salts remaining in the mother liquor. The potash deposits of Carlsbad, N. Mex., have been attributed to the precipitation of the mother-liquor salts in the final stages of the evaporation of a Permian Sea. The Stassfurt deposits are believed to have a similar origin.

Under certain conditions a body of sea water may become isolated from the circulating ocean currents by a reef, sandbar, or other means; and under suitably dry and warm climatic conditions the evaporation proceeds until the salts are partially or entirely deposited. With continuous or periodic influx of sea water to replace evaporation, large deposits of salt have been built up—in some instances several thousand feet in thickness. Deposits of this type have been called lagoonal. During the Permian age two famous salt deposits of the lagoonal type were laid down—one in northern Germany and the other in eastern New Mexico. A second large bedded deposit in the United States is the Silurian salt deposit, which underlies Michigan, New York, Pennsylvania, Ohio, and West Virginia. It was formed in much the same manner as the Permian beds by the evaporation of a large inland sea known as the Silurian Sea, which became separated from the ocean and gradually evaporated. As no mother-liquor salts were precipitated it is assumed that evaporation was never completed.

Playa deposits are formed by leaching of surrounding sediments, followed by the evaporation of the water leaving the salts. The composition of the brines and salt beds of these deposits generally do not resemble sea water; those of California and Nevada contain in addition to sodium chloride much carbonate, sulfate, and potash as well as appreciable percentages of boron.

Salt domes are large vertical structures of salt, resulting from deformation of bedded salt deposits under great pressure. The plastic nature of halite and its low density, compared with the surrounding rock, permits deeply buried sedimentary deposits to be forced upward through zones of weakness in the overlying rocks, forming vertical columns or domes of salt extending several thousand feet in height and cross section. If the bedded deposit at the base of the dome is sufficiently large, the salt columns may rise to the surface. Surface features may or may not indicate the presence of underlying salt domes; most have been detected by geophysical methods and proved by drilling. There are 300 salt domes reported to exist in the gulf coast area from Alabama to Mexico.

In addition to those of the gulf coast area, salt domes have been found in other parts of the world, notably in Colombia, East and West Germany, Spain, Rumania, Egypt, Algeria, Morocco, Iran, and U.S.S.R.

Production Methods

Salt is produced in three ways: (1) By solar evaporation of sea water, lake, and other brines; (2) by room-and-pillar mining of bedded and dome deposits similar to mining coal; and (3) by solution mining methods in which water is injected into the salt deposit, forming an artificial brine, which is pumped to the surface, where the salt content is utilized.

Throughout the world, solar evaporation is the most widely used of the three methods because of its simplicity. However, in the United States, because of climate and other factors, less salt is produced by solar evaporation than by either of the other two methods. Solar salt is produced in California, Hawaii, Nevada, New Mexico, and Utah by highly mechanized processes best exemplified perhaps by the operation of the Leslie Salt Co. on the southern shores of San Francisco Bay (*39*). Here are found all factors necessary for an economically successful solar plant: (1) Large areas of low-lying flatlands, (2) a clay subsoil, which quickly becomes impervious to brines, (3) low rainfall, (4) high net evaporation, (5) drying winds, (6) comparatively long seasons free from precipitation, and (7) nearby markets.

A salt "farm" consists of concentrating ponds and crystallizing ponds. The ratio of the area of these types of ponds is approximately 15 : 1. A unit often consists of 9 or 10 concentrating ponds and several crystallizing ponds. The No. 1 concentrating pond is flooded with sea water in the fall, usually by opening floodgates at high tide. As evaporation increases the density of brine, initially about 3.0° Baumé, the brine is pumped successively through the various ponds, taking advantage of the forces of gravity and prevailing winds where possible until it reaches 26.0° Baumé and is saturated with sodium chloride (NaCl) In the early concentrating stages, most of the calcium and iron compounds precipitate and the brine then goes to the crystallizing pond where it is further concentrated to 29.0° Baumé.

In the concentration range between 26° and 29° Baumé, virtually nothing but sodium chloride is deposited to a depth of 4 to 6 inches on the flat, smoothly rolled bottoms of the ponds. As further concentration of the brine causes excessive crystallization of magnesium salts, the remainder of the brine (bittern) is either wasted or sold for the recovery of magnesium and bromine.

The salt is harvested each year before the autumn rains begin by specially designed tractor-mounted machines, which break up the salt with horizontally mounted revolving picks. A short conveyor delivers the salt to hopper cars, which carry it to the washer. After washing with saturated brine, followed by a fine spray of fresh water, the salt is stockpiled in the open. A hard crust soon develops protecting the pile from rain loss, estimated to be only 5 or 10 percent. Five to 7 years is normally required to bring a pond to full production, which is about 40 tons per acre in this area. Most of the salt is marketed as undried crude 99.4 percent NaCl, and the remainder is kiln dried, 99.8 percent NaCl, and vacuum refined salt with a purity of over 99.9 percent NaCl.

Rock salt is mined on a large scale in Michigan, Texas, New York, Louisiana, Ohio, Utah, New Mexico, and Kansas (*3, 4, 33*). The room-and-pillar method is used principally. Rooms tend to be large but vary in size in different mines, depending on the thickness of the seam and other factors. In the Retsof mine near Rochester, N.Y., a 9½-foot seam is mined at a depth of about 1,000 feet. Rooms are 63 feet wide and about 500 feet long. Pillars are 57 feet wide and alternate 185 and 220 feet long. This system permits removal of 70 percent of the salt, leaving 30 percent in the pillars. The mined-out area of the Retsof mine is approximately 1,600 acres, making it the largest salt mine in the Western Hemisphere (*29*). In dome-type deposits, such as those of Louisiana, the rooms may be more than 100 feet high.

Unlike most mines where the desired mineral is a comparatively small seam mixed with and surrounded by gangue material, a salt mine is usually completely enclosed in salt. The nature of the material is such that the roof between pillars is self-supporting, and no timbering is required. Moisture on the outside of the salt body tends to form a crystallized crust, which protects the interior of the body from moisture and seepage.

Salt mining is similar to coal mining and is highly mechanized. In one mine an undercutter cuts a slot 10 feet deep at the base of the wall, which is then drilled and blasted. About 0.4 pound of dynamite per ton of salt is required. To eliminate copper contamination of the salt, aluminum blasting caps and iron leg wires are used. Pieces of the wire are later removed magnetically. The broken salt is loaded mechanically into cars or trucks and hauled to an underground crusher. Belt haulage has proved satisfactory in some mines following the devel-

opment of a portable crushing machine, which reduces the lumps to a size that the belts can handle. At the surface the salt is crushed, screened, graded, and made ready for the market.

Bench mining of rock salt in a massive Louisiana salt dome successfully overcame problems of the conventional face drilling system. A 50-foot-wide bench was prepared by drilling a row of seven vertical holes 8½ feet back from the face of the bench. The holes were drilled to a 34-foot depth, allowing 4 feet to collect cuttings not cleaned from the hole. After undercutting through the holes with a shortwall cutter having a 9-foot bar, the holes were charged with a 60-percent strength semigelatin explosive. A typical blast, requiring 186 pounds of explosive, broke about 900 tons of salt ready for loading. (*17*, *43*).

Ammonium nitrate-fuel oil mixtures are used as a blasting agent in several large rock salt mines (*30*). Fuel oil, amounting to 6 percent of the weight of ammonium nitrate, was added to plastic bags of ammonium nitrate prills, and the bags allowed to stand 24 to 48 hours before being placed pneumatically into the hole.

About two-thirds of the U.S. salt output is produced by introducing water into a cavity in the salt deposits and removing the brine. This procedure is relatively simple and has particular advantage when the salt is to be used as a brine as, for example, in chemical uses such as soda ash and caustic manufacture. Holes are drilled through the overburden into the deposit and cased with iron pipe. Water is introduced into the deposit through a smaller pipe inside the casing. A nearly saturated brine is formed in the cavity at the foot of the pipe. This brine is pumped or airlifted through the annular space between the pipes. Numerous techniques have been developed to control the shape of the cavity so that a saturated brine will be formed and eventual subsidence and caving of the cavity will result in the least damage to the well. Most of these techniques involve positioning of the water intake and brine exit pipes in the cavity and the employment of a cushion of air to control the degree of contact between solvent and salt formation. After adjacent wells have been operated 1 or 2 years, their cavities may become connected. When this occurs the usual practice is to introduce water into one well and remove brine from the other.

In recent years hydraulic-fracturing techniques to form channels between wells, developed by oil producers to increase output, were adapted to solution mining of salt with great success and increased efficiency. In this system a series of wells drilled to the base of a salt formation are caused to interconnect by injecting water under high pressure into one of the wells and continuing to pump water into the well until a fracture occurs to a nearby well or wells. In mining, fresh water is introduced in one string and saturated brine is removed from the other (*13*).

The cavities developed in salt mines both by dry mining and solution mining techniques have been found to be admirably adapted as storage vaults. Rock salt has strength enough to support itself over moderate spans without danger of collapse. Salt formations have good thermal conductivity and are relatively impervious to seepage of water, so the cavities have an even temperature and relatively low humidity. Principal rock-salt areas in the United States have a good record of earthquake stability. Storage of petroleum products and radioactive wastes in salt cavities is said to be economical and safe (*31*). Many physical and chemical properties of salt beds are well adapted to storage of hot chemical materials in liquid form. Tests made in the Carey Salt Miles at Hutchinson, Kans., were described (*18*).

As a part of a program to explore the peaceful uses of nuclear energy, the Atomic Energy Commission triggered a nuclear device in a cavern created in a salt dome near Carlsbad, N. Mex. The design, methods, and costs of sinking the Gnome shaft to set the charge were described (*16*, *37*).

Preparation for Market

Mined rock salt usually receives no treatment other than crushing and grading. Treatment of brine varies, depending on the impurities present. Some brines are acidified, aerated, treated with chlorine, and clarified to remove traces of hydrogen sulfide and iron before being delivered to the soda plant or the evaporator.

Evaporated salt is salt produced from brines, either natural or artificial. In table 1 evaporated salt includes all salt produced by solar evaporation as well as evaporation by the use of fuel. The category "in brine" refers to the salt content of brines produced and used as such.

The two main types of evaporators used by the salt industry are vacuum pans and graniers. The first produces the fine granulated cubic crytals of salt familiar to all of us; the second produces larger hopper-shaped crystals required in the processing of foods, particularly cheese and butter, and for other uses requiring a high rate of solubility.

Most evaporated salt is a product of the vacuum pan, a large cylindrical vessel, which

may be 18 feet in diameter and 60 feet high, with a conical top and bottom. In older models, steam-heated calandria encircles the vessels just below the midsection, and a large impeller helps to circulate the brine upward through the tubes of the heater and down through the center downtake. Crystallized salt collects in the conical bottom and is removed as a slurry. The pans are operated under partial vacuum to take advantage of reduced boiling temperature of the brine under lower pressure. In newer models, the brine is heated by circulating through a heat exchanger outside the main body of the evaporator.

Economy is substantially increased by operating several of the pans in series, using the vapor produced in one pan to heat the brine in the next; each succeeding pan operates on a slightly higher vacuum. This is known as multiple-effect evaporation, and three or four effects are common in the salt industry.

Over the years many improvements both in the design and operation of vacuum pans have been evolved. Calcium sulfate scale, which formerly crusted the heat-exchange tubes of the calandria and had to be drilled out each week, is no longer a problem. Scaling is now largely controlled by maintaining a certain concentration of fine calcium sulfate crystals in the evaporator brines. The dissolved calcium sulfate, which tends to precipitate in the pans as the temperature increases, is thus provided with small, circulating nuclei on which to grow, and the heating tubes are not encrusted. The slurry of salt crystals and brine emerging from the evaporator is washed with a saturated salt solution to remove fine particles of both calcium sulfate and salt. These are recycled to the evaporator.

A second problem encountered in vacuum evaporators is that of "salting" or encrusting the heating surfaces with cakes of salt. The remedy for this situation is believed to be in higher velocities and heavier slurries of salt in the pans.

Because of the corrosive nature of salt, the older pans of cast iron with copper heating tubes are gradually being replaced with pans of more resistant alloys such as monel. This not only permits longer useful life for the equipment, but also causes less contamination of the salt. These large, expensive machines are a factor in the high investment costs of the salt industry (*44*).

Because of the demand by the food-processing industries for salt having the characteristic hopper-shaped crystal produced in grainers, these rather inefficient evaporators are still in use. Grainers are shallow troughs up to 120 feet in length in which brine is heated by steam pipes. Evaporation takes place at the surface where the crystals first form and float, growing circumferentially and finally sinking to the bottom, where they are collected by mechanical rakes.

As grainers are essentially single-effect evaporators their steam economy is low. Several improvements have been proposed, based on the principle of flash evaporation. The Alberger process is one that has been used for a number of years. The product, a flake salt, can be substituted for grainer salt in many applications, except where large crystals are needed, such as in curing hides and salting fish.

A new process for producing highly pure evaporated salt assaying 99.99 percent NaCl employing a double-effect evaporator was developed and placed in operation (*9*). This method uses the recrystallizing process and utilizes the excessively fine low-grade rock salt, which may exceed 15 percent of the total output of a mine (*35*). Compacting machines for agglomerating rock salt fines were developed. The preheated fine salt was fed between spring-loaded rotating rolls and emerged as a continuous ribbon of salt, which was broken into granules and screened to produce the desired size (*20*).

A new method of solids separation having particular application to upgrading rock salt was patented and its development was described (*6*). This thermoadhesive method is based on the greater transparency of sodium chloride crystals to infrared radiation, compared with such typical impurities as anhydrite, dolomite, and shale. Under infrared radiation the impurities are selectively heated more than the salt crystals. The irradiated impure salt is then spread evenly on a high-speed conveyor belt with a heat-sensitive surface. When the belt rounds the head pulley the cooler rock salt particles are thrown further forward than the impurities, which stick to the belt, and a concentration is achieved.

Sodium Carbonate

Sodium carbonate is a very soluble salt found naturally in certain spring and lake brines and in deposits formed by evaporation of similar brines. Trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$) is the most common sodium carbonate mineral found in nature. It crystallizes from solution when carbon dioxide gas is bubbled through solutions of sodium carbonate having a concentration greater than 9 percent. Carbonation of less concentrated solutions precipitates sodium bicarbonate.

Among the less common minerals containing sodium carbonate are the following: natron,

$Na_2CO_3 \cdot 10H_2O$; thermonatrite, $Na_2CO_3 \cdot H_2O$; nahcolite, $NaHCO_3$; burkeite, $2Na_2SO_4 \cdot Na_2CO_3$; hanksite, $9Na_2SO_4 \cdot 2Na_2CO_2 \cdot KCl$; northupite, $MgCO_3 \cdot Na_2CO_3 \cdot NaCl$; personite, $Na_2CO_3 \cdot CaCO_3 \cdot 2H_2O$; gaylussite, $Na_2CO_3 \cdot CaCO_3 \cdot 5H_2O$; and shortite, $Na_2CO_3 \cdot CaCO_3$ (*22*, *38*, *40*).

The largest known deposit of relatively pure sodium carbonate mineral in the United States was discovered in Wyoming in 1938. While drilling for oil near Green River, a bed of trona was penetrated at a depth of about 1,500 feet. Further test drilling revealed a horizontal trona deposit in the Green River formation resulting from the evaporation of an ancient lake. The deposit is relatively free of chlorides and sulfates and contains 5 to 10 percent insoluble matter (*14*, *28*).

In 1947 the Intermountain Chemical Co., an affiliate of Food Machinery & Chemical Corp., sank a 12-foot-diameter, concrete-lined shaft to the Wyoming deposit and began mining trona. Since then a modern mine and treatment plant have been constructed. A 10-foot seam of trona is mined at a depth of 1,500 feet by the conventional room-and-pillar system with total pillar recovery. Rooms are 8 feet high, 20 feet wide, and 250 feet long on 65-foot centers. Continuous miners (machines) have been used, but the hardness of the trona reduced the speed of advance to one-fourth the rate in coal (*8*, *15*).

From the face, the broken trona is loaded on cable-reel shuttle cars by conventional coal-loading machines, which have been reinforced to cope with the heavier and more abrasive trona. Two shuttle cars normally operate between the working face and the main haulage conveyor belt. All mobile equipment is mounted on rubber tires. Balanced skips in a two-compartment shaft hoist 3,000 tons of trona per day to the surface processing plant.

Laminated shales of little inherent strength lie above the trona bed, posing a problem of roof support. After studying various methods, roof bolts were adopted as the standard roof support.

Directly beneath the trona lies an oil shale that is subject to heaving. Floor heaving continues to be a problem in this mine.

In theory, a ton of pure trona is convertible to 0.704 ton of sodium carbonate by calcination driving off water vapor and carbon dioxide. However, in practice, trona is usually dissolved and recrystallized, eliminating many insoluble impurities and permitting recovery of sodium carbonate crystals of the desired form. The surface refining plant of the Intermountain Chemical Co. requires about 2 tons of crude ore for 1 ton of finished sodium carbonate.

Mining operations at the Big Island trona mine of Stauffer Chemical Co. near Green River, Wyo., were begun in 1962 (*5*). Two circular, cement-lined shafts were completed to the lower of two minable trona beds. The service shaft was 830 feet deep and the ore shaft 930 feet below the surface.

The designed daily capacity of the mine, using conventional room-and-pillar mining, was 1,200 tons of ore, averaging 90 percent trona. Thirty-five percent of the ore was left behind in supporting pillars.

All equipment was operated electrically except for one diesel-powered shuttle car. The mining cycle was begun by cutting a narrow slot 10 feet deep at the top of the working face. After drilling the face and blasting with ammonium dynamite, the broken ore was loaded mechanically into rubber-tired shuttle cars and carried to the main-haulage conveyor belt. At the end of the conveyor, before being hauled to the surface, the ore passed through a 24- by 60-inch single-roll crusher which reduced the size of the lumps to minus 5 inches.

The back was supported by roof bolts 54 and 60 inches long placed on 4-foot centers. Mine openings were 9 to 10 feet high and 16 feet wide. Three to four feet of trona were left in the back for support, as the marlstone and shales surrounding the trona are unstable.

Proper ventilation and other precautions necessary in a gassy mine were required because of the presence of methane in the surrounding shales.

Discovery of superheated brines rich in minerals created considerable interest among chemical and power producers in the Salton Sea area of southern California. Five wells were drilled in an effort to develop geothermal power known to be a possibility in the area. Unexpectedly high concentrations of minerals found in the brines were believed to improve the economic feasibility of a combined chemical and power producing project. The brine from one well flowing at 280,000 pounds per hour at 199°C had the following concentrations in parts per million: Sodium, 70,000; calcium, 34,470; potassium, 24,000; iron, 4,200; borax as B_4O_7, 537; lithium, 150, and chlorine, 201,757. Although the economic potential of the brines was supposed to be high, their utilization depended upon developing an economically feasible scheme for extracting and processing the minerals into commercial products.

In California, sodium carbonate is produced from the complex brines of Owens Lake and Searles Lake by processes involving carbonation, evaporation, and cooling. In the plant completed in 1958 by Columbia Southern Corp. and operated by Pittsburgh Plate Glass Co.,

Chemical Division, since 1960, saturated brines of Owens Lake are pumped into tall carbonating towers, where trona crystals form under carefully controlled conditions. The crystals are separated from the mother liquor, washed, dried, and sold as technical-grade sesquicarbonate. Various grades of sodium carbonate also are prepared by further refining and calcining the crude sesquicarbonate.

Two processes are used to recover sodium carbonate from Searles Lake brines. One employs carbonation of the brines precipitating sodium bicarbonate, which is dried and calcined. The other employs evaporation to precipitate the double salt burkeite ($Na_2CO_3 \cdot 2Na_2SO_4$) which is redissolved and reevaporated in the presence of NaCl. When this solution cools, glaubers salt crystals are formed and separated from the mother liquor. Further cooling produces crystals of sal soda ($Na_2CO_3 \cdot 10H_2O$). On heating, they melt in their own water of crystallization and are evaporated to produce the monohydrate, which on calcination produces the desirable dense soda ash of commerce.

Most of the U.S. soda ash consumption is produced by the Solvay or ammonia-soda process. The raw materials are salt and limestone; ammonia, required as an intermediate in the process, is nearly all recovered and recycled.

Plants are situated near abundant supplies of salt, as about 1.7 tons is required on a practical basis for each ton of sodium carbonate produced. In most instances, salt in the form of brine is produced by pumping water into wells drilled into salt formations and removing the saturated brine.

The brine is passed first to ammoniating towers where it is saturated with ammonia gas, then to carbonating towers where ammonium bicarbonate is formed. A reaction between the ammonium bicarbonate and salt produces sodium bicarbonate, which precipitates and is filtered off. Drying and calcination convert the bicarbonate to sodium carbonate, liberating carbon dioxide, which is reused. The ammonium chloride remaining in the solution after the sodium bicarbonate is removed is treated with lime and heated, driving off ammonia, which is returned to the system. Calcium chloride, largely a waste product, is formed. The reactions may be expressed by the following equations:

$$NH_3 + H_2O \rightarrow NH_4OH.$$
$$NH_4OH + CO_2 \rightarrow NH_4HCO_3.$$
$$NH_4HCO_3 + NaCl \rightarrow NaHCO_3 + NH_4Cl.$$
$$2NH_4Cl + Ca(OH)_2 \rightarrow 2NH_3 + 2H_2O + CaCl_2.$$
$$2NaHCO_3 \rightarrow Na_2CO_3 + H_2O + CO_2.$$

Sodium Sulfate

Sodium sulfate minerals occur in natural brines and in solid masses in playa lakes and among sedimentary rocks. Because the minerals are quite water soluble, solid deposits and concentrated brines are usually found in areas with little drainage and a dry climate.

The principal sodium sulfate minerals are thenardite (Na_2SO_4), mirabilite or glauber salt ($Na_2SO_4 \cdot 10H_2O$), and glauberite ($Na_2SO_4 \cdot CaSO_4$). Other minerals containing sodium sulfate are glasserite ($3K_2SO_4 \cdot Na_2SO_4$), blodite ($MgSO_4 \cdot 2Na_2SO_4 \cdot 4H_2O$), hanksite ($9Na_2SO_4 \cdot Na_2CO_3 \cdot KCl$), and burkeite ($2Na_2SO_4 \cdot Na_2CO_3$) (*41*).

One theory of the formation of natural sodium sulfate involves a reaction between gypsum and bentonitic shales. Exchange of the calcium ion of the gypsum with the sodium ion of the bentonite produces sodium sulfate, which dissolves in ground water. Eventual evaporation of the water leaves sodium sulfate deposits.

The effect of temperature on the solubility of sodium sulfate in water plays an important part in its production and purification. The solubility of mirabilite increases as temperature increases up to a temperature of 32° C (90° F). Above this temperature thenardite becomes the stable solid phase, and the solubility of this salt is inversely related to the temperature.

Because of the inverse solubility-temperature relationship of sodium sulfate above 32° C, dehydration of the crystals by heat is attended by buildup of scale on the heat-transfer surfaces, making the process inefficient. Some success is claimed for submerged combustion in this difficult operation.

On the other hand, advantage may be taken of the direct solubility-temperature relationship of mirabilite below 90° F to cause crystallization of the salt from brines merely by chilling. Sometimes the brines are sprayed into the air or pumped into shallow surface ponds during the winter months when temperatures are low enough to cause crystallization of mirabilite. These crystals are gathered and dehydrated in preparation for marketing. This method, known as brine pumping, is used in mining and processing natural deposits in Saskatchewan (*24*).

Sodium sulfate is derived from natural brines and also from byproduct liquors produced in several chemical processes. For many years the chief source of byproduct salt cake was the Mannheim furnaces for producing hydrochloric acid (HCl) from salt and sulfuric acid according to the equation $2NaCl + H_2SO_4 \rightarrow Na_2SO_4 + 2HCl$. Although still an important source,

newer methods of producing HCl, such as from organic chlorination processes, have reduced the market for Mannheim acid and have threatened to render the Mannheim furnaces obsolete.

Another important source of salt cake is the rayon industry. Less important sources of salt cake are the bichromate, phenol, boric acid, lithium carbonate cellophane, and formic acid industries.

Sodium Metal

Metallic sodium is a silvery white, reactive metal found in nature only in combined form. The process of electrolyzing fused sodium chloride to produce sodium and chlorine is so efficient that sodium is among the cheapest of the nonferrous metals.

Sodium reacts violently with water, producing sodium hydroxide and hydrogen, which may be ignited by the heat of the reaction. Moist air causes rapid oxidation of the metal, which must be stored in sealed containers or under a liquid such as kerosene with which it does not react.

Sodium has a specific gravity of 0.97, is malleable and soft enough to be cut with a knife, and has a high heat-transfer coefficient. Sodium has a relatively low melting point (98° C), a high boiling point (883° C), good thermal stability, low neutron-absorption cross section, and does not corrode stainless steel. These qualities have led to its use as a coolant and heat-transfer substance, particularly for nuclear reactors.

Virtually all sodium produced in the United States comes from Downs cells, an arrangement wherein sodium chloride is fused and electrolyzed, yielding chlorine at the anode and sodium at the cathode. Enough calcium chloride is added to the bath to lower the melting point of the bath from 800°C to the range 575° to 585°C (*32*).

Sodium is a powerful reducing agent, and its usefulness has been increased in recent years by the use of sodium dispersions, which are finely divided sodium particles suspended in a nonreactive fluid. Better control and efficiency in sodium reactions results from the use of sodium in this form.

Tetraethyl and tetramethyl lead additives to automotive fuels are produced commercially by reacting a lead-sodium alloy with ethyl chloride.

USES

Salt

In the United States the greatest consumer of salt is the chemical industry, which used 65 percent of the salt produced in 1963. Chlorine-caustic production alone, by electrolysis of brine, absorbed about 39 percent, and soda ash, historically the greatest single consumer of salt, took 21 percent. All other chemical uses consumed 5 percent. Much of the salt used by the chemical industry is consumed as brine.

Salt used on roads to melt ice and snow and to stabilize dirt roads consumes an important tonnage, as shown by the quantities used by State and local governments. This use of salt is one that has shown remarkable growth in recent years. This use accounted for 13 percent of the total salt output in 1963, compared with 8 percent in 1958. However, criticism has been expressed because of the corrosive effect it has on vehicles.

Large quantities of salt are consumed in the growing and processing of food. Meatpackers and tanners are foremost users in this field, as well as feed dealers and mixers. The canning, baking, fishing, dairy, and other food-processing industries also consume large quantities of salt.

An important and growing use of salt is in the regeneration of water softeners using the ion-exchange principle. Salt is also used in textile dyeing, soapmaking, pulp and paper manufacturing, metallurgy, ceramics, rubber, icemaking, and oil refining.

It may be assumed that salt sold to grocers is principally used as table salt. Although this use is the most commonly known one, it takes only about 3 pounds per 100 pounds used. Personal requirements for salt, exclusive of that used in processing food, vary but average between 10 and 17 grams or 0.3 and 0.5 of an ounce a day per person.

Salt has been suggested as a carrier of various food supplements to combat dietary deficiencies. In addition to the iodine supplement, which has gained wide acceptance, the inclusion of many of the vitamins and minerals including fluorides has been suggested. Official sanction by the Food and Drug Administration has been withheld in view of the supplements added to bread and other food products.

Less refined salt products containing calcium, and many other minerals have been used by certain populations for generations and no doubt have contributed to the dietary need for these minerals.

Sodium Carbonate

Sodium carbonate is used in the production of many organic and inorganic chemicals such as sodium tripolyphosphate (a detergent ingredient), sodium silicates, sodium bicarbonate, and lime soda caustic. This use in producing

chemicals accounted for 26 percent of the total U.S. sodium carbonate output in 1963.

Forty-four percent of the total output in 1963 was used in the glass industry to react with the glass sand, lime, and other ingredients of the melt, which on cooling and solidifying becomes the familiar glass of commerce. Bauxite is digested with sodium carbonate solution producing soluble sodium aluminated, which is hydrolyzed to produce alumina. However, many alumina plants use caustic soda, at others either caustic soda or soda ash can be used. Sodium carbonate is used in the metallurgy of other nonferrous ores, including some uranium ores. Sodium carbonate is also used in manufacturing paper. Smaller quantities of sodium carbonate are used in cleaners, water softeners, soap, and miscellaneous applications.

Two formerly important uses of sodium carbonate in which consumption has been decreasing are in the manufacture of caustic by the lime-soda process and in the production of sodium bicarbonate.

Sodium Sulfate

The kraft paper and paperboard industry requires an estimated 70 percent of the total sodium sulfate output in the United States. Salt cake aids in digesting pulpwood by dissolving the lignin, and releasing the cellulose fibers, which are processed into various paper products. In the cooking process a portion of the sodium sulfate is reduced to sodium sulfide.

Much of the salt cake is recovered and recycled, but in order to replenish losses, 175 to 200 pounds of the salt is required per ton of pulp, depending upon the type of wood being pulped and other factors.

Up to one-half of the total alkali content of glass batches may be introduced as sodium sulfate, although 5 percent for fining and scum prevention is normal. Excessive quantities increase the temperature requirement and may damage furnace refractories.

Other uses of sodium sulfate are as a filler in synthetic detergents, for stockfeed, in medicinals, textiles, dyes, and ceramic glazers, and in producing miscellaneous chemicals.

Sodium Metal

Metallic sodium is used chiefly in producing tetraethyl lead (TEL) and tetramethyl lead (TML), two compounds added in small quantities to motor fuels to increase their antiknock characteristics. Other primary uses of metallic sodium include metal descaling, ore reduction, and manufacture of sodium peroxide, hydride amide, cyanide, borohydride, and other chemicals.

The properties of sodium have become recognized in the field of heat transfer. Sodium is used to cool the valves in some internal combustion engines and for removing the heat from atomic piles.

Liquid sodium has several potential advantages as a nuclear reactor coolant. It has excellent heat-transfer characteristics; it boils at a high temperature, enabling the production of high-temperature steam without coolant pressurization; and it does not react with uranium. Among the disadvantages of liquid sodium are its chemical reactivity, particularly with water and oxygen, and the radioactivity of the sodium isotope created by neutron bombardment. As more reliable equipment for handling high-temperature molten sodium is developed, its use probably will be extended.

An experimental sodium reactor has operated successfully at Santa Susana, Calif., producing 6,000 kw for commercial distribution (*12*). Two much larger, sodium-cooled, graphite-moderated, prototype powerplants reached their designed power levels in 1962 and 1963, respectively. One is a 75,000-kw powerplant at Hallam, Nebr., and the other is a sodium-cooled, fast, neutron type at Lagoona Beach, Mich., rated at 60,900 kw. Each of the two larger reactors utilized about 300 tons of pure sodium to begin operation. Subsequent requirements are for replenishing losses, which are not large.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Byproduct salt is recovered during the concentration of calcium chloride brines resulting from soda ash manufacture. Salt is also produced by the use of sodium to reduce metallic chlorides such as titanium tetrachloride ($TiCl_4$) and as a byproduct in the manufacture of various organic and inorganic chemicals. These production methods are comparatively recent and result from the growth of the chemical industry.

Sea water, certain natural brines, and salt deposits contain various minor minerals, which, under proper conditions, may be recovered at a profit. Among these are bromine, calcium chloride, and magnesium compounds. Methods suggested for recovery of the mineral from the seas were reviewed and analyzed (*7*, *34*).

The potash deposits of New Mexico contain salt, which is separated from the potash. Some of this salt is sold. On the other hand, in the recovery of minerals from Searles Lake brines the salt content is wasted (*39*).

As most of the sodium sulfate produced in the United States is a byproduct or coproduct of certain commodities, such as rayon and HCl, any fluctuation in the production of these commodities immediately affects sodium sulfate production. In turn, sodium sulfate demand is influenced by the demand for paper and paper products. The producers of natural salt cake supply whatever production is needed to balance production against consumption.

Sodium carbonate and the products of the chlor-alkali industry, chlorine and caustic soda, are interrelated because they are all produced from a common raw material—sodium chloride. Continued increase in the demand for chlorine periodically threatens an oversupply of caustic soda, as the two are coproducts of salt-brine electrolysis. Thus far the market for caustic soda has kept pace with production; however, the sodium carbonate market is a possible outlet for excess caustic soda if barriers of price and traditional usage can be overcome. Some of the newer plants are designed for using either caustic or soda ash (*11*). One direct result of the increased consumption of chlorine is that byproduct caustic soda is replacing that formerly produced by the reaction of sodium carbonate and calcium hydroxide, and a formerly important use of sodium carbonate has become one of minor importance.

ALTERNATE MATERIALS

Salt is so abundant and low in cost that few substances can be profitably substituted for it. In dust, ice and snow control on highways, the physical and chemical characteristics of calcium chloride, aluminum chloride and certain other substances may be equal or superior to those of salt. However, economic factors usually favor salt.

In an underground salt mine, coarse grades of salt have been used as aggregate in concrete. This is only feasible where the structure is protected from moisture. The resulting "salt-crete" made with saturated brine, cement, and graded rock salt develops 75 percent of the strength of ordinary concrete.

Although salt is essential to health, certain illnesses are attributed to excessive retention of sodium in the body fluids. In the treatment of such illnesses low-salt or salt-free diets may be prescribed in which various salts such as potassium chloride (KCl) and flavoring extracts are mixed and substituted for salt.

A mixture of sodium carbonate and sulfur is a practical but more costly substitute for sodium sulfate in the digestion of wood chips for paper pulp.

Caustic soda may be used instead of soda ash in extracting alumina from bauxite.

Magnesium may be substituted for sodium as a reducing agent in certain metallurgical operations such as the reduction of $TiCl_4$ to titanium.

There are several substitutes for liquid sodium in cooling atomic reactors. Water, both light and heavy, and gases, such as helium and carbon dioxide, may be substituted for sodium to remove the heat from certain types of nuclear reactors.

SECONDARY SOURCES AND RECOVERY

Secondary recovery generally is not a significant feature of these industries. However, sodium sulfate is being recovered from waste liquors by the paper and pulp industry. Recovery systems not only collect the salt for recycling but also help to control stream-pollution problems. Average makeup of sodium sulfate per ton of pulp has been reduced from 200–400 pounds to 175–200 pounds and further reductions are possible. Recovery systems usually employ Cottrell precipitators.

RESERVES

Sodium Chloride

Exclusive of naturally occurring brines such as the seas, salt lakes, and salt springs, salt as rock salt reserves in the United States are astronomical; they have been estimated at 60,000 billion tons. At 100 times the present consumption and at a 50-percent recovery, these reserves are sufficient for 100,000 years. Each year as prospecting and exploration by drilling to greater depths continues primarily for petroleum and natural gas, many beds or domes of salt are being discovered. It can therefore be assumed that the United States has adequate salt reserves and resources for the present and future expanding needs.

The rock salt resources of the United States occur in four major areas or deposits and many other smaller outlining deposits (*14*, *21*, *27*).

Presently, the most productive deposits are the Silurian salt beds of the Northeastern States, which are one of the great accumulations of salt in the world. These deposits, in the Salina formation or group which is of late Silurian age, have an estimated average thickness of 150 feet over an area of 100,000 square miles underlying parts of New York, Pennsylvania, West Virginia, Ohio, Michigan, and southwestern Ontario.

The Permian basin deposits underlie parts of Kansas, Colorado, Oklahoma, Texas, and New

Mexico. Salt, which occurs in strata of Permian age, underlies an area about 650 miles from north to south and 150 to 250 miles from east to west, or about 120,000 square miles. The thickness of the salt-bearing beds are variable, but over much of the basin they range from 0 to 600 feet.

Salt deposits commonly called the gulf coast embayment are said to underlie 180,000 square miles of southern Arkansas, Mississippi, Alabama, eastern and southen Texas, and Louisiana and continue southward beneath the Gulf of Mexico. In southern Arkansas and northern Louisiana, bedded salt has been found at great depth in drill holes. It is thought that these Louann salt beds of Jurassic age continue southward at a greater depth than has been reached in drilling and that they are the source of the salt forming the more than 300 known salt domes along the coast of Texas and Louisiana and in the interior of northern Texas, northern Louisiana, and southern Mississippi. These domes are massive, extending several thousand feet both horizontally and vertically, with the top in many cases extending to very near the surface; which allows for easy and low-cost extraction.

Recent drilling for oil and gas in the Williston basin has disclosed 11 salt beds at depths ranging from 4,000 to 12,000 feet below the surface and from 100 to 400 feet in thickness. The Williston basin is a large sedimentary, structural basin underlying most of North Dakota, eastern Montana, northern and central South Dakota, and part of southern Canada. The 11 beds contain an estimated total volume of 1,700 cubic miles of salt in that part of the Williston basin underlying North Dakota.

In addition to these four major deposits, small occurrences of salt are known to underlie parts of many other States, including eastern Utah and southwestern Colorado in the Paradox basin, eastern Arizona and western New Mexico in the Supai basin, central Utah in the Sevier Valley, southeastern Nevada in the Virgin Valley, southwest Wyoming, northwestern Nebraska, and southern Florida.

Sodium Carbonate

Sodium carbonate requirements are supplied by manufactured soda ash from the ammonia-soda ash process and from natural sources of trona mined from the Green River formation in Wyoming and from brines from Searles and Owens Lakes in California. Each year a greater portion of the sodium carbonate production is being produced from natural sources; 9 percent in 1953 compared with 19 percent in 1963.

The area of the trona bed currently being mined in Wyoming is about 60 square miles, the thickness ranges from 7 to 16 feet, and the depth averages 1,500 feet. It is estimated that more than 650 million tons of soda ash can be produced from this area (*14*), which would supply the total U.S. needs for soda ash for more than 100 years at the present consumption rate. In addition, the reserves of brine in California from which sodium carbonate, sodium sulfate, and other minerals are recovered are large.

Sodium Sulfate

The supply of natural sulfate in Western United States is virtually inexhaustible with a reserve of hundreds of millions of tons (*36*). In addition to the presently mined natural sodium sulfate deposits of California, Texas, and Wyoming, deposits occur in Arizona, Nevada, New Mexico, North Dakota, Oregon, Utah, and Washington (*2*, *45*, *46*). Large deposits of sodium sulfate worked in Saskatchewan, Canada, are estimated to contain 200 million tons of glaubers salt (*24*). Large quantities of natural sodium sulfate occur at Lodosa in the Ebro Valley in Spain.

In addition to the byproduct and coproduct source and to the tremendous reserves of natural salts, there are plentiful reserves of the raw materials, salt, limestone, and sulfur from which to manufacture sodium sulfate and carbonate to meet all future demands for these compounds.

CONSERVATION PRACTICES

The primary sources of salt, sodium carbonate, and sodium sulfate are so ample that conservation is seldom considered. Although oil-well brines have a high salt content, they are more generally a disposal problem than a source of salt. Some sodium sulfate is recovered from some pulp and paper plant waste, previously discharged in streams, and is reused in these plants.

Large-scale conversion of saline water to fresh water must be considered as a factor that may influence future salt production. However, salt is generally a low-cost material and the bulk of it must be produced near the point of use to minimize the transportation cost. In addition, in present-day conversion plants only about one-half or less of the water is removed as fresh water from the sea water, whereas about nine-tenths of the water must be evaporated from the brine before salt will crystallize. If the salt is to be recovered from the brine by solar evaporation, the saline water conversion plant must be favorably located so that certain factors are present, as described in the "production

methods" section, for an economically successful solar plant operation.

SOURCES OF STATISTICAL INFORMATION

An annual survey of the salt producers in the United States and Puerto Rico is conducted by the Bureau of Mines. Coverage of the industry is virtually 100 percent; the respondents report tonnage and value of the various types of salt sold or used. They also record information on the markets for which the salt is destined and the State to which shipments are made. The information is tabulated and assembled in tables published in Mineral Industry Surveys and the Minerals Yearbook.

Figures on imports and exports of salt are obtained from the Bureau of the Census and published in the Minerals Yearbook.

All producers of natural sodium sulfate and sodium carbonate are canvassed monthly by the Bureau of Mines, and the production information is included in the Bureau of the Census Current Industrial Reports Series. These producers are also canvassed annually, and the commodity data are published in Minerals Yearbook.

Figures on the annual production of sodium metal are published by the Bureau of the Census.

PRODUCTION, CONSUMPTION, AND TRADE

Salt

U.S. salt production has shown steady growth since 1946 and more than doubled between 1946 and 1963. During this period, world production nearly tripled. Production of salt in the United States for 1959–63 and the average for the preceding 5 years is shown in table 1. U.S. salt production of 30.6 million tons was about 29 percent of the world production of 105 million tons in 1963.

In the United States about two-thirds of all salt is produced as artificial brine by drilling into deposits of salt and injecting water. Most brine is used for chemical purposes, and the wells are owned and operated by the producing companies. Salt from these "captive" wells is usually transformed or incorporated into another product and is seldom sold as salt.

Consumption of salt by various uses or consumer groups for 1959–63 and the average for the preceding 5 years is shown in table 2. Direct and indirect uses of salt in the United States for the specific years of 1953, 1958, and 1963 are shown in table 3 to point out the changes in the uses. Direct use as a freezing point depressant, primarily for deicing and melting snow on roads, has increased substantially as has the indirect use for manufacturing chlorine-caustic; however, the

indirect use for producing soda ash has decreased.

Imports and exports of salt, as shown in tables 4 and 5, are minor factors in the salt economy; imports were 4.4 percent of the apparent consumption and exports were about one-half of the imports in 1963. Nearly three-quarters of the 1963 U.S. salt imports came from the bordering countries of Canada and Mexico, but substantial quantities also came from the Bahamas, Spain, Tunisia, and Egypt. Of the U.S. salt exported in 1963, nearly three-quarters was shipped to Japan and about one-fifth went to Canada.

A new tariff law referred to as the Tariff Classification Act became effective on August 31, 1963. The duty on salt imported into the United States in brine is 10 percent ad valorem, in bulk $0.017 per 100 pounds, and other (packaged) $0.035 per 100 pounds.

Sodium Carbonate and Sulfate

Domestic production figures for sodium carbonate and sodium sulfate, natural and manufactured, are shown in tables 6 and 7.

Although Solvay soda plants continue to produce the bulk of the soda ash consumed in the United States, an increasing proportion, 13 percent in 1958 and 19 percent in 1963, is derived from natural sources.

Soda ash is consumed chiefly by the glass and chemicals industries. In 1962, 44 percent of the output was used in producing glass, 26 percent in chemicals, 9 percent in pulp and paper, 5 percent in soap and detergents, 4 percent each in aluminum and for water treatment, and 8 percent for miscellaneous purposes.

Imports of sodium carbonate usually are negligible. U.S. exports in 1963 were 3 percent of the total sodium carbonate production and were higher than they have been since 1956.

The duty on sodium carbonate, calcined (soda ash) or hydrated and sesquicarbonate is $0.0025 per pound. For crude sodium sulfate (salt cake) the duty is free, anhydrous $0.50 per ton, and crystallized (glaubers salt) $1 per ton.

Natural sources provided 36 percent of the sodium sulfate produced in the United States in 1963. The remainder was recovered as byproducts of chemical processes, which produced rayon, cellophane, hydrochloric acid, sodium bichromate, boric acid, phenols, and miscellaneous chemicals.

The kraft paper industry consumed an estimated 70 percent of the total U.S. sodium sulfate production. It is also used in making glass, ceramic glazers, detergents, stock feeds, dyes, textiles, medicines, and various chemicals.

U.S. imports for consumption of sodium sulfate in 1963, 13 percent of the total U.S. production of manufactured and natural sodium sulfate, were the lowest since 1959. More than 52 percent came from Belgium-Luxembourg, and 42 percent from Canada. The remainder was

[4] Included with salt cake (crude).

from the United Kingdom, West Germany, and the Netherlands. Exports, about 4 percent of the U.S. total output of sodium sulfate, went primarily to Mexico and Canada.

Sodium

Domestic output of metallic sodium, as shown in table 8, is used chiefly in producing tetraethyl and tetramethyl lead, fuels additive to increase their antiknock characteristics. Other important uses include metal descaling, ore reduction, and the manufacture of sodium peroxide, hydride amide, cyanide, borohydride, and other chemicals.

TABLE 8.—*Sodium metal production in the United States*

Year:	*Short tons*
1954–58 (average)	124,176
1959	112,019

1961	109,100
1962	119,084
1963	125,566

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in salt, sodium carbonate, and sodium sulfate, not only because of ample natural reserves but also because of abundant raw materials and capacity for producing manufactured varieties. The United States has an estimated 85 percent of the world production of metallic sodium.

PRICES AND COSTS

Prices of rock and table salt quoted in Oil, Paint and Drug Reporter have remained steady since February 1958: $1.09 per 100 pounds for rock salt in paper bags and in carlots, f.o.b. New York, and $1.34 per 100 pounds for vacuum, common fine, table salt on the same basis. The average value of rock salt (bulk salt and pressed block) at the mine as reported to the Bureau of Mines has decreased from an average of $6.87 per ton in 1958 to $6.19 per ton in 1963. Similarly, the average value of evaporated salt (open pans or grainers, vacuum pans, and solar salt and pressed block) decreased from $16.58 per ton in 1958 to $16.14 in 1963. Salt brine is seldom sold because it is usually produced and used as such by the same company. For such captive wells, the values are usually arbitrarily assigned. The average value of the salt in brines as reported by producers in 1963 was $3.19 per ton, compared to $3.30 in 1958.

Packaged-salt prices have not advanced in proportion to other commodities; a 26-ounce box of salt costing 10 cents in 1925 cost 11 cents in 1963.

Salt is a cheap, bulky commodity, and transportation charges are an important part of the cost. For this reason salt is sold largely in marketing areas near the producing areas.

Other factors besides transportation costs affect the price of salt. Salt is sold on a delivered basis; the grade of the salt, whether or not it is bagged, the size of the shipment, and the distance to market may be reflected in the price.

Salt is consumed in every part of the Nation for many different purposes. To insure profits, the industry depends on high sales volume and low unit costs. Although salt deposits are more than ample and reasonably well scattered in the Nation as a whole, they are not close to all centers of population and industry. In some instances the cost of transportation from the mine or producing area to the consumer is a major part of the delivered price.

Salt production requires a large capital investment in mining, refining, and packaging equipment; for solar salt a large investment in land is added. Nearly 90 percent of the total salt production sells for less than $10 per ton, which means that many tons must be sold to equal the fixed charges on the plant investment.

Because the quality of salt from one producer usually is substantially the same as that from any other, the only way to meet competition is through price. Transportation costs being an

important factor in the price, the producer with favorable freight rates between producing area and market has an advantage. This fact and the need to maintain a large sales volume in order to meet high fixed costs combine to make the salt industry highly competitive.

Prices quoted for sodium carbonate, sodium sulfate, and metallic sodium by Oil, Paint and Drug Reporter in 1963 were unchanged from those quoted at the close of 1958. Dense soda ash (58 percent Na_2O) in carlots and at the works sold for $1.60 per 100 pounds in bulk and $1.90 in paper bags. On the same basis light soda ash was quoted at $1.55 and $1.85, respectively.

Domestic salt cake (100 percent Na_2SO_4) in bulk and at the works sold for $28 per ton. Sodium sulfate of technical detergent and rayon grade sold for $34 per ton in bulk at works and for $38 per ton in bags and in carlots. Technical anhydrous sodium sulfate was priced at $56 per ton in bags and carlots.

Sodium metal in bulk, in tank cars, at works, was quoted at $0.17 per pound. Fused metallic sodium in lots of 18,000 pounds or more at the works was $0.195 per pound and in 5- or 12-pound bricks on the same basis was quoted at $0.21 per pound.

TAXES

For tax purposes a depletion allowance of 10 percent is allowed by the Internal Revenue Code for both foreign and domestic deposits of salt. Sodium sulfate and sodium carbonate are permitted a depletion allowance of 15 percent for both domestic and foreign deposits.

TRANSPORTATION

Salt is transported mainly by rail, and whether or not a producer can sell profitably in a given area depends in large measure on the freight rates. Some salt is moved by barge and some by ship. Over short distances salt brine is sometimes moved by pipeline. A new service to the chemical industries of the Beaumont-Port Arthur area was started in 1959 by a Texas concern, which began to supply brine by pipeline to customers.

Transportation of sodium sulfate and sodium carbonate is largely by rail. In some areas, particularly in the South, sodium carbonate is moved by barge. There are also shipments by sea. Bulk sodium metal is transported by tank cars specially equipped with heating pipes to melt the metal so that it can be pumped in and out of the cars.

Natural soda ash sources are found only in the western half of the United States and ammonia soda producers have always held a geographical advantage in being nearer to eastern markets where 80 percent of the soda ash is consumed. This advantage has been offset in part by reduced freight rates for soda ash and development of a high-capacity, 95-ton freight car, enabling western producers of natural soda ash to compete in many areas previously unavailable to them. The grade of the finished product, whether made from salt or natural soda compounds, is virtually the same (*25*). A substantial reduction in transcontinental freight rates was put into effect in October 1962, making western salt cake more competitive with that of eastern in the southeastern paper pulp area. Other freight rates were adjusted to enable eastern producers to maintain their share of markets (*26*).

RESEARCH

Research on production methods, uses, and products is carried on to a great extent by individual companies. Some of the major producers of salt and sodium compounds maintain large research laboratories in the search for new materials, methods, uses, and products and the improvement of product quality. Many improvements in mining and milling methods have been developed by the salt industry in the last 5 years. Examples of some of the technologic developments in mining include improvements in salt solution mining methods (hydraulic-fracturing techniques applied to salt mining), in bench mining methods in salt domes, and in blasting methods (application of ammonium-nitrate explosive). Milling developments include double-effect evaporation (recrystallizing) to purify salt, compaction of fines (as ribbons that are crushed and sized) using rollers to utilize surplus fines, and thermoadhesive methods of separating salt from waste.

Improved and more efficient chlorine caustic cells have resulted from research programs of industry.

Sodium metal and chlorine gas, primary products of the electrolysis of salt, have found wide application in many fields as a result of research programs. Particularly in the field of metallurgy, both sodium and chlorine have become increasingly important in the preparation of metals not amenable to conventional reduction procedures.

Producers of both soda ash and salt cake constantly seek new and improved methods for crystallizing the salts in their various forms from solution. For example, a process developed by a major producer depends upon refrigeration rather than evaporation for crystallizing sodium sulfate (*10*).

The Bureau of Mines has examined deposits of natural sodium sulfate in North Dakota, Utah, and Wyoming (*5*, *26*). A report was published (*42*) on a method of analyzing demand for mineral commodities, using a case study of salt. Data on methods and costs of shaft sinking and drifting in salt were reported (*16*).

A satisfactory solution mining technique for trona deposits has been the goal of a research program conducted by a large producer of soda ash. This company also maintains a mining-research team to study problems associated with mining trona. Use of a continuous miner is being studied.

Much research effort has been expended on sodium metal, both in perfecting its production and in finding new applications and handling procedures. Present production research includes reduction of sodium carbonate with carbon at a high temperature and condensing the resulting sodium vapor. Improvements in electrolytic techniques have also come about through research.

OUTLOOK

SODIUM CHLORIDE

The United States should continue to be the largest producer and consumer of salt; per capita salt consumption in the United States increased from 261 pounds in 1953 to 330 pounds in 1963. This ever-increasing per capita consumption coupled with a growing population and ample reserves are indications for an outlook of continued rise in the production and use of salt. Increased consumption will result as it has in the past, from new and expanded uses for salt and from a public demand for more and finer products requiring salt for processing or manufacturing them.

Salt will continue as a mainstay of the chemical industry because salt is one of the basic raw materials used for producing chemicals. Two-thirds of all salt sold or used in the United States in 1963, 20 million tons of the 31 million total, was consumed to produce chlorine, caustic soda, soda ash, salt cake, hydrochloric acid, and other chemicals. The remaining one-third of the total had hundreds of direct uses required by individuals as a nutrient or flavor, food preservative, freezing point depressant, and for processing in miscellaneous industries such as metals, ceramics, rubber, oil, paper and pulp, and water treatment.

Salt, through its importance to the chemical industry and through its widespread direct and indirect uses, will continue to reach into every segment of the industrial economy. This is evidenced by the fact that salt consumption has always correlated closely with the gross national product (GNP). Based on this and an anticipated annual growth rate of 3.8 percent (compounded) in the GNP, salt consumption in the United States is expected to increase from 31 million tons in 1963 to 60 million tons by 1980 and to 125 million tons by the year 2000. The average annual rate of growth of salt consumption during the last decade, 1953–63, has been 4.0 percent, exceeding that of GNP. If this trend continues, salt consumption by 2000 may quintuple that of 1963.

Changes in the consumption patterns for salt reflect the changing technology and demands by individuals and industries. Before 1955 Solvay soda production was the chief consumer of salt; in this process the chlorine content is largely wasted. However, the demand for chlorine by the chemical industry has been increasing steadily and has caused the chlorine-caustic industry to expand so that since 1955 the chlorine-caustic industry surpassed the soda-ash industry as a consumer of salt. In 1953, 29 percent of the salt sold or used by producers in the United States was consumed in the production of chlorine-caustic soda, compared with 35 percent in 1958, and 39 percent in 1963. This trend of an increasing amount of the salt output being used each year for chlorine production accompanied by a decreasing amount consumed in manufacturing soda ash is expected to continue.

Other growing uses for salt that are expected to continue to increase are those for road stabilization and highway snow and ice removal. These uses constituted an estimated 5 percent of the total salt production in 1953, compared with 8 percent in 1958 and 13 percent in 1963. Although it now represents less than 2 percent of the total salt output, more salt is being used each year in the regeneration of water softeners using the ion-exchange principle.

SODIUM CARBONATE

The total U.S. production of sodium carbonate, including both manufactured and natural soda ash production, should continue its growth at about the same rate it has in past years. The past growth compares closely with the anticipated growth rate of GNP (3.8 percent) for the next 10 to 20 years. On this basis, total soda ash production should reach 11 million short tons by 1980 and 23 million short tons by the year 2000.

780–887 O—65——54

The recent growth in the soda ash industry has been largely from natural soda ash rather than ammonia soda production. The high capitalization required for new ammonia soda plants compared with natural soda ash production installations is the reason for the stalemate in new ammonia soda plant construction and increased interest in natural soda ash output. As a result, natural soda producers have increased plant capacities and other chemical companies have opened or announced plans for opening new mining and processing plants or are conducting exploration and development programs on vast underground trona deposits in Wyoming. Natural sodium carbonate output supplied 19 percent of the total manufactured and natural soda ash production in 1963, compared with 8 percent in 1953. This trend of a larger share of the market for sodium carbonate being supplied by natural soda ash is expected to continue.

Although not foreseen in the immediate future, growth in chlorine consumption under present technology eventually may cause an overproduction of the coproduct, caustic soda, which is a substitute for soda ash, and thus depress the demand for soda ash. However, new uses and substituting it for other chemicals has absorbed the extra production of caustic soda.

Another factor that may effect the future output of soda ash is the increased use of liquid detergents resulting in greater use of potassium compounds at the expense of sodium compounds. Reduction in the freight rates for shipping soda ash from western producing areas to eastern users has made western natural soda ash production competitive with eastern manufactured soda ash. The shift from the use of glass to plastic containers for some commodities has reduced the demand for soda ash for the production of glass, the major consuming industry. The alumina industry, which formerly relied heavily on soda ash to digest alumina ores, has largely converted to the use of caustic soda. However, in many plants either caustic soda or soda ash may be used.

SODIUM SULFATE

Production of sodium sulfate is expected to show continued growth, subject to severe fluctuations, because two-thirds of the total production of manufactured and natural output is recovered as a byproduct of chemical processes, which produced rayon, cellophane, hydrochloric acid, sodium bichromate, boric acid, phenols, and miscellaneous chemicals. The trend of a greater share of the total being supplied by natural sodium sulfate production is expected to continue; in 1953 natural represented 24 percent of the total compared with 36 percent in 1963.

The trend toward recovery of hydrochloric acid as a byproduct of certain chlorination reactions should diminish the importance of the Mannheim furnace for producing both sodium sulfate and hydrochloric acid. Widespread use of other fibers such as nylon in place of rayon reduced the production of byproduct salt cake from rayon manufacturers. Trends toward lower consumption of sulfate per ton of pulp and recovery and reuse of sulfate in the digestion of pulp, primarily affected to reduce stream pollution, slackened the demand for sodium sulfate for this use. Cellophane manufacturers could produce a substantial quantity of byproduct salt cake, but only one had installed recovery equipment.

Despite these fluctuations in supply of byproduct salt cake, several Texas and California natural sodium sulfate producers have expanded their plant capacities in late years. Natural sodium sulfate producers, which have ample reserves and production capacities, are expected to fill any demand gaps that may appear in industries normally supplied by byproduct salt cake.

SODIUM METAL

The supply and demand outlook for sodium metal is for continued minor fluctuations of production. The chief use of metallic sodium, in producing tetraethyl lead (TEL) and tetramethyl lead (TML)—two compounds added to motor fuels to increase their antiknock rating—will be affected by the production and use of economy cars that do not require high-test fuels. An increasing use of jet aircraft, which use no antiknock fuel additives, may adversely affect the demand for antiknock fuel. The introduction of gas turbines or other propulsion devices in place of internal combustion engines may also curtail the demand for sodium to produce tetraethyl lead. However, increased and expanded use of sodium metal for other and new uses is expected to take up any slack in demand.

Although the present consumption of sodium metal in nuclear reactors is negligible, large-scale developments of power by sodium-cooled reactors would require sizable quantities of very pure sodium at the beginning and modest quantities for makeup.

PROBLEMS

The problems of the salt industry are chiefly those of maintaining production and transportation costs low enough to continue to produce salt as a high-volume low-unit-cost commodity. To do this, improvements in mining, producing, processing, handling, and marketing methods and techniques are constantly needed to reduce labor costs or to compensate for increased labor and material costs.

One of the major problems of the salt industry is the high capital investment necessary for a plant to produce salt on an economical basis. The corrosive nature of salt and salt solutions causes rapid deterioration of the plant and equipment and contamination of the product. This is reduced by wider use of more expensive metals such as stainless steel and Monel. A second reason for the required excessive plant investment is the large-volume output or high minimum capacity necessary for an operation to produce salt at a low-unit cost.

Arresting the external corrosion of well casing in brine wells is a continuing problem. When used on highways for dust and ice control, salt causes deterioration of vehicles and road surfaces.

The salt industry also is faced with the problem of continually improving methods of upgrading the quality of rock and evaporated salt by removing or discarding the impurities at a low cost to meet industry or consumer demands. This is being done and must continue to be done through advances in the beneficiation methods such as the recently developed and employed recrystallizing, electronic scanning, thermoadhesive, and other methods of purifying salt. Caking of salt during storage causes a problem in handling the material with mechanized equipment.

The salt industry must consider the problem of how it will participate and be affected in certain areas, particularly those with a deficient supply of fresh water, if desalting of sea water becomes a major commercial reality and if it is feasible to utilize the effluent or brines from the saline water conversion plants for producing salt and other chemicals.

Many of the problems of producing and marketing sodium carbonate are similar to those for sodium chloride. High capital investment required for constructing new ammonia-soda plants has been a restrictive factor in developing new or for increasing plant capacity for manufacturing sodium carbonate. This has resulted in the increased development and use of the natural soda ash deposits of the Western United States. As with salt, transportation costs for soda ash are an important part of the delivered price of the commodity. Therefore, the problem of transporting the natural soda ash produced in the West to the consumers and major markets at a low cost must be considered.

Other problems of mining and processing sodium carbonate from natural sources are: (1) floor heaving, which interferes with efficient underground mining in one operation; (2) lack of an efficient solution mining method for underground trona deposits; and (3) lack of simple methods for controlling the crystallization of desired types of sodium compounds from solution. Lack of markets for byproduct calcium chloride produced at ammonia-soda plants contributes to the production costs of manufactured sodium carbonate.

The major problem in the sodium sulfate industry is that most of the market is supplied by byproduct material recovered from the production of other commodities and this supply fluctuates with the demand and production of other chemicals. The natural sodium sulfate producers are located in the Western United States and their production costs must be reduced if natural sodium sulfate is to compete with byproduct manufactured sodium sulfate because sodium sulfate must remain a low-unit-cost item and transportation costs from the West are relatively high. The industry also has technical problems relating to purifying, evaporating, and dehydrating byproduct sodium sulfate crystals from solution.

Problems of metallic sodium are largely technical and relate to the extreme reactivity of the metal, particularly in its liquid and vapor forms. The reactivity presents difficulties in handling, controlling reactions, and maintaining metallic sodium in the required state of purity.

Rapid technological changes in consuming industries pose problems for sodium compounds and sodium producers; markets are threatened and curtailed before new ones are created.

STEEL

By Robert A. Whitman [1]

STEEL is primarily a refined alloy of iron and carbon, with carbon varying from 0.01 to 1.7 percent. When alloying elements are specified or intentionally added, in excess of certain limits established by the industry, to impart desired mechanical or chemical properties not otherwise obtainable with iron and carbon and nominal alloys, the product is classed as alloy steel.

The domestic steel industry, including rolling mills, is comprised of 218 companies with 422 plants, employing over one-half million people with an annual payroll of about $5 billion. Approximately 75 percent of this industry is located in the six States of Illinois, Indiana, Ohio, Michigan, Pennsylvania, and New York.

Annual capacity figures have not been reported by the steel industry since 1960. At that time capacity was reported at 148.6 million ingot tons. If capacity continues to expand at the rate of about 2 million tons annually, the capacity in 1965 should be about 160 million ingot tons.

The United States pours over one-fourth of the steel made in the world. Production in 1963 was nearly 109 million tons of steel ingots and steel for castings.

Eight and one-half million tons of ingot steel, 8 percent of the total output, came from basic oxygen converters in 1963. Open-hearth furnaces accounted for 81 percent, electric furnaces 10 percent, and Bessemer furnaces for about nine-tenths of a percent. Oxygen steelmaking was introduced into the United States in 1954. Five years later, in 1959, it accounted for 1.9 million tons or 2 percent. This increase in oxygen steelmaking in the last decade is indicative of the way that the steel industry has modernized during that period. For the last 15 years the steel industry has averaged $1 billion per year in capital expenditures. For the first 10 years most of this outlay was for increased production, but for the last 5 or 6 years the emphasis has shifted to increased productivity and newer products. Continuous casting machines and computers to calculate charges for blast furnaces, open-hearth and basic oxygen furnaces, and to control settings and speeds of rolling mills have been introduced.

The outlook for steel in the United States is for a continued gradual increase in consumption at a rate slightly higher than the population growth rate. A steel production figure of about 150 million tons is forecast for 1980.

The steel industry is spending about $100 million annually for research to improve both methods and products. Methods of reducing production costs, conserving raw materials, and improving existing products are being studied and developed by the industry. Fundamental research in the metallurgy, chemistry, physics, and interdisciplinary fields of these sciences as related to steelmaking is being conducted by private foundations and universities. The Bureau of Mines research program includes determination of physical and chemical properties of pelletized iron concentrates, causes of fuming in oxygen steelmaking, improvement of high-strength alloy steel ingots with rare-earth alloy additions, upgrading of submarginal iron ores by reduction-roasting with ferrous scrap, mechanisms of high-strength steel and cobalt hardening of stainless steel.

BACKGROUND

The exact date when steel was first made is not well established. However, archeological specimens estimated to have been made as long ago as 1000 B.C. indicate edges that were hardened by rapid quenching of the heated carburized steel. Another ancient steelmaking process, known as the crucible process, consisted of melting wrought iron in a clay crucible with

[1] Commodity specialist.

carbon to increase the carbon content of the iron. Steels produced by these processes include the Wootz steel of India, steel for the famous blades of Damascus, Syria, and the equally famous steels of Toledo, Spain.

During the Middle Ages both cementation and crucible methods appear to have been lost to civilization. The cementation process was revived in Belgium about 1600, and Benjamin Huntsman of England rediscovered the crucible process in 1742. The major breakthrough for the industry was the invention of the Bessemer process in 1856 in England. Although this process bears the name of Henry Bessemer, with a patent issued in 1856, Henry Kelley had experimented with the process as early as 1847 in the United States. The next great step in the creation of the steel industry was the invention of the open-hearth process by Karl Siemens in 1868.

The earliest instance of application of electricity to metallurgy is a patent granted on March 16, 1853, to the French chemist, Pichon. The first practical application of electric melting of steel was made by Sir William Siemens in England in 1879. Following the Siemens method came the Heroult electric-arc furnace in France in 1888–92. The next major advance in steelmaking occurred in 1952 with the installation of the first commercial plants to make steel by the Austrian Linz-Donawitz process or the oxygen steelmaking process at Linz and Donawitz, Austria.

The first recorded steel production in the United States was 917 tons of "blister" steel made in 1810 from bar iron. In 1832, the Girrard Brothers established a crucible-steel works in Cincinnati, Ohio. The steel industry, however, marks the beginning of commercial production of steel with the first commercial Bessemer production at Wyandotte, Mich., in September 1864. Thus in September 1964, the steel companies ushered in the second century of commercial steelmaking in the United States.

The prevalence of low-phosphorus iron ore in the United States prompted the development of the Bessemer process during the latter half of the 19th century, as opposed to the Thomas process, which is for high-phosphorus iron ore. Open-hearth steel production increased rapidly between 1900 and 1916, owing mainly to greater demand for quality steel and the inability of the Bessemer process to consume scrap. By 1925 open-hearth production made up 84 percent of total steel; by 1958 this figure had grown to 76 million tons, or 89 percent of total steel. Five years later in 1963, production of steel by the basic oxygen converter had risen to 8.5 million tons, and open-hearth production represented only 80 percent of the total steel produced. In 1964 production of steel by the basic oxygen converter had reached 15 million tons and open-hearth production had dropped to about 77 percent of total production.

Since World War II commercial production of steel by the crucible method has virtually stopped and production of steel by the Bessemer method has declined to less than 1 percent of the total. Electric production remains around 10 percent of total ingot production.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF INDUSTRY

The United States produces and consumes over one-fourth of the world's steel supply. In 1963, there were about 275 companies engaged in the manufacture of steel products. Of these there were 95 companies with 163 plants producing steel for ingots and castings. There were 16 companies that produced 1 million tons or more of ingot steel. The industry had an average annual payroll for over 787,000 employees of more than $5 billion. There were 244 blast furnaces which produced 72 million tons of pig iron. Total estimated investment of the steel industry was over $14 billion, and the net revenue from steel products sold approximated $14.5 billion (*5*).[2]

Over 75 percent of U.S. steel output is produced in the northern band of six States from New York to Illinois and including Michigan. There are heavy concentrations in the Pittsburgh-Youngstown area and in the Gary-South Chicago area. Table 1 gives steel production by States.

TABLE 1.—*Production of steel, by States*

[Thousand short tons]

State	1963
Pennsylvania	25,193
Ohio	18,777
Indiana	15,548
Illinois	9,214
Michigan	8,437
New York	5,386
Rhode Island, Connecticut, New Jersey, Delaware, Maryland	7,258
Alabama, Tennessee, Mississippi	3,851
Virginia, West Virginia, Georgia, Florida, North Carolina	3,677
Arizona, Colorado, Utah, Washington, Oregon, Hawaii	3,615
California	3,387
Minnesota, Missouri, Oklahoma, Texas	3,337
Kentucky	1,580
Total	109,261

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The term "pig iron" denotes a class of products made by reducing iron ore in the blast furnace. Included in the pig iron classification is silvery pig iron, an intermediate product between pig iron and ferrosilicon. These higher silicon-content irons can be made in either blast or electric furnaces. Chemical contents specified for grades of pig iron vary according to its intended end use. The following designates the various pig irons in the United States:

Designation		*Phosphorus content, percent*
LP	Low phosphorus	0.035 maximum
LPi	Intermediate low phosphorus	0.036 to 0.075
Bes	Bessemer	0.076 to 0.100
M	Malleable	0.101 to 0.300
B	Basic—Northern	0.400 maximum
Fl	Foundry—Northern, low phosphorus	0.300 to 0.500
Fh	Foundry—Northern high phosphorus	0.501 to 0.700
Fs	Foundry—Southern	0.700 to 0.900
Bs	Basic—Southern	0.700 to 0.900
S	Silvery	0.300 maximum

Silicon varies from 0.50 to 3.50 percent for the true pig irons and from 5 to 17 percent for silvery pig iron. Maximum limit for sulfur for most grades is 0.050 percent. Carbon content which cannot be controlled to close limits ranges from 3.50 to 4.40 percent and is generally not specified (*7*). Detailed chemical analyses according to grade designations are given in the reference cited. Pig iron may also be classified according to the raw materials used, for example, *charcoal pig*, *coke pig*, *hematite pig*, *titanium pig*, or *chromium-nickel pig*. In Europe, *Thomas pig iron*, which contains 1.7 to 2.2 percent phosphorus, is used for making steel in the Thomas (basic-lined) converter.

Iron and steel scrap is refuse ferrous materials, either alloyed or unalloyed, of which iron and steel are the principal components. It is classified as home and purchased scrap. *Home scrap* is produced at the iron and steel plant during the steelmaking and rerolling processes, which include such items as skulls, ingots, butts, crops, clippings, borings, and defective products discarded as well as old plant scrap. *Purchased scrap* includes scrap bought from other steel plants as well as scrap obtained from fabricators, railroads, other industrial plants and iron and steel scrap dealers. Purchased scrap is further classified as industrial and obsolescent. Industrial scrap is still further divided into prompt industrial scrap and other scrap. *Prompt industrial scrap* is the waste or byproduct of processes of fabricating iron and steel products. The *other industrial scrap* comprises products and parts of plants that have completed their service of life and have been discarded because of failure, obsolescence, or other reasons. Nonindustrial *obsolescent scrap*, sometimes referred to as *country scrap*, is the product of the same forces as the other industrial scrap. It comprises all kinds of equipment, usually worn out or outmoded (*8–12*).

Recirculated or home scrap accounted for about 64 percent of the scrap consumed in 1963 (*11*).

Up to 75 grades have been used by the trade in classifying iron and steel scrap. Many of the grades are similar in physical form and chemical composition. Because of this, the Bureau of Mines has condensed the many grades to 14 classifications, which cover all grades of iron and steel scrap (*4*, *12*).

Steel is primarily a refined alloy of iron and carbon containing up to 1.7 percent carbon. When alloy elements are intentionally added to steel to impart desired mechanical or chemical properties not otherwise obtainable with carbon alone, it is classed as an *alloy steel*. However, the ingredient that exerts the most influence on steel is carbon. High-grade razor steel contains about 1.25 percent of carbon; spring steel, 1 percent; steel rails, from 0.50 to 0.75 percent; and soft sheets may have as little as 0.04 percent of carbon. Steel low in carbon can be easily welded, but cannot be hardened appreciably; with carbon above 0.33 percent, welding is more difficult and can be done only by the use of borax or some other flux, or by the electric or thermit processes.

The hardness of steel may be altered by heat treatment to be one of the hardest metals known. For example, a fully hardened carbon steel with 1.20 percent carbon will have a hardness of Rockwell C 70 and an approximate tensile strength of 550,000 pounds per square inch. In tool steel, ingredients other than carbon are often used to influence its hardenability, wear resistance, and secondary hardness. These additives include tungsten, molybdenum, chromium, vanadium, and cobalt. Also, steel can be made into one of the strongest metals known through both the addition of alloying elements and heat treatment. By cold rolling and working at about 1,000° F strengths of over 350,000 pounds per square inch are possible (*1*, *16*, *19*).

Steels that derive their properties mainly from carbon, with no guaranteed or specified minimum alloy content, are classed as *carbon steels*. Some manufacturers class carbon steels according to the carbon content as follows: *High carbon*, over 0.55 percent; *medium carbon*, 0.25–0.55; and *low carbon* or *mild steel*, under 0.25. Others classify them according to the method of manufacture such as *acid open hearth*, *basic open hearth*, *electric*, or *Bessemer*. This classification may be extended further to

include the method of deoxidation used, for example, if oxygen is partly or completely removed by adding deoxidizers such as aluminum and silicon, the resulting steel is classed as *semi-killed* or *fully killed*, respectively. In *rimmed steel* part of the oxygen, nitrogen, and hydrogen is liberated from the steel during the rimming or effervescent action that occurs during solidification. The remainder stays in the steel and forms blowholes. In *mechanically capped steel*, all the gases are trapped in the steel by placing a heavy metal cap over the ingot mold during solidification of the ingot. Small quantities of aluminum are added to the latter two grades to control ingot structure.

Properties of all these steels may be modified by heat treatment to control microstructure and mechanical properties. For example, a coarse-grained carbon steel may be heated above the upper critical range 1,335° F and quenched in water to produce a hard steel with a greater tensile strength. Depth hardening is obtained by adding alloys that retard the rate of transformation of austenite to pearlite and ferrite. Flame hardening, case hardening, and nitriding are methods used when only the surface is to be hardened. Cold rolling also alters microstructure and mechanical properties (*13*, *19*).

The Bureau of Mines uses the American Iron and Steel Institute's specification for alloy steels which includes stainless and any other steel containing one or more of the following elements in the designated percentages: Manganese in excess of 1.65, silicon in excess of 0.60, and copper in excess of 0.60. The specification also includes steel containing the following elements in any amount specified or known to have been added to obtain a desired alloying effect: Aluminum, boron, chromium up to 3.99 percent, cobalt, columbium, molybdenum, nickel, titanium, tungsten, vanadium, zirconium, and other alloying elements (*4*).

Stainless and heat-resisting steels are generic terms. They do not designate any one steel but rather a whole family of steels whose common characteristic is a comparatively high chromium content. Stainless steel is basically an alloy of iron containing over 10 percent chromium. When chromium is added to iron in such quantities it imparts throughout the entire body of the metal remarkable resistance to corrosion and heat. Other elements may be added to the iron-chromium combination to obtain steels with special characteristics. The most important of these is nickel, which is used to produce 18–8-type steels; that is, 18 percent chromium, 8 percent nickel, balance iron. Other useful additions are columbium, manganese, molybdenum, nitrogen, selenium, silicon, sulfur, titanium, and zirconium, all of which result in modifications for special services or fabrications.

The standard stainless steel grades may be grouped according to microstructure, chemical composition, and response to heat treatment as follows:

1. *Ferritic.* Nonhardenable steels containing 11.5 to 27 percent chromium, with generally low-carbon contents (ranging from less than 0.08 to a maximum of 0.20 percent).
2. *Martensitic.* Hardenable (by quenching) steels containing 11.5 to 18 percent chromium, with carbon contents (ranging from less than 0.10 percent to 1.20 percent maximum).
3. *Austenitic.* Steels containing 16 to 26 percent chromium, 3.5 to 22 percent nickel, and 0.03 percent maximum to 0.25 percent maximum carbon, hardenable without quenching.

Nonstandard grades of alloys not included in these classifications that are still recognized as stainless steel, include special specifications of the standard grades and stainless steels with additions such as tungsten, vanadium, aluminum, copper, and phosphorus to convey special properties. These steels are used for certain applications. Two widely used heat-resistant steels not mentioned are AISI types 501 and 502, containing 4 to 6 percent chromium. These steels have good strength at elevated temperatures and are corrosion-resistant rather than stainless (*19*).

TECHNOLOGY

Steelmaking Materials

Steelmaking processes, using pig iron produced by the blast furnace, include the open hearth, Bessemer, and oxygen converters. The electric furnace utilizes nearly 100 percent scrap, however, on rare occasions up to 50 percent molten pig iron has been used. On a national basis the quantity of scrap consumed in all furnaces including iron foundries is approximately the same as pig iron.

Molten pig iron tapped from the blast furnace is usually transferred in ladles via railroad cars to refractory-lined hot metal mixers in the open hearth or oxygen steelmaking department, where it is kept hot until needed in steelmaking furnaces.

Although it is possible to reduce sulfur in the electric furnace, the removal of sulfur in the open hearth is somewhat uncertain, and when the open hearth fuels such as coke oven gas, fuel oil, tar, and the like contain any considerable amount of sulfur, the problem is aggravated.

To produce an acceptably low-sulfur steel, without increasing steel furnace refining time

sulfur must be removed from the iron when it is produced in the blast furnace.

Iron and steel scrap supplies approximately 50 percent of all metallics used in iron and steel furnaces in the United States. The essential characteristics governing the usefulness of scrap are its chemical composition and physical form. The use of rusted or corroded scrap may result in a metal yield as low as 60 percent. Scrap containing undesirable elements may affect refractories or cause other difficulties during melting and refining or cause the steel to be unfit for its intended use. The increase in residual copper, nickel, and tin in carbon steel is a major problem at many steel plants. Tin and copper cause minute surface tears in steel. Nickel and copper increase hardenability which adversely affects deep drawing properties.

In addition, the problem of scrap availability and price also must be considered.

The density of scrap is related directly to steel production. Furnace-scrap-charging boxes that give high scrap weights per cubic foot, using dense material, decrease furnace-charging time and make it possible to pull all the scrap in at one time (that is, it is unnecessary to melt down part of the scrap to make room for the complete charge). Heat losses during prolonged charging increase melting time. At some steel plants steel production rates have been increased by as much as 20 percent by using charging boxes with high-scrap weights per cubic foot (*3*).

There is a direct relationship between the composition of scrap and pig iron and the composition of the steel bath and slag. The elements present, except carbon, may be divided into four groups, according to their oxide stability and chemical reactions among the various elements present under oxidizing conditions in open-hearth furnaces. The removal of carbon depends on the degree of oxidation of the bath (*2*).

The four groups are:

Group 1.—Elements almost completely taken up by the slag: Silicon, aluminum, titanium, zirconium, boron, and vanadium.

Group 2.—Elements distributed between the slag and metal: Manganese, phosphorus, sulfur, and chromium.

Group 3.—Elements remaining almost completely in solution in the steel: Copper, nickel, tin, molybdenum, cobalt, tungsten, and probably arsenic and antimony.

Group 4.—Elements almost completely eliminated from slag and metal: Zinc, cadmium, and lead.

The elements in group 1 have no direct effect upon the composition of the metal, since they oxidize and are held in the slag. High-silicon scrap is undesirable, because the high-silica slag formed during the melting period attacks the furnace walls.

The effect of the elements listed in groups 2 and 3 depends on furnace practice and kind of steel being produced. Manganese is usually desirable, except in low-metalloid grades (0.10 percent maximum all elements except iron). Phosphorus usually is undesirable, but the maximum amount permissible is governed by the type of furnace practice, the grade of steel, and other components of the charge. For example, more phosphorus is usually permissible if the silicon content is low. Sulfur, arsenic, antimony, and tin are undesirable because they increase surface imperfections. Chromium, copper, nickel, molybdenum, cobalt, and tungsten may be desirable or undesirable, depending on the grade of steel being produced and the type of furnace used. For example, copper could be an asset for copper-bearing sheets for roofing but a detriment to type L tin plate having a 0.06 maximum copper specification (used for the certain corrosive foods).

The elements in group 4 have no effect on the slag or metal bath since they are eliminated during the melting and refining period, but they may be detrimental to the furnace and auxiliary equipment. Zinc oxide may clog tubes in waste-heat boilers. Excessive zinc in the charge also tends to shorten silica-brick life in roof and end zones of furnaces. Lead tends to melt and form channels between brick refractories, thus allowing molten steel to penetrate through the bottom.

The distribution of the foregoing four groups of elements in electric-furnace steelmaking is the same under basic oxidizing conditions but will vary under a reducing condition.

As there are only a few acid-lined furnaces in the United States, these are not discussed in this chapter.

The scrap portion of open-hearth charge ranges from 100 percent to zero, the balance being cold or molten pig iron. The average for hot-metal plants is 40 percent scrap, while cold-melt plants use 85 percent scrap. The national average for electric furnaces is 98 percent scrap and 2 percent pig iron. A Bessemer converter consumes very little scrap unless oxygen is used.

Additive Metals in Steel

Metals and other materials are added to steels to improve its physical properties. Some act as scavengers, counteracting the harmful effect of sulfur, removing gases, or decreasing inclusions. Others are added for their alloying effect or as both an alloy ingredient and scavenger.

Several theories and formulas are used by the iron and steel industry to determine the kinds and quantities of the alloys necessary to obtain desired mechanical properties.

A comparison of the effects of the chief alloying elements in steel is given as follows (*18*).

Strengthen ferrite

P—very strong
Si, Mn—strong
Ni, Cu, Cr, Mo, W—fairly strong
V—weak

Confer depth hardening

Mo, W, Mn, Cr—strong
Si—medium
Cu, Ni—weak
V—very weak

Restrain grain growth of austenite

Al—very strong
V, Ti, Zr—fairly strong
Mo—medium
Cr, Si—weak
Mn—very weak
Ni—practically no action

Form carbides

Ti, Nb, V—very strong
Cr, Mo, W—strong
Mn—fairly strong
P, Ni, Cu, Si—no carbides

Stabilize martensite and troostite on tempering

Mo, W—strong
V—fairly strong
Cr—weak
Mn—very weak
Others no appreciable stabilization

Decrease eutectoid content

Mn, Cr, V—considerably
Ni, Mo, W—somewhat
Si, Cu, Al—no appreciable effect

Some Specific Effects and Reason for Use

Al—Control of grain size; removes gases and impurities.
Cr—Small amounts improve hardening qualities; more than 10 percent prevents rust.
Co—Holds cutting edge at high temperatures; making magnet steels.
Cu—Over 0.75 percent, confers power of precipitation hardening.
Cu or Cu+P—Even in small amounts, confer improved resistance to atmospheric corrosion.
Pb and S—Improve machinability.
Mn—Small amounts remove gases from steel; 1 to 2 percent increases strength and toughness; 12 percent imparts great toughness and resistance to abrasion.
Mo—Minimizes temper brittleness; increases strength, ductility, and resistance to shock.
Mo, W—Confer high-temperature strength, especially in the presence of other carbide-forming elements.
Ni—Confers toughness without brittleness, and especially confers low-temperature impact toughness.
V—Increases strength, ductility, and resiliency.

The alloy steel may be used only as a surface skin. Thus stainless steel clad plate is made of an ordinary carbon steel to which there is uniformly and permanently bonded a veneer or cladding to one or both sides. This clad material may be substituted for a 100 percent stainless plate. It is less expensive and in most cases offers the same corrosion resistance as the steel or alloy for which it is substituted. Thickness of cladding generally ranges from 5 to 20 per cent of total thickness. In addition to cladding with stainless steel, high-purity nickel, aluminum, copper, titanium, and other metals may be used.

Steelmaking Processes

Steel may be made in an open-hearth furnace, a basic oxygen converter, an electric furnace, or a Bessemer furnace. The relative positions of the various steelmaking processes in the United States are given in figure 1 and table 14. Steel is the result of chemical reactions involving the refining of pig iron and scrap by oxidation and slag reactions whereby the quantities of carbon, silicon, and other removable, unwanted elements are lowered while the content of other elements is increased or decreased, depending on the kind of steel desired (*2*, *9*, *13*). Data on free energy of formation of oxides, sulfides, nitrides and carbides, and stability of oxides and sulfides for many of the metal and nonmetal compounds at steelmaking temperatures of 3,000° F are useful in predicting or determining the nature of the reactions that take place in steelmaking practices. For example, to predict the course of reactions between metals, slags, and gases (such as, reactions that occur in the control or removal of harmful impurities in steel), free energies of formation, heat capacities, and activities of the reacting substances are required.

The open-hearth furnace accounts for more than 75 percent of U.S. steel production. Modern open-hearth furnaces are of the reverberatory type, with a hearth in the shape of a large oval dish. At each end of the furnace are ports (where the fuel and air meet) connected to the refractory checkers-regenerators by flues. Through a system of valves and flues the checkers are connected either to the incoming air supply or the stack for waste gases. The utilization of heat from waste gases is possible by these valves, which automatically change the direction of the flow of air and gases about every 15 minutes to maintain a checker temperature of 1,800° to 2,200° F which is required for efficient operations.

Open-hearth furnaces are of two types—basic and acid. Basic furnaces are lined with magnesite or dolomite, while acid furnaces are lined with silica brick (*9*). In the basic furnace a lime basic slag facilitates the removal of silicon, phosphorus, and a limited quantity of sulfur. In the acid-lined open-hearth furnace, silica or acid slag does not eliminate phosphorus and sulfur, therefore, special types of pig iron are required for this type of furnace as well as carefully selected scrap. For this reason, practically all the open hearths in this country are of this basic type which facilitates the removal of these impurities.

Steel produced from each open-hearth furnace charge averages about 175 tons with furnace capacities per heat ranging up to 600 tons. The charge consists of pig iron (molten or cold), scrap, and limestone; and iron ore, if more than 50 percent molten pig iron is used. Molten metal is added after the scrap is partly melted.

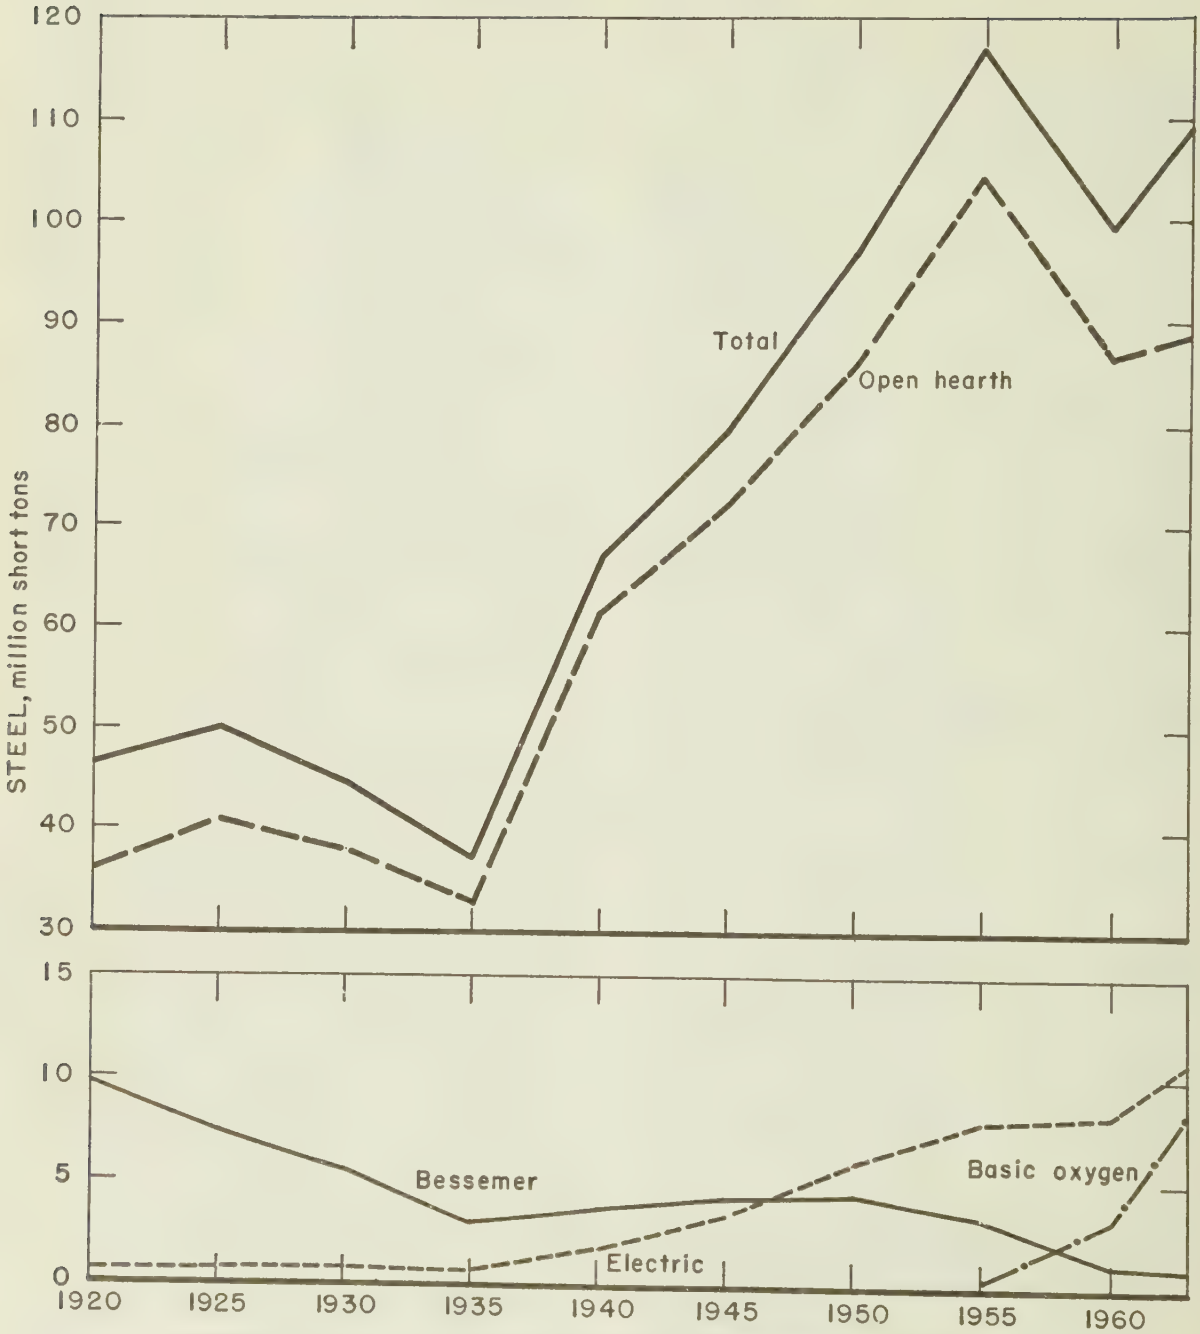

FIGURE 1.—Comparison of U.S. Steel Output by Various Steelmaking Processes.

Plants that do not operate blast furnaces utilize cold pig iron and some carbonaceous material or both. During subsequent refining of the heat nearly all the manganese, phosphorus, and silicon are oxidized and retained in the slag. Plans utilizing high-phosphorus pig iron (over 0.2 percent) use additional limestone in controlling phosphorus. Sulfur removal to the requirement of less than 0.05 percent is difficult with sulfur-containing raw materials, including fuels. Large slag volumes, high slag basicity, and fluid slags with good bath action tend to aid desulfurization. High temperatures also aid in sulfur removal.

Oxygen steelmaking, which accounted for 12 percent of the steel produced in 1964, was introduced into the United States in 1954. There are two oxygen-converter steel processes used in the United States, the Linz-Donawitz (LD) process and the Stora-Kaldo process (see fig. 2). With one exception, all oxygen steelmaking in the United States is in LD furnaces. The LD process is the fastest known process for making high-quality, low-nitrogen steel. Heats of from 80 to 300 tons can be finished in 30 to 60 minutes from tap to tap. Tables 4 and 5 give data on various heats. This process is particularly adaptable to the usual run of basic pig iron produced in the United States. Its success depends upon the tonnage quantities of oxygen delivered to the furnace at low cost. The basic oxygen converter is a pear-shaped, tiltable vessel having a charging hole on top and a tapping hole near the top on one side. These converters range in size from outputs of 50 to 300 tons per heat. A typical 140-ton furnace shell is 22 feet 11 inches inside diameter, and 28 feet 1 inch high inside the shell. The diameter of the mouth opening is approximately 10 feet 2 inches inside the lining (*22*, *23*, *25*).

The first step in the production of the heat is the calculation of the amounts of hot metal, scrap, and fluxes to be charged to produce steel of the desired analysis, and the temperature at the conclusion of a predetermined oxygen flow.

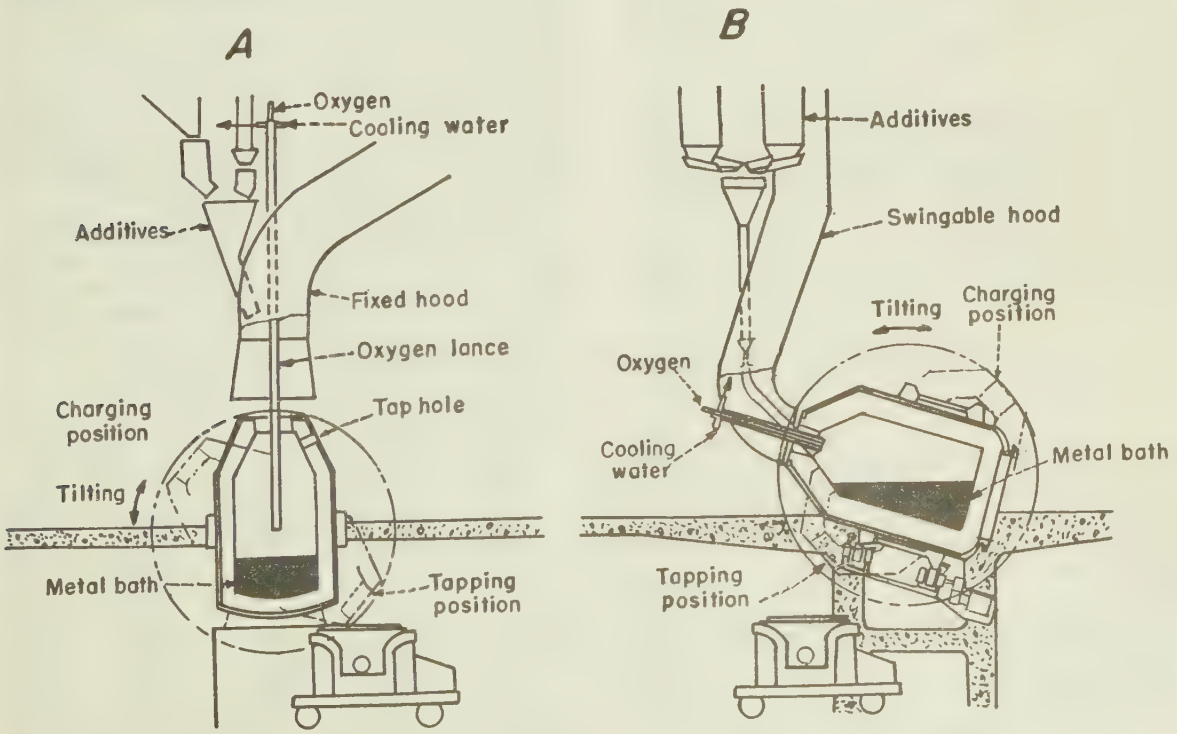

FIGURE 2.—Basic Oxygen Furnaces (A) Linz-Donawitz (B) Stora-Kaldo.

These calculations are based on the chemical analysis and temperature of the hot metal and include in the calculation the weight of the scrap, burnt lime, fluorspar, and the amount of oxygen to be used. Most steel mills using oxygen converters have them controlled with computers. After the calculations for the charge are made, scrap is dumped into the furnace first, immediately after this hot metal is added, the furnace is rotated upright, the oxygen lance is lowered, and the oxygen blow begins. Oxygen is blown into the furnace at supersonic speeds. Under normal operating conditions, the time elapse from the start of the charge of scrap to the start of the oxygen blow is from 3 to 5 minutes. Fluxes are added after the introduction of oxygen. At the conclusion of the blow steel samples are taken, the temperature noted, and adjustments can be made. If the melt is too hot, additional scrap can be put in for cooling; if the melt is too cool the oxygen lance is relowered and oxygen blown in for a short period. The furnace then is rotated to the tap hole side and molten steel poured into the teeming ladle. After the conclusion of the tap, the furnace is rotated in the opposite direction to dump slag in the cinder box. The furnace is then returned to the charging position ready to receive burden for the next heat. Total elapsed time from tap to tap is from 30 to 60 minutes, depending on size.

Refractory life has been improved. One source reports an average of 223 heats per lining for heats averaging 140 tons of steel. This is an average consumption of 15 pounds of brick per ton.

At first it was thought that the basic oxygen process was suitable only for regular low-carbon steel, but as operating efficiency increased the product includes practically the full spectrum of grades of steel.

The Stora-Kaldo process, the other oxygen steelmaking process used in this country, uses a tiltable converter similar in shape to the LD unit. However, during the steelmaking process the converter is inclined to about 17° from the horizontal and rotates on its longitudinal axis at speeds up to 30 rpm. One of the disadvantages of this process has been the extremely high consumption of refractories. Another small experimental converter, which may show promise in the future, is the Fuji circular converter. Pilot runs have used both a doughnut shape with a refractory island in the center, and a teacup shape with the island removed. In both installations a circular motion is imparted to the molten steel by the oxygen lances. The hot metal circulates at about two rotations per minute, and the slag blanket at a slower speed, thus there is a constant interaction between the hot metal surface and the slag as the metal flows in its circular path. This method effectively removes phosphorus and sulfur and leaves less oxygen and nitrogen than in open-hearth steel. In this method also there is a high rate of consumption of refractories (*25*).

Electric-furnace processes are used to make virtually all types of steel. The products include the entire range of stainless steels, high-alloy steels, high-speed and other alloy tool steels, low-alloy constructional steels, and plain carbon steels. Two types of electric furnaces are used in steelmaking, the arc type and the induction type (*13*, *17*).

Electric-arc furnaces are of the stationary or tilting design and vary in size of melts from a few hundred pounds to 200 tons. Although there are several types of arc furnaces, the most common is the direct arc in which the charge is melted by heat generated by the current arcing from the electrode to the bath. Table 6 shows the growth of electric arc furnaces with respect to size, power input, charging methods, and production rates in the United States.

Carbon is usually removed by oxidation to approximately the quantity desired in the finished steel. Sources of oxygen include iron oxide as ore, mill cinder, roll scale, and oxygen

injected through lances. When refining is completed, the heat is tapped into a ladle. To obtain the desired analysis, ferroalloys are added to the furnace before tapping, or in the ladle as the heat is being tapped. Aluminum or ferrosilicon is added if a deoxidized steel (semikilled or fully killed) is desired. If rimmed or mechanically capped steel is being made, small quantities of deoxidizers are used to control rimming action or ingot structure. As phosphorus and sulfur cannot be removed by the acid process, production of high-quality steel by this method requires raw materials with low impurities.

Selection of scrap charge (98 percent scrap, 2 percent pig iron U.S. average) of the electric furnace is made according to the grade of steel being produced. The furnace can be operated to permit highly efficient recovery of alloys by proper slag manipulation. Oxidizing and reducing slags may both be used in the same heat, depending on the composition of the charge and the analysis of the product. Limestone, lime, silica sand, crushed coke, aluminum, and fluorspar are materials used for slag constituents. The elimination of elements is the same as in the open hearth under basic oxidizing conditions. Sulfur may be removed from the metal with a reducing slag containing over 2 percent calcium carbide. In the presence of chromium, the removal of carbon is difficult because of the chemical affinity chromium has for carbon. Carbon may be absorbed by the metal while part of the chromium is being oxidized and going into the slag.

To oxidize carbon in a charge containing a high percentage of stainless-steel scrap requires an excess of oxygen and extremely high temperatures (over 3,200° F). Oxygen supplied through a lance into the molten bath is now used to a large extent instead of iron ore as the oxygen source. Oxidation of the metalloids is an exothermic reaction which reduces the energy requirements. With either source of oxygen considerable chromium is oxidized along with the carbon, and the resultant slag will contain a high percentage of chromium oxide. Chromium oxide may be reduced and returned to the metal by adding lime and crushed ferrosilicon.

The control of hydrogen in stainless steel is a frequent problem of many producers. Hydrogen may result from reducing moisture in the charge materials, water leaks in the furnace-cooled system, inadequately dried ladles, or high humidity in the atmosphere. When an appreciable quantity of hydrogen is absorbed in a stainless steel melt, it results in bleeding and porous ingots. Argon and helium gas and dry air are effective for purging hydrogen from the bath.

In an induction furnace, an electric current is induced in the metallic charge, causing it to become hot. Because of the action of the induced current, the metal bath is in constant circulation, and the swirling motion tends to homogenize the bath. The charge is carefully selected to produce the composition desired in the finished steel. Additions are mainly limited to small quantities of ferroalloys as final deoxidizers. Induction furnaces range in capacity from a few pounds up to 3 tons or more. Special steels and alloys, superior in quality to those produced by other methods of manufacture, may be produced in induction furnaces by melting in a vacuum or under pressure in an inert gas atmosphere. In such operations, the furnace and mold are enclosed in airtight containers, which can be evacuated or put under pressure with an inert gas. When the melting is complete, the crucible is tilted to pour molten metal into the ingot mold, and the metal solidifies under vacuum.

The Bessemer process was the first of the three processes used commercially in large-scale production of steel. A Bessemer converter is a pear-shaped vessel 10 feet or more high, open at the top, lined with acid refractory material,

and mounted on trunnions, so that it can be tilted to receive the hot metal and to pour the steel when a "blow" is finished.

Molten pig iron, 15 to 40 tons at a time, is poured into a Bessemer converter, and a blast of air is introduced from the bottom through a number of small openings in a specially designed base of refractory material. As the air is forced through the liquid metal, carbon and some of the undesirable elements, except phosphorus and sulfur, contained in the pig iron are oxidized and form slag constituents or escape as gases. The nitrogen content of Bessemer steel averages between 0.012 and 0.016 percent compared with 0.004 to 0.006 percent in the open-hearth process (*13*, *19*). The metalloids, particularly carbon, react with the ferrous oxide in the blown metal at high temperatures, and the gaseous product of reaction contributes to a lower inclusion content. Completely deoxidized steel, made by this method, is useful in such applications as pipe for structural purposes or where pipe is subjected to high pressures, because of its high yield-point and elastic-ratio characteristics (*21*). In addition to the steel tapped and teemed into ingot molds from the Bessemer converter, a considerable quantity is transferred while molten to tilting open-hearth furnaces for further refining. This is known as the duplex process.

Vacuum melting reduces gases and metals, decreases inclusions, and results in improved composition control. A comparison of the gas content of heat-resistant alloys by air melting and vacuum melting is given in table 7. Refractories are one of the problems in vacuum melting. For example, the oxygen level may increase after it has been reduced to low levels because of the oxygen contained in the refractories. Oxygen increases the loss of alloying elements to the slag; these elements also may remain in the steel as an oxide inclusion. Table 8 illustrates how vacuum melting removes metals, which may or may not be desirable,

TABLE 7.—*Decrease in gas content on consumable-electrode, vacuum remelting* [1]

Gas	Alloy	Air-melted electrode, ppm	Consumable electrode vacuum remelting, ppm	Decrease, percent

from steel. These data were determined from a series of binary alloys (iron plus up to 1 percent residual or alloying elements). One manufacturer claims that the life of a ball-bearing steel, AISI 52100, was increased by 400 percent when vacuum melted, as compared with conventional arc-melting methods.

Casting

Another innovation which is being adopted more slowly in the United States than oxygen steelmaking is continuous casting. In continuous casting the hot metal is teemed into a tundish of suitable design and the metal runs from this through nozzles into a water-cooled copper mold. This mold often has a vertical oscillation which prevents the freezing metal from solidifying to the mold. The casting has time to form only a thin skin while in contact with the mold, which is usually from 20 to 36 inches long, before it enters into the secondary cooling stage. This consists of jets of water played directly on the casting and may be from 10 to 30 feet long depending on the casting size, cross section, specific heat, and other factors.

Originally continuous casting machines were extremely high as it was a completely vertical process, but later, as shown in figure 4, machines have incorporated the use of bending rolls so that the casting, before it becomes cold, is rolled out horizontally. Some of the advantages claimed for continuous casting machines, besides lower capital investment and operating costs, are a greater yield of semifinished products from hot metal, elimination of ingot molds, hot tops, stripping cranes, soaking pits, and primary mills, and improvement on the internal quality of steel because of faster solidification, greatly improved surface quality through elimination of ingot casting and the primary mills (*21*). Table 9 gives a list of continuous casting plants in the United States.

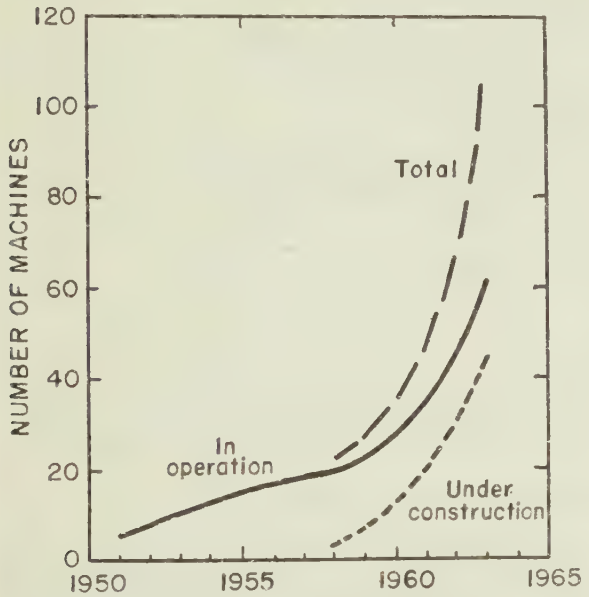

FIGURE 3.—Growth of Continuous Casting.

Pressure casting, which has been used for several years for railroad wheels, is also being more widely adopted by the industry. The principal advantage also of pressure casting is greater recovery of hot metal in final casting, and better surface control. A process being advocated to utilize the advantages of vacuum melting or casting, and the savings in continuous and pressure casting, is vacuum degassing. One type of operation consists of inserting a refractory nozzle extending from a vacuum vessel through the slag layer of a heat of steel in a conventional ladle. When vacuum is applied the amount of steel exposed is cycled by lowering and raising the vessel. This method was developed by Dortmund-Horder-Hutten Union (D–H). The other unit more recently introduced into this country is called Ruhrstahl-Heraeus (R–H). This unit has two refractory tubes extending from the vacuum chamber which dip below the surface of the molten metal. After vacuum jets have raised the liquid steel to a certain level in the tubes, argon, or other gasses, can be introduced through one tube. Advantages claimed for this method are—faster degassing time, minimum heat loss, and possibility of using reactive gasses in the vessel. Thus, hydrogen could be used instead of argon to further reduce oxygen levels (*25*).

USES

From 1959 through 1963 over 20 percent of the direct shipments of steel products went to the automotive industry. During this period direct shipments to the construction industry have averaged 16 percent and those to warehouse distribution centers have averaged 16 percent. Since the construction industry buys much of its steel from the warehouse distributors, it is probable that for the last few years the construction industry has been consuming about as much steel as the automotive industry. Steel for containers, packaging, and shipping materials has averaged over 9 percent of total shipments for the last 5 years. Steel for all kinds of industrial machinery, electrical machinery, appliances, and other domestic and commercial equipment accounted for about 14 percent of the shipments, leaving about 24 percent for shipbuilding, aircraft, oil and gas, mining, agriculture, ordnance, and export. Table 10 gives distributions of steel for consumption by market classifications (*5*).

Steel service centers, warehouses, and distributors get about 13 million tons of steel shipped directly to them. This is distributed to almost all of the other consumer markets, therefore, it is difficult to assign certain amounts to various market classifications. For the last decade the percentages of steel used have remained about the same for the various market classifications.

The improvements that have been made in steel make it difficult to make good comparisons by weight since, with new alloys, lighter weight

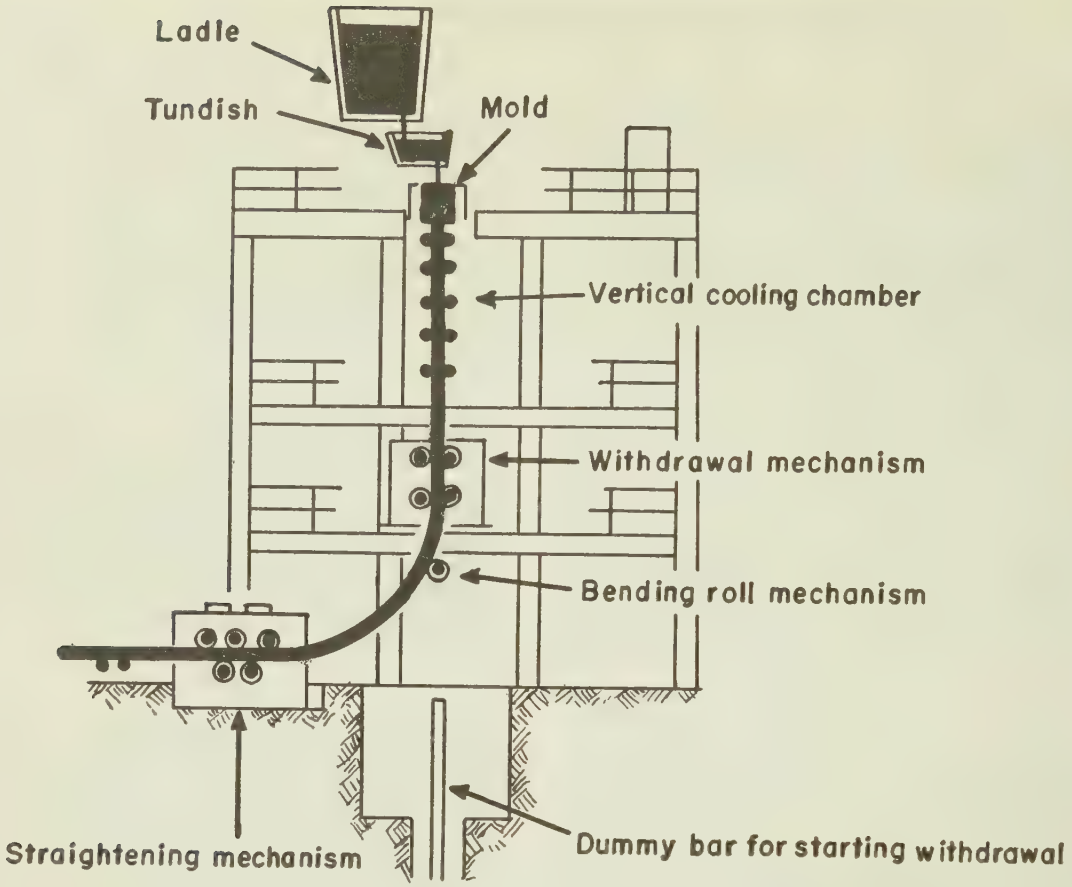

FIGURE 4.—A Vertical Continuous Casting Machine With Bending Rolls.

Source: American Iron and Steel Institute.

steels now do the same job as heavier steels did formerly. Thus steel company research led to the development of a new high-strength linepipe of larger diameter, that has greater resistance to corrosion. This allows for the transportation of more gas and oil for longer distances under greater pressure with less steel. Similarly for containers the steel industry is now making tin plate much thinner. This increases the total overall advantage as the lighter-weight stronger steel products have greater corrosion resistance and therefore longer life. As these advantages combined with lower transportation costs become more evident, the per capita consumption of steel will start to rise gradually.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Coke byproducts and their derivatives number in the hundreds but principally comprise coke breeze, coke-oven gas, tar, ammonium sul-

fate, ammonium liquor, and light oils. Coke breeze is used for agglomerating iron ore, and coke-oven gas is used as a fuel for heating coke ovens in steelmaking and reheating furnaces. Useful products from light oils vary from benzene to xylene. A recent development in coke-plant technology is the removal of hydrogen from coke-oven gas. The recovered hydrogen is used in manufacturing ammonia.

Blast-furnace gas and slag are byproducts of blast furnaces. Blast-furnace gas is used for heating coke ovens, blast-furnace stoves, steel furnaces, and power generation. Blast-furnace slag is used as aggregate ballast for railroads, in manufacture of cement, mineral wool, sewerage filtration, agriculture, and for many other purposes. The annual value of blast-furnace slag produced in the United States is $40 to $50 million. In addition, approximately 8 million tons of flue dust is recovered annually, which is used in making sinter or is charged directly into the blast furnace.

The main byproduct of steelmaking furnaces that is reused is open-hearth slag which is utilized as a source of manganese and flux (calcium and magnesium) in blast furnaces. Some 5 million tons goes annually for this purpose. In addition, several million tons of iron is recovered from slag dumps annually and is used in blast and steelmaking furnaces. In the Birmingham, Ala., area, open-hearth slag from the duplex process of the Ensley plant is employed as a soil conditioner because of its available phosphorus. Iron recovered from electrostatic precipitators installed at open-hearth and oxygen furnaces is agglomerated and charged back into blast and steel furnaces. In addition, the majority of open-hearth plants generate a considerable part of their electrical energy requirements from waste-heat boilers.

Steel scrap (20 to 30 percent of ingot output) is generated in rolling mills through the cropping of blooms and slabs and other shearing necessary to remove defects and meet size specifications. This material constitutes home scrap. There is a 2- to 3-percent scale (iron oxide) loss everytime that steel is heated for rolling. This scale may be charged directly into blast furnaces or be used in steelmaking furnaces. When used in steelmaking furnaces, it is a source of metallics and oxygen for refining the melt.

ALTERNATE MATERIALS

Metals and nonmetals competing with steel have captured some of the market when steel was in short supply; but its versatile properties and relatively low cost makes steel still the most prominent material for structural applications and other purposes in use today. The principal competing materials are aluminum, plastics, glass, and concrete.

Research to improve steel, to modify or combine it with other materials, and to adapt it to the end product has resulted in its resurgence. Steel products have become lighter, stronger, and more corrosion resistant, thus displacing substitutes such as aluminum in the automotive market, which is steel's biggest market. Steel panels coated with colored plastics are being used in construction. New rolling techniques make steel much thinner and more practical for foil and containers. Better alloy steels of higher strength are recapturing some of the structural market leading to revision of building codes to accept these lighter, stronger steels. Steel pipe is coated with plastic to resist corrosion or lined with glass to carry corrosive materials.

The steel industry is putting greater emphasis on market research and product development for the consumer. Many of the materials formerly regarded as substitutes have been incorporated into the design of new steel products to modify or improve the characteristics of the steel.

SECONDARY SOURCES AND RECOVERY (11)

Ferrous scrap comprises over half of all the metallics charged into iron and steelmaking furnaces in the United States. In recent years the proportion of scrap used has decreased, partly because of the use of oxygen in steelmaking furnaces, but the importance of recycling 65 to 75 million tons of metal a year as a secondary raw material cannot be overlooked. The presence of contaminant metals as alloying elements in scrap has been a positive deterrent to its use, but it is felt that the development of metallurgical separation methods will supplement the huge scrap metal disintegrators recently introduced to remove contaminating materials. Table 11 gives the proportion of iron and steel scrap and pig iron used in furnaces in the United States at 5 year intervals since 1953, while table 12 shows the consumption in short tons of iron and steel scrap by the type of manufacture and by the grade of scrap in 1963.

CONSERVATION

Conservation of the metal represented by creation of 75 million tons of steel products annually is extremely important from a raw material and waste disposal standpoint. Hot metal, molten iron of known composition, is the most satisfactory raw material for steelmaking, but

TABLE 11.—*Proportion of iron and steel scrap and pig iron used in furnaces in the United States*

[Percent]

Type of furnace	1953		1958		1963	
	Scrap	Pig iron	Scrap	Pig iron	Scrap	Pig iron

TABLE 12.—*Consumption of iron and steel scrap by type of manufacturer, by grades, in 1963*

[Thousand short tons]

Grades of scrap	Steel ingots and castings	Steel castings	Iron foundries and miscellaneous users
Steel scrap, excludes rerolling rails:			
Carbon	51,206	2,560	3,826
Alloy, excludes stainless	2,399	127	129
Stainless	666	29	22
Cast iron, includes borings	5,020	338	8,299
Total	59,291	3,054	12,276

the steel in scrap is an alloy of iron with other elements. This represents a serious drawback in the conservation of steel products. As these alloys become more complex the elimination of the alloying or contaminating element becomes more difficult. The necessity for work on the conservation of steel has been highlighted in recent years by the increasing numbers of scrap automobile bodies that have been stripped of useful components and remain as small steel jungles, lowering the use value of the property that they are on and destroying the aesthetic values of the surrounding property.

SOURCES OF STATISTICAL INFORMATION

Steel-ingot-production data are published by the American Iron and Steel Institute, and pig iron production and consumption of pig iron and ferrous scrap are published by the Bureau of Mines. Statistics on the production of steel ingots and steel castings by ingot producers and independent foundries are provided by the Bureau of the Census. Data on the production of iron castings are not published by any association or Government agency. The Bureau of the Census publishes monthly statistics on shipments of iron castings.

Statistics on the supply and consumption of iron and steel scrap are collected and published monthly by the Bureau of Mines. These data are also collected by the American Iron and Steel Institute for the steel industry, which excludes the noncaptive foundries and other miscellaneous users.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic production of iron and steel in 1963 accounted for about 26 percent of the world estimated production of steel ingots and castings. Tables 13 to 16 show salient iron and steel statistics and domestic and world production of pig iron and steel. U.S. imports and exports of iron and steel products are given in tables 17 and 18.

Production of steel by the new basic oxygen process has grown fourfold since 1958 at the expense of other methods of manufacture, and in 1963 accounted for about 8 percent of the domestic output.

Imports and exports constitute only a small part of the total domestic supply and demand for pig iron, scrap and steel. However, large quantities of certain products such as sheets and plate, structural iron and steel, rods (wire, nail, and flat) and steel pipe and tubing are imported for consumption. Data on the quantity of steel used by the various consuming industries are given in the section on Uses.

Tariff rates on iron and steel products vary with the type of product and composition (particularly alloy content); how manufactured, hot or cold rolled, cast or forged, coated or clad. Typical duty rates on some iron and steel products are shown in table 19. On some iron products containing *chromium*, *molybdenum*, *tungsten*, or *vanadium* over a specified quantity, additional duties are applicable. These rates are shown in table 20 (*26*, *27*).

STRATEGIC CONSIDERATIONS

Steel is essential to civilian uses and defense purposes. Plants are relatively widely dispersed even though most of them are concentrated in the northeastern part of the United States. Nevertheless, several plants must receive strategic considerations because of their size.

In 1963, the five largest steel companies in the United States had 59 percent of the total industry sales. They are as widely dispersed as is economically feasible and their general concentration in the States bordering the Great Lakes gives them the advantage of a broad waterway for the transportation of raw materials. The United States is self-sufficient in iron for steel but not in all of the alloying elements used. See production of steel, by States, in table 1.

GOVERNMENT PROGRAMS

The steel industry is not subject to any defense programs and is only concerned with the effect of the stockpiling program on metals used in alloys. The Bureau of Mines has an experimental blast furnace which it is operating in cooperation with the steel industry. The Bureau, through its Mineral Resource Offices, has been studying the generation and movement of ferrous scrap throughout the United States, and has been given a large role in the waste utilization study which is a part of the large beautification program for the United States.

PRICES AND COSTS

The domestic steel industry uses f.o.b. mill prices for all its steel products. The following tabulation gives 1964 prices of steel, pig iron, and scrap: [3]

Composite finished steel	$0.06368 per pound
Pig iron composite	63.11 per long ton
Steel scrap, heavy-melting composite	33.67 per long ton

[3] Iron Age.

TABLE 15.—*World production of pig iron (including ferroalloys) by countries* [1] [2]—Continued

[Thousand short tons]

Country [1]	1954–58 (average)	1959	1960	1961	1962	1963
Oceania: Australia [9]	2, 288	2, 829	3, 240	3, 549	3, 879	[10] 4, 032
World total (estimate)	209, 970	247, 230	285, 270	282, 370	291, 820	308, 970

[1] Pig iron is also produced in Republic of the Congo, but quantity produced is believed insufficient to affect estimate of world total.
[2] This table incorporates some revisions. Data do not add to totals shown due to rounding where estimated figures are included in the detail.
[3] Estimate.
[4] One year only as 1958 was the first year of commercial production.
[5] U.S.S.R. in Asia included with U.S.S.R. in Europe.
[6] Based on figures from Chinese sources. 1958 does not include approximately 4,000,000 tons produced of sub-standard grade iron produced at small plants. 1959 production probably includes pig iron obtained from reworking the low-grade product of 1958 and an unreported quantity (probably relatively small) of sub-standard iron from small plants most of which were shut down early in the year.
[7] Includes foundry iron through 1962.
[8] Average annual production 1955–58.
[9] Includes scrap.
[10] Excludes ferroalloys.

[1] Includes wire cloth as follows: 1962, $1,455,917 (7,463,741 square feet); 1963, $1,638,819 (3,404,155 square feet).

Source: Bureau of the Census.

The composite finished steel price as quoted from Iron Age is computed on the base of the following 10 carbon-steel products: Hot-rolled bars, structural shapes, plates, rails, pipe, wire, and hot- and cold-rolled sheets and strip. Although scrap prices formerly fluctuated widely the extensive development by integrated steel mills of their own iron ore facilities in the decade after World War II reduced the volume of scrap used by the steel industry and therefore reduced the extent of price fluctuations. Greater use of hot metal and the advent of the basic-oxygen converters further depressed the use of scrap, especially the lower grades. The composite price of No. 1 heavy melting scrap is

TABLE 19.—*Typical duty rates of iron and steel products (27)*

	TSUS No.	Rate of duty—1964	Statutory rate of duty
Iron and steel scrap.[1]	607.11	Free	Free.
Pig iron and cast iron.[2]	607.15	20 cents per ton	$1.125 per ton.
Spiegeleisen [2]	607.20	75 cents per ton	75 cents per ton.
Plates and sheets	608.84	8 percent ad valorem	20 percent ad valorem.
Structural steel	609.80	0.1 cent per pound	0.2 cents per pound.

[1] Duty temporarily suspended as provided by P.L. 88-324, effective July 1, 1964.
[2] May not contain more than: Chromium, 0.2 percent, molybdenum, 0.1 percent, tungsten, 0.3 percent, and vanadium, 0.1 percent.

TABLE 20.—*Duty added for amount of alloying element in iron products (26)*

	Rate of duty 1964	Statutory rate of duty
Over 0.2 percent by weight chromium.	1.5 cents per pound on chromium content in excess of 0.2 percent.	3 cents per pound on chromium content in excess of 0.2 percent.
Over 0.1 percent by weight molybdenum.	35 cents per pound on molybdenum content in excess of 0.1 percent.	65 cents per pound on molybdenum content in excess of 0.1 percent.
Over 0.3 percent by weight tungsten.	50 cents per pound on tungsten content in excess of 0.3 percent.	72 cents per pound on tungsten content in excess of 0.3 percent.
Over 0.1 percent by weight vanadium.	40 cents per pound on vanadium content in excess of 0.1 percent.	$1.00 per pound on vanadium content in excess of 0.1 percent.

TABLE 21.—*Composite price of No. 1 heavy-melting scrap, per long ton*

[Pittsburgh, Chicago, and Philadelphia]

Year	Composite price			Year	Composite price		
	High	Low	Average		High	Low	Average
1949	$41.36	$19.33	$27.56	1957	$59.37	$32.33	$46.75
1950	44.02	26.58	34.75	1958	43.10	32.73	38.08
1951	46.15	42.00	43.15	1959	45.67	34.41	40.49
1952	42.00	40.10	41.79	1960	41.83	28.33	32.95
1953	44.60	31.33	39.52	1961	39.42	31.50	36.28

1955	50.42	34.48	40.19	1963	28.67.	25.33	27.11
1956	64.59	45.08	53.82				

Source: Iron Age.

given in table 21. This illustrates the price fluctuations over a 15-year period.

The steel industry has averaged over $1 billion a year for the last 15 years in capital outlays for property additions, improvements, and acquisitions. Capital expenditures in the first years of this period were aimed primarily toward expanding the industry's production capabilities. However, in the past 5 or 6 years the shift has been toward increased productivity and the development of new and improved products. These expenditures have been divided between new plant construction or old plant modernization; between relining an open-hearth or constructing an oxygen converter; between rebuilding a bloom mill or starting continuous casting. This makes an estimate of cost-per-ton for this period of capital construction very difficult.

To illustrate for a specific year, 1963, 85 companies produced steel ingots and castings, employed an average of 520,000 people, and produced 109.3 million ingot tons of steel for which they received $14,453 million, with a net income of $782 million.

A summation of expenses involved in production are—

	Millions
Employment costs	$5,607
Products and services bought	6,174
Depreciation, depletion, and amortization	996
Taxes—Federal, state, and local	927
Interest	127

This means that the employment costs are 38.4 percent of total revenue, money expanded for products and services 42.3 percent, reserves for wear and exhaustion 6.8 percent, taxes 6.3 percent, and dividends 3 percent (*5*). Table 22 gives the components of this cost for 1954–63.

Capitalization as of December 31, 1963, was comprised of—

	Millions
Earned surplus	$6,887
Capital surplus	919
Preferred stock	640
Common stock	2,563
Total stock and surplus	11,009
Total long-term debt	2,689
Total capitalization	13,698

TABLE 22.—*Employment costs in steel industry*

[Millions]

Year	Wages and salaries	Social security and other employment benefits	Pensions	Total
1954–58 (average)	$4,329	$248	$221	$4,798
1959	4,578	325	237	5,140
1960	4,838	470	228	5,536
1961	4,673	466	213	5,352
1962	4,765	548	168	5,481
1963	4,841	585	181	5,607

TAXES

Federal taxes on the 1963 income of the iron and steel companies (representing 85 companies) was about $646 million, or 4.5 cents on each sales dollar.

Local, State, and miscellaneous taxes incurred by the iron and steel companies in 1963 were over $281 million.

The total of Federal, State, and local government taxes paid by these companies was over $927 million, exclusive of social security, and similar employee benefits, or 6.4 cents on each sales dollar.

TRANSPORTATION

The mode of transportation of iron and steel raw materials except coal, fluxes and refractories and iron and steel products is given in table 23. The iron and steel products moved by railroads include billets, blooms, ingots, bars, rods, slabs, nails, wire, woven wire, manufactured iron and steel products, and iron and steel products not classified. The iron and steel products moved by water include finished, semifinished, and rolled, iron and steel and pipe and castings. Data are not available on transportation of iron and steel products by truck.

The cost of transportation usually is less for raw materials than for finished products and therefore steel mills are located near markets.

TABLE 23.—*Transportation of raw material metallics for the iron and steel industry and iron and steel products in 1962*

[Thousand short tons]

	Railroad [1]	Water [2]
Iron ore	129,155	99,428
Iron and steel scrap	26,734	5,941
Pig iron	5,100	1,268
Ferroalloys	2,479	[3] 4,312
Iron and steel products	87,146	13,119
Total	250,614	124,068

RESEARCH (10, 24)

The steel industry engages in fundamental or basic research in physics, chemistry, physical chemistry, thermodynamics, and all branches of metallurgy, and the industry also supports research in these subjects in private foundations and university laboratories. According to a survey report by the National Science Foundation, the industry expended $5 million per year for basic research in primary ferrous products 1957–59 inclusive, $8 million in 1960, and $7 million in 1961.

Applied research and development (R&D) in the steel industry is directed toward lowering production costs, conserving raw materials, im-

proving quality of existing products, and developing new products. The industry expended $60 million for R&D in primary ferrous products in 1959, $68 million in 1960, and $74 million in 1961. These figures, although developed by a comprehensive sample survey of industry, are believed to be low because the cost of research on fabricated metal products was not included. It is noteworthy that in November 1964, the United States Steel Corp. was continuing to introduce an average of two or more new or improved products every month. All the larger steel companies maintain research establishments that in setting, size, and appearance, resemble university campuses. Others maintain research laboratories commensurate with their scale of production, and even the smallest engages in some form of steel research. All this activity leads to the conclusion that current steel industry annual expenditures for R&D probably are as high as $150 to $175 million. Industry estimates placed the total at over $100 million in 1964, with an estimated 5,000 scientists, engineers, and supporting personnel working in research (*24*).

The Department of Defense and the Department of the Interior, through its Bureau of Mines, are responsible for essentially all the Government's research on iron and steel. Defense Department research is directed toward development of high-strength and high-temperature steels for service in armor, guns, aircraft, missiles, and other such military equipment. The work is done principally by contract with private industrial concerns, private foundations, and universities. Some Defense research has been done under cooperative agreements with the Bureau of Mines and other Government agencies. Department of Defense iron and steel research is typified by its maraging steel project in which the ultimate objective was to (1) determine the pertinent properties of maraging steels, (2) delineate the optimum techniques for processing and fabricating them, (3) define the important problems to be expected in using them, and (4) identify means to eliminate these problems.

The Bureau of Mines iron extractive metallurgical studies effectively cover the field from basic research through the first stages of applied research. It stops short of development except for small-scale constructing of research equipment. The Bureau operates an experimental blast furnace at Bruceton, Pa., for research, usually cooperatively with major steel companies. Research on the kinetics and mechanisms of iron oxide reduction and development of a mathematical model of a blast furnace are conducted at other Bureau laboratories. The Bureau's research on steel is on a very modest scale. It has to do principally with controlling fume, investigating the mechanisms of high-strength steels, and improving the quality of high-strength alloy steel ingots by adding rare earth alloys to melts during refining.

Steel research is so intermingled with and dependent on other work of the Department of Defense that it is not practical to calculate its cost. The Department's R&D expenditures have been at the rate of over $6 billion per year. A very small part of this was solely for iron and steel. Bureau of Mines expenditures for iron and steel research have been about $1.5 million annually since 1960.

OUTLOOK

Steel production should reach 137 million tons by 1975 and 150 million tons by 1980. This projection is based upon a growth rate for the steel industry at a rate slightly above that for the U.S. population through the balance of this century. Per capital steel consumption will now gradually increase because technical advances within the industry will make steel more attractive from an engineering, economic, and aesthetic viewpoint. The production figures for 1975 and 1980 are based upon a projected population increase using a 1.6 percent annual compound rate forecast by the Bureau of Mines. The growth factor derived from this population projection was modified because of the changes in steelmaking, improvements in steels, and the effect of competition furnished by other metals used as substitutes for steel.

Steel production has fluctuated during the last 20 years from extreme lows in 1946 and 1958 to extreme highs in 1955 and 1964. The average per capita consumption of steel based on ingot production for 1944–53 was 1,208 pounds, and for 1954–63 the average consumption rate was 1,160 pounds per capita. This shift to a lower consumption rate represents the fulfillment of the post World War II consumer demand, the inroads made by alternate materials and the better strength to weight ratio of improved steels.

By 1980, U.S. requirements for pig iron will be about 93 million tons and for scrap about 75 million tons. This projection is based upon the assumption that pig iron and scrap will remain basic ingredients in the furnace charge and that production from open-hearth furnaces will drop to about 40 percent of the total output of steel.

Basic oxygen converters will supply 45 percent of the total production with electric furnaces and others supplying 15 percent. Assuming that open-hearth furnaces will use about 59 percent pig iron (41 percent scrap), basic oxygen converters about 70 percent pig iron, and electric furnaces 100 percent scrap, an overall ratio of 45 percent scrap and 55 percent pig iron is expected to hold through 1980.

Further research on prereduced pellets may result in their use directly in steelmaking furnaces. Obsolescent ferrous scrap presents such a real disposal problem for the country that any changes in steelmaking will be modified to use scrap. For example, each junked automobile of those now littering the countryside could contribute about one ton of ferrous scrap. Five million cars per year are being scrapped now and, with this number steadily increasing, there will be a constant pressure on both industry and Government to utilize this scrap to keep the eyesore of auto junkyards at a minimum. Pressure casting and continuous casting techniques which will reduce the available scrap generated in integrated steel mills will increase use of purchased scrap. No new open-hearth furnaces will be built in the next decade, since steelmakers seem to be able to make all grades of steel in the basic oxygen converters satisfactorily, and the lower capital cost and greater operating flexibility make the oxygen converters more attractive when open-hearth furnaces need replacing.

The attempt to integrate steelmaking from furnace through continuous casting to continuous rolling, all controlled by automation, is proceeding slowly. Improved steel quality will come from vacuum degassing installed in connection with continuous casting. Computer control will probably take over only as the art of steelmaking becomes the science of steelmaking.

The population shift westward into an area which traditionally has favored wood and concrete for construction will not affect per capita steel consumption significantly since higher strength, lighter weight steels apparently are supplanting the bulkier concrete in the crowded Western urban areas.

Although world steelmaking capacity is now increasing faster than world steel consumption, the imbalance will change with the emergence of the less developed countries in Africa, Asia, and Latin America. In the immediate future the amounts spent on modernization will increase productivity enough to help the U.S. steel industry regain some of its losses in the export market.

PROBLEMS

The principal problem of the steel industry is to meet foreign competition and thus stem its increasing loss of position in domestic and world markets. The problem resulted from countries of Western Europe and the Japanese completely rebuilding their steel industries after World War II, incorporating technical innovations that enabled them to produce better steel at less cost. Meeting foreign competition leads to many other problems in reducing production costs and maintaining quality.

Cost problems result because accelerated steelmaking also speeds up equipment depreciation, necessitating either excessive repair or premature replacement. Also the short life of refractories in oxygen furnaces and the decreased number of heats between furnace relining needs much study.

Another problem in production is the need for retraining labor in the use of new machinery and automation devices which are installed to increase productivity.

There is also increased need for control of exhaust gases from the new accelerated steelmaking techniques, which are responsible for air pollution in the metropolitan areas.

Customer demand for products finished under more rigid specifications presents a continuing quality problem. Ways must be found to use the poorer grades of limestone and coal, which in many instances are all that is available after depletion of the high-grade.

Steelmakers have a quality problem in that scrap is furnished by independent dealers and processors, some of whom do not supply material that meets purity requirements. Use of obsolescent scrap is also a problem because there is a lack of data on its supply and movement, and there is no satisfactory method for analyzing it in bulk.

The need for faster, more sensitive analyses is a growing problem as the industry becomes more and more automated.

Another barrier to improved production and quality is the need for better understanding of the chemistry and physical chemistry of steelmaking and for more thermodynamic data with which to control the makeup of charges and operation of steelmaking furnaces.

STONE

By Perry G. Cotter [1]

STONE generally means rock fragments or blocks removed from their original environment for use in construction or industry. Production of dimension stone for buildings, memorials, and other structures demands methods which are essentially different from those used to produce crushed stone. Uses are also fundamentally different, and therefore the branches of the stone industry must be viewed differently. For the preceding reasons the stone chapter consists of three sections: Dimension stone (except slate), slate, and crushed and broken stone.

DIMENSION STONE (EXCEPT SLATE)

Dimension stone competes at a disadvantage with an ever-increasing variety of other building materials, largely because it is costly to mine, prepare, transport, and install and because of the modern trend to construct buildings having a much shorter life expectancy than was customary 50 years ago. However, there is a renewed recognition of stone's unique properties for ornamentation and for protection against the weather, and demand for many varieties is rising. The principal varieties of stone—marble, granite, limestone, and sandstone—are used mainly for buildings and memorials, but substantial quantities are still produced for curbings, flagging, and miscellaneous uses.

The durability, strength, color, and density have important bearings on the value of stone for building and ornamental uses, but public preference is changeable and stones which are greatly in demand may lose their markets almost overnight.

The outlook for the memorial stone industry is only fair because more and more cemeteries are forbidding installation of grave stones, but stone for construction should continue to maintain a slow rate of growth in production.

Problems of the industry are need for improvement of quarrying and machining operations, utilization of waste, and development of means for lowering final costs of stone put in place.

BACKGROUND

Size and Organization of the Industry

At the beginning of the 20th century, dimension stone was produced in much greater tonnage than crushed stone, but in 1963 dimension stone production accounted for only about 0.4 percent of the total quantity. Nevertheless, there are about 700 active plants and value of sales exceeds $96 million annually in 45 States.

Quarrying and dressing blocks of stone may well be the most ancient of the mining industries. In the United States use of stone for construction began with the earliest settlements and production attained its zenith many years ago. Decreasing demand, however, began in the early 1890's, caused by development of steel skeleton construction and the rising use of concrete. Reinforced concrete, in fact, became an essential part of the skeleton structure, but that was only one of its many structural uses. Concrete, a stone-like material that can be poured in place, or can be cast or molded into any desired shape, has such decided advantages over stone, both in cost and convenience, that over half a century ago it began to replace stone extensively. Stone, however, is still preferred for its attractive appearance in many structures.

Other branches of the dimension stone industry besides building construction also suffered from competition with concrete. It has taken

[1] Commodity specialist.

780-887 O—65——56

the place of flagstones in sidewalk construction, and it has extensively displaced curbstones and paving stones on city streets. This reduced market has posed many problems for stone producers.

Dimension stone producers may be divided into three main categories, based upon plant operations. The first group quarries stone and sells it as rough blocks or slabs; the second quarries stone and also uses it in manufacturing finished products; and the third group only buys sawed slabs or rough blocks of stone and manufactures a finished product. Bureau of Mines production data are compiled on the basis of quantities and values of sales of both rough blocks and finished products by primary producers.

Geographic Distribution of the Industry

The Appalachian Mountains extending from Maine and Vermont to Georgia and Alabama form a region in which igneous and metamorphic rocks abound. Important deposits of granite and marble have been developed in this territory. The extensive middle western area lying between the Appalachian belt and the Rocky Mountains is characterized by nearly horizontal sediments such as the famous limestone deposits of Indiana, and the well-known sandstones of Ohio. Commercially important granite deposits also occur in this area, notably in Minnesota, South Dakota, Wisconsin, Missouri, Oklahoma, and Texas.

In the Rocky Mountain belt numerous igneous and metamorphic rocks occur, and from this belt westward to the Pacific coast, igneous rocks prevail. Limestones, which occur, though not as abundantly as in the East, have in places been metamorphosed into marbles. Volcanism of comparatively recent geologic age has produced lavas, rhyolites, and volcanic tuffs that rarely occur in the Eastern or Central States. Sandstones suitable for commercial use occur in widely distributed deposits in nearly every State. About half the States are currently producing sandstone.

Building and ornamental stones are plentiful in many sections of the world. The marbles of Africa, Italy, France, Spain, Belgium, and England; the granites of Scotland, Finland, Norway, and Sweden; the granites and marbles of Canada; the travertine of Italy; and the onyx marble of Mexico.

Definition of Terms, Grades, and Specifications

Naturally occurring rock material cut, shaped, or selected for use in blocks, slabs, sheets, or other construction units of specified shapes or sizes, used for external or interior parts of buildings, foundations, curbing, paving, flagging, bridges, revetments, or for other architectural or engineering purposes is termed *dimension stone*. This term is also applied to quarry blocks from which pieces of fixed dimension may be cut (*3*).[2] Aggregates combined with cement to form building units, terrazzo granules, facing granules, and reconstituted or synthetic marbles and granites are not considered dimension stone. Marble, granite, limestone, and sandstone provide the bulk of dimension stone, although slate, diorite, basalt, diabase, and others are used locally or for specific purposes. *Marble* denotes a metamorphic rock composed essentially of calcite, dolomite, or a combination of the two, but long usage of the term by the quarry industry also includes serpentines, alabaster, onyx, travertines, and some granites. *Granites* are essentially fine to coarse-grained rocks of igneous origin with quartz and feldspar as the major components and as accessory minerals the various micas, pyroxenes, and olivine. A German definition limits the term granite to one composed essentially of quartz with equal parts of biotite and muscovite mica, but quarrymen customarily include with the granites, quartz-diorites, syenites, quartz-porphyries. Gabbros, schists, and gneisses. *Limestone* is a sedimentary rock composed of calcium carbonate. Usage includes under this term dolomitic limestone or dolostone, oolitic limestone, and crystalline limestone. Some highly crystallized limestones can be polished and are properly termed marbles. *Sandstones* are composed of quartz grains cemented with calcium carbonate, iron oxide, clay, feldspar, or silica. *Quartzites* are composed of silica grains so firmly cemented by silica that fracture occurs through the grains rather than around them. The term *freestone* although commonly understood to refer to a free-splitting sandstone is somewhat ambiguous and is also applied to a number of other sedimentary rocks. In addition to stone cut or shaped according to architects or builders specifications, the Building Stone Institute defines a number

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

of other units (*8*). Rectangular blocks having sawed, planed, or rock-faced surfaces are termed *ashlar*. Rough, irregular pieces of broken stone, partly trimmed, squared, or irregular are called *rubble*. Large irregularly shaped stones, used for facing bridge abutments and breakwaters, are termed *riprap*.

Because stone is a natural product, blocks from various quarries, and even from different ledges within the same quarry, vary greatly in texture, color, and durability, and for that reason architects and builders desire freedom in selection. Therefore, architectural specifications relate primarily to workmanship and surface finish, and engineering specifications are concerned with strength and durability. The stone is usually selected by the purchaser from samples and brochures furnished by the producer, and with due consideration given to the reputation of the stone and dealer. For massive buildings the ability of the quarryman to furnish large tonnages of stone having uniform color, texture, and soundness is fundamental.

The desirable properties of dimension stone, in addition to those relating to workability and the tests that measure it, depend upon whether the stone is to be used for interior or exterior work. For interior use, desirable properties include attractive color and texture, reasonable strength, and resistance to abrasion and cleaning solutions. Exterior building stones, if ornamental facing veneers are excepted, may be less attractive in color than those used for interior trim, but must have greater resistance to daily and seasonal changes in temperature, freezing of water, and atmospheric contaminants.

Long-term use of either interior or exterior stone, under a variety of environmental conditions, indicates durability under similar conditions, and may show its suitability for a particular purpose. However, conditions are subject to change, for example, when coal replaced wood for heating and industrial uses many European cathedrals deteriorated rapidly. Furthermore, the application of the time test alone may prevent many good stones from being considered as construction material. In order to forecast the probable behavior of new stone, the National Bureau of Standards and others have conducted research and devised tests to determine resistance to abrasion, fire, atmospheric acids, and solubility in water, as well as methods to determine the physical properties of strength, porosity, toughness, elasticity, and density (*5–7*). The American Society for Testing and Materials Committee C–18, Natural Building Stone, is presently engaged in developing specifications and test methods for a wide variety of dimension stones.

Specifications have been established for stone used in Federal buildings and are itemized in a 13 page pamphlet entitled Stone Work, issued by General Services Administration, Public Buildings Service, May 1955. The specifications indicate the physical and chemical properties required and cover the dimensions, design, surface finish, workmanship, and methods for setting.

For non-government construction architects or builders may prepare specifications, but more often they are guided by specifications prepared by the various building stone institutes or associations with such modifications as may be mutually agreed upon.

Monumental stone specifications, particularly for Federal cemeteries, are most exacting, and only stone of highest quality is used. The stone must be free from such flaws as cracks, hairlines, iron spots, and other blemishes. Texture and color must be pleasing, and the stone must usually be able to take and maintain a high polish with good contrast between polished and hammered surfaces. The arrises, developed in carving, must be sharp and free from any tendency to crumble. Demands for color and style in memorial stone are continually changing factors. For these reasons waste in production of memorial stone may amount to as much as 85 percent.

Technology

Geology

Among the geological features of a rock that are significant in its use as a dimension stone are jointing, sedimentary stratification, and secondary cleavage. Nearly all rocks are jointed. The joints may be open and conspicuous or closed and almost imperceptible. Closed or incipient joints cause planes of weakness known variously as rift or gain which largely determine the shapes of the blocks which may be extracted from a quarry. Where properly distributed they may facilitate quarrying; in other cases they may prohibit extraction of large-sized blocks. Some rocks of otherwise good qualities are so cut by joints that they are useless for anything but crushed stone. The bedding planes of sedimentary rocks also influence the utility of stone and like joints may be useful or disadvantageous. The secondary cleavage of some rocks enables them to be split into uniform slabs.

The durability of a rock depends in part on its perviousness to water, which may enter along bedding planes, fracture planes, or through minute pore spaces between the mineral particles. The water may cause chemical changes

or by freezing and thawing cause the rock to weaken and disintegrate. For this reason the less pervious rocks usually have greater durabilty.

As minerals resist weathering to different degrees, the mineral composition of a rock is a factor in determining its durability. Abundant mica, especially where segregated along the stratification planes, permits easy splitting of the rock; it may weather more quickly than surrounding minerals giving a pitted appearance. Flint or chert in abundance is deleterious to limestones and marbles because, being more resistant, it stands out in relief on weathered surfaces, interferes with smooth cutting and polishing, and often causes the rock to splint along the lines of the flint inclusions.

Mining and Milling

Methods for quarrying dimension stone vary according to the type of rock, depth of the deposits, and ultimate use. The damaging effect of explosives on dimension stone has been recognized for many years, and blasting is avoided wherever possible. The usual procedures followed are to cut the stone from the quarry face into large blocks with channeling machines or wire saws, undercut the stone at floor level, break the stone free by wedging, and turn the stone down on piles of rubble or old tires by use of a derrick. The mass of stone is then cut into blocks of the desired size by drilling and wedging, and the blocks are hoisted from the quarry by stifleg derricks. Common limestone mill block sizes are 10 by 4 by 3 feet and 10 by 4 by 4 feet.

To obtain primary separation from ledges, most quarriers of granite and structural sandstone prefer drilling and broaching. Deep holes are drilled close together in a straight line, usually with detachable tungsten carbide bits and hollow drill steel, and the partitions between the drill holes are removed with broaching tools. The most modern method for cutting out granite blocks utilizes an oxygen-kerosine jet flame, but many quarries make the primary cuts with the wire saw. Wire sawing equipment consists of one- and three-strand wire cables, up to 16,000 feet long, running over pulleys as a belt. When fed by a slurry of sand and water, and held against the rock by tension, it cuts by abrasion. The wire saw conserves power, labor, and stone (*2*).

Quarrying marble, limestone, and softer sandstone is usually accomplished by the use of electrically powered channeling machines that operate by a chopping action upon three to five steel chisels, similar to that of a reciprocating drill. As the machine travels back and forth upon a track it makes channels about 2 inches wide and 4 feet apart. After the cut is made blocks are separated at the quarry floor by wedging, and further divisions are made by plug and feather splitting (*1*).

In the mill dimension stone blocks are cut to predetermined shapes as specified by the contract. The various machines for sawing, planing, jointing, grinding, turning, and fluting have a resemblence to those used in the wood working industry, except that the saws are set with diamond teeth and the other operations utilize silicon carbide grinding wheels. Pneumatic hoists and wheeled conveyors now minimize the amount of physical labor required. Carving operations require the most skill. Large statues are carved using pneumatic hand tools, with reference to plaster models, but smaller repetitive designs are frequently carved free hand by operators who have long experience. Designs and inscriptions for memorial stones are cut from drawings on plastic sheets. The sheets are then cemented on the previously polished stone and sand or shot blasting cuts the design into the sections of the stone not protected by the plastic sheet.

The quarrying and milling of dimension stone have been covered in detail in Bureau of Mines publications. Later information is given in "The Stone Industries" (*2*), and in "Industrial Minerals and Rocks" (*1*).

Uses

Dimension stone is used as building stone, monumental stone, paving stone, curbing, and flagging.

Although with the advent of steel and concrete construction, the dominant position of dimension stone for load-bearing structural uses declined, the industry has adapted to the changes, and emphasis is now placed on the economical production of thin slabs of veneer for both interior and exterior application. Furthermore, although granite and marble continue to be held in highest regard for facings because they are colorful and can take and retain a high polish, the more drab limestones and sandstones are now produced with many varieties of textured surfaces which are attractive to architects and are in increasing demand.

Memorial stones have the highest unit value. Included under this category are tombstones, statuaries, and grave markers. Mausoleums, sarcophagi, and commemorative memorials are fundamentally structural units, and although the quality of stone entering into their construction is similar in grade to monumental stone, in other aspects they are dissimilar.

Flagstones are used around small commercial buildings and residences for decoration, utility, and lawn protection.

The use of surface plates for high-precision measurements in machine shops and instrument work has become standard practice. These plates are made from granitic or basaltic rock of various types, although the generic name is *black granite*, and are extremely hard, nonwarping, rust-and-corrosion proof, and dimension changes are slight under variations in temperature.

Byproducts and Alternate Materials

Byproducts consist of quarry blocks, which have been rejected because of structural flaws or blemishes, and spalls or fines produced during trimming or shaping operations. Rejected blocks are sometimes used for breakwaters and revetments, and other waste material is used for riprap and roadstone. Waste marble and limestone is often burned for lime or ground and used for whiting and as mineral fillers.

Waste, which in many places amounts to 80 or 90 percent of quarry production, is an ever-present problem for producers, and in some areas the piles of waste accumulated during the years cover valuable deposits of dimension stone and make recovery costly.

Building stone has been replaced to a large extent by concrete, glass, brick, stainless steel, aluminum, porcelain enameled steel, and plastics. The put in place cost of many of these alternate materials is lower than that of stone, but stone is still preferred for the more dignified buildings where its architectural adaptability, permanence, and prestige are of prime importance.

Reserves

Although rock formations suitable for dimension stone are numerous, those having the requisite qualities that can be commercially exploited are commonly confined to restricted areas. Nevertheless, in the major producing districts the reserves are apparently adequate for many years' operation. No definite reserve figures are available.

Sources of Statistical Information

Statistical data of the industry are obtained from the individual producers and compiled annually by the Bureau of Mines. As Bureau figures are based on actual sales of quarry products, these products are recorded at the point where they first enter trade. If the quarryman sells stone in rough blocks, his sales are so recorded. If he owns a processing plant and fabricates the rough blocks into finished building stone, the sales of the finished products are recorded. Part of the Bureau's data pertain to the rough-block stage of preparation and part of them to the finished-product stage. Hence the total value of production indicated by Bureau figures represents a combination of the two stages.

Substantial quantities of stone enter foreign trade. Import and export data are compiled from records of the U.S. Department of Commerce.

Production, Consumption, and Trade

Although unique types of dimension stone, or those used for special purposes may be shipped appreciable distances, the usual marketing areas are restricted because of the relatively high cost of transportation, packaging, and handling. Production and consumption of dimension stone are virtually synonymous, although stocks of blanks for memorial stones are maintained by both producers and dealers.

Building and ornamental stones, both quarry blocks and finished stones, are imported in substantial quantities by domestic quarrymen and by importers. Imports are valued at about $20 million per year. Most of the imports consist of marbles from Italy, Spain, France, Greece, Portugal, Belgium-Luxembourg, and Mexico. Exports of building stone, chiefly to Canada, are approximately $1.6 million per year. Granite and other igneous rocks are imported from Finland, Sweden, and Canada. Travertine is imported from Italy, and onyx marble from Mexico.

Tariff regulations on stone are very complex because they involve many varieties, several stages of manufacture for each variety, and tariff changes from time to time. Tariff information on dimension stone can be found in the Dimension Stone section of "Industrial Minerals and Rocks" (1).

Prices

Compared with other building materials, prices of stone are relatively high because stone is difficult to work and requires many hand operations. Also, because of its high unit weight, transportation expense adds substantially to the delivered cost. Price increases of stone in the past decade have not advanced out of proportion with those of other materials.

Transportation

Because of the weight, bulkiness, and handling difficulties of the product, transportation expense adds greatly to the unit delivered cost. Freight is an important factor in competitive marketing, although stone is commonly shipped long distances to satisfy special architectural demands.

TABLE 1.—*Dimension stone sold or used by producers in the United States, by kinds*

[Thousand short tons and thousand dollars]

Kind of stone	Quantity	Value	Quantity	Value	Quantity	Value
	1954–58 (average)		1959		1960	
Granite	591	$24,944	654	$26,588	600	$28,773
Basalt	73	391	14	377	14	365

Research

Research by the dimension stone industry and manufacturers of machinery has resulted in improvements in methods for extracting and shaping stone. Installed costs have been reduced by the development of modular units and precast sections, and a wide variety of surface finishes have been made available. The larger companies have conducted research on increasing durability of their products, adaptability of stone for interior and exterior work, and color stability. Associations of memorial stone producers have conducted marketing research programs designed to improve the quality of stone offered to the public and to increase the dependability of dealers. Diamond set gang saws, capable of cutting 40 or more sections of veneer stone at once, have resulted from industrial research.

A few educational institutions have conducted research on dimension stone, particularly on the problems of utilizing waste products. The National Bureau of Standards has conducted research on the physical and chemical properties of stone, its durability and on development of test methods by which various stones can be evaluated (*5–6*).

TABLE 3.—*Annual average value of dimension stone in the United States*

[Per cubic foot]

Year	Building stone (dressed)				Memorial stone (rough and dressed)	
	Granite	Marble	Limestone	Sandstone	Granite	Marble
1954–58 (average)	$7.62	$10.18	$2.62	$2.67	$5.61	$11.80
1959	9.20	12.20	2.69	2.97	5.67	16.56

1963	10.55	13.03	2.89	3.40	5.88	14.92

OUTLOOK

It appears unlikely that the dimension stone industry will, in the near future, approach the production volume of the pre-World War II era. Three factors limit production: (1) increasing demand by builders for more efficient structures with greater rental or usable space—obtained by functional design, modular construction units, and elimination of dimension stone as a load-bearing material—and with esthetic values gained through use of horizontal and vertical lines rather than the heavy columns and monolithic carvings common some years ago; (2) continuing competition from alternate building materials such as glass, metals, ceramic tiles, plastic panels, and precast concrete panels faced with exposed aggregate, colored glass, or mosaic tile; and (3) continuing growth of memorial parks and similar types of cemeteries which restrict or prohibit use of monuments and private mausoleums, thereby adversely affecting the segment of the dimension stone industry that produces monumental stone.

More favorable trends are seen in the growing use of dimension stone panels and veneers as independent units of construction to protect interiors of buildings from the weather and to give attractive exteriors. New efficiencies in cutting thinner stone slabs, combined with the development of insulating panels faced with ornamental stone veneers, should also increase demand for dimension stone. The increased use of crushed and graded stone for exposed aggregate panels should enable dimension stone quarries to dispose of some waste material at a profit. Improved methods for attaching panels to structures make this sector of the industry more competitive by lowering labor costs.

PROBLEMS

Specifications and standard tests by which durability of stone may be forecast are either unavailable or not generally accepted as valid. There appears to be no significant correlation between compressive strength tests and durability, either in surface behavior (architectural appearance) or bulk behavior (engineering use). Present accelerated weathering tests based on resistance to freezing and crystallization tests such as the sodium sulfate soak are unreliable. The standard Los Angeles and Deval tests give insufficient information for rating building stone.

Present methods of producing dimension stone yield a high percentage of waste which can be disposed of only on a highly competitive market after costly additional processing.

The lack of dimensional standardization increases cost of many building stone units. Costs remain high and broad use of dimension stone is restricted because mechanization of stone processing plants and development of methods for quantity production have lagged.

Lack of uniform terminology causes confusion among producers, builders, and architects.

Spalling, discoloration, and fracturing of stone after it is in place are continuing sources of concern and tend to lessen confidence in durability of some stones.

The industry, in general, lacks complete knowledge of many modern materials that may be used to seal porous stone for protection against weathering and decay.

The principles involved in cleaning stone buildings, and the deleterious effects of some techniques now in general use, have received insufficient consideration.

Continuing problems are those relating to increasing efficiency of drilling, blasting, sawing, shaping, finishing, and handling stone.

SLATE

Slates are argillaceous rocks of sedimentary origin which have the common property of splitting readily in thin plates.

Because of increased competition from a wide variety of lower priced substitutes, markets for most uses of slate have been declining for many years.

Utilization of the enormous dumps of waste slate and increased efficiency in production methods are vital to the industry.

BACKGROUND

Size, Organization, and Geographic Distribution of the Industry

In 1963 there were 49 slate quarry operations in the United States. There are two branches of the industry which are not only virtually independent of each other, but are to some extent competitive. One branch comprises the preparation of roofing slates and millstock of various kinds. The other prepares slate granules used on composition roofing, slate flour for fillers, and lightweight aggregate. Total sales of the two branches are about $11 million per year.

The slate industry is centered in four principal locations: Lehigh and Northampton Counties, Pa., near Bangor, Pen Argyl, Windgap, and Slatington, Pa.; Monson, Maine; New York-Vermont area near Granville, N.Y., and Poultney, Vt.; and Buckingham County, Va.

Slate has also been produced on a small scale in Arizona, Arkansas, California, Georgia, Michigan, Tennessee, and Utah.

Definition of Terms, Grades, and Specifications

Slate is a fine-grained metamorphic rock that has a more or less natural cleavage, which permits it to be split readily into thin smooth sheets. The most common slates are dark gray to black, owing to carbonaceous material present in the original muds, but other varieties may be light gray, red, green, or purple. The average slate contains over 50 percent silica, 15 to 20 percent alumina, and smaller amounts of iron (hematite, pyrite, or magnetite), carbon, sulfur, and other elements.

Electrical slate is principally of the mica variety and should have high mechanical and dielectric strength, be readily machinable, and have low porosity. Structural slate, used for sanitary purposes, laundry tubs and sinks, must also have a low porosity, and for floor tile, steps, and flagging a high transverse strength is required. Blackboard slate specifications usually require that the material be free from blemishes or other imperfections. Roofing slate is sold in squares. A *square* is a sufficient number of any size to lay 100 square feet of roof, allowing the standard 3-inch lap. The estimated weight of a square of ¼-inch slate is 1,000 pounds.

Strength, porosity, bulk density, color fastness, resistance to weathering, and cleavage are the factors which determine suitability of slate for roofing.

The standard Federal specification for roofing slate is designated Slate; Roofing, SS–S–451, dated July 26, 1932.

The term *ribbons* applies to wavy or banded structures that appear in certain slates, notably those in Virginia and Pennsylvania.

The term *millstock* includes all forms of structural slate used in exterior or interior construction.

Technology

Geology

Slates were originally deposited in shallow water as fine, even-grained muds composed of very fine particles of clay. The early layers were compacted into a dense, bedded rock by the weight of accumulated sediments, and eventually heat and pressures induced by earth movements, developed in the beds a tendency to part along even planes. It is this property which is termed "slate cleavage" (*1*). During this process of metamorphism certain chemical changes occurred in the particles, which composed the original clay, and these changes also assisted in the development of parting planes by orienting the particles in positions normal to the direction of pressure.

Mining and Milling

Slate is usually obtained from open quarries. In Pennsylvania where the beds are nearly vertical and the slaty cleavage dips 5° to 15° from horizontal, the quarries are deep and relatively narrow. A maximum depth of 700 feet has been attained and depths up to 450 feet are not uncommon. Open bed planes known as loose ribbons commonly make quarry walls. In the absence of loose ribbons quarry walls are maintained as far as possible parallel with, and at right angles to major joints. In the New York-Vermont area where slaty cleavage dips at angles of 40° to 50°, quarries are wider and shallower. In Virginia where the slaty cleavage is almost vertical the quarries are deep and wide. In Maine where the major commercial slate bed is narrow and nearly vertical, underground shaft mining is followed.

Primary cuts in the Pennsylvania quarries were made originally with channeling machines which travel back and forth on a track and cut a channel with reciprocating chisel-like bars. In 1926 the Bureau of Mines assisted the industry in introducing the wire saw. When fed with a slurry of sand and water, and held by tension against the rock, it cuts by abrasion. This equipment replaced channeling machines in the Pennsylvania slate region, but it has not

been adopted in other slate-quarrying centers. In the New York-Vermont area and in Buckingham County, Va., primary breaks are made with small charges of explosives in drill holes, advantage being taken wherever possible of open joints and bed seams.

Experiments are being made by the industry in the use of diamond circular saws for making primary cuts in quarries, but no definite results are yet available.

At quarries where roofing slate is made, the quarry blocks are subdivided by drilling and wedging parallel to the slaty cleavage and rift, which is a second direction of splitting less pronounced than slaty cleavage and usually at right angles to it. In the third direction at right angles to both slaty cleavage and rift there is no tendency to split. It is known as the hard way and designated locally as the *sculp*. The slabs of slate split on cleavage and rift to the desired dimensions are usually broken by sledging in the sculp direction, but sometimes they are cut to length with circular saws. The splitters take the blocks that have been reduced to the thickness of eight slates, and split them into roofing shingles with a thin chisel and mallet, always splitting in the center of each block and subdivision thereof. The trimmer takes the shingle from the splitter and trims it to the largest commercial size obtainable. A common trimming machine has a straight blade operating like a paper cutter.

Blackboards, electrical panels, table tops, sinks, and all types of structural slate products such as steps, baseboard, and window sills are made in mills usually equipped with overhead traveling cranes of about 5-ton carrying capacity. Quarry blocks brought to the mill are first measured and marked according to the sizes required for the uses for which they are best adapted. They are then placed on saw beds and cut to size. Saws range from 24 to 48 inches in diameter and make cuts about ⅜-inch wide.

Uses

For generations, both in Europe and the United States, virtually the only use for slate was for roofing. Some slate roofs built in the eighth century are still compact and weather resistant. If the cost of slate roofing could be brought within the range of other types of roofing many people would prefer it to tiles, asphalt shingles, and asbestos shingles. Deterrents to greater use of slate roofing, in addition to the prime cost, are cost of installation, and the extra strong framing and roof trusses required for support. Millstock is used in exterior or interior construction as veneer, mantels, lavatory slabs, electrical panels, laundry tubs, billiard table tops, grave vaults, and blackboards.

Byproducts and Alternate Materials

Waste slate when ground to a fine powder is used as a filler in putties, linoleum, wallboard, abrasives, polishes, ceramic ware, and paints. Slate, crushed and screened to obtain minus 8-mesh, plus 35-mesh particles, is used for roofing granules. Small amounts of waste slate are bloated at a temperature of approximately 2,000° F to form lightweight aggregate.

Slate has to meet competition from many sources. As a roofing material, alternates such as sheet metal, wood shingles, asbestos-cement shingles, tiles, rolled roofing, and built-up roofing are available. For blackboards it competes with colored glass, porcelain enameled steel, and special painted surfaces. For electrical panels, marble, soapstone, and plastics are in competition, and for other structural uses, marble, granite, limestone, sandstone, and concrete products are readily available.

Even the waste products, such as slate flour and expanded slate, must meet competition from ground marble, silica, limestone, and expanded shales and clays.

Reserves

No systematic exploration of slate deposits has been made in the United States. From the geology of the Pennsylvania formations, as described by Behre, the deposits of commercial slate are evidently extensive enough to maintain the industry at current rate of production for many years. The resources in New York, Vermont, Maine, and Virginia are also extensive, although unmeasured.

Sources of Statistical Information

Statistics of the domestic slate industry are compiled annually by the Bureau of Mines. Data on imports and exports are assembled by the Bureau from figures compiled by the Department of Commerce. Foreign statistics are available for some countries, notably Great Britain.

Production and Consumption

Production and consumption of slate are virtually synonymous as stocks are moderate and more or less constant. The domestic industry has adequate facilities to supply all demands for slate, although temporary shortages may develop at times for certain types due to

unforeseen demands, for example, an abnormal call for roofing slate after a hurricane. Slate is predominantly a peacetime industry. Wars tend to depress rather than stimulate production.

Statistical data on slate can be found in the dimension and crushed stone tables of this chapter.

Prices

The average reported price for slate roofing squares, in 1963 was $24.26, approximately the same as in 1958. Millstock prices increased from 89 cents per square foot in 1962 to 95 cents in 1963. Flagstone prices, because of competition from many small local producers, remained about the same; 13 cents per square foot. Granules (including crushed slate for lightweight aggregates) declined in average value from $11 per ton in 1958, to $4.42 in 1963.

Research

Continuing research on production methods and utilization of waste is conducted by the College of Mineral Industries, Pennsylvania State University. Results of research are published as phases of the program are completed (*10–13*).

Research was conducted by the Bureau of Mines in conjunction with the industry and the National Slate Association beginning in 1926 and individual tests on bloating abilities of slate are made at the Bureau of Mines, Norris Metallurgy Research Laboratory, Norris, Tenn. Results of other research are described in Bureau of Mines Technical Paper 469.

OUTLOOK

Indications are that production of dimension slate will continue at the same low level that has been maintained for the past 5 years. For most uses of slate alternate materials are available at lower prices. Moderate increases may be expected in slate production used for lightweight aggregate and for mineral fillers. The expected increase in construction of schoolrooms, which could expand demand for slate blackboards, has been delayed because of reluctance of many communities to vote bond issues. Some increase is expected in demand for modular rubbed or riven slate veneer for curtain walls and interior flagging. This may offer an outlet for some types of slate that split unevenly.

PROBLEMS

Slate production is handicapped by falling demand and high production costs. Disposal of waste, approximately 90 percent of output, continues to be one of the most vital problems of the industry. Not only does this enormous proportion of waste increase cost of producing usable stone, but the huge waste dumps cover deposits which might be worked at a latter date.

Reluctance or financial inability of the industry to change from outmoded manufacturing methods and to adapt methods for winning and processing slate which have demonstrated their worth in other divisions of the stone trade tend to keep production of dimension slate a craft industry with accompanying high costs.

Again, higher labor costs, a direct result of lack of practical slate splitting devices, contribute to the decline of roofing slates, formerly the chief product of the industry.

CRUSHED AND BROKEN STONE

Crushed and broken stone, a basic construction, chemical, and metallurgical raw material, is a major commodity in both tonnage and value. Limestone is the most important rock, accounting for about 71 percent of the total crushed stone production. Large quantities of basalt, granite, and quartzite or sandstone also are used.

Accelerated highway and industrial construction are major factors in the increasing demand for crushed and broken stone. The bulk of stone production goes into construction projects; the remainder is used in cement manufacture and for chemical, metallurgical, and agricultural purposes.

The industry will continue to grow approximately at the same rate as the national population and economy. Its growth closely parallels trends in such basic economic indicators as gross national product, value of construction, and population.

Various types of this low-value commodity are produced in many sections of the country. Reserves are being depleted at a high rate, but adequate sources of supply remain although at progressively greater distances from consumption centers.

The competitive position of crushed stone in relation to sand, gravel, slag, and lightweight

aggregates makes cost control a major operating requisite. Quality control is also an important factor—rigid requirements have produced many different specifications for crushed stone for various purposes. Zoning regulations continue to be a serious factor because they handicap the utilization of deposits close to metropolitan areas and require the development of more distant deposits.

Other perennial problems relate to improving mining and beneficiation techniques, research on blasting practices to reduce damage from vibrations, transportation, and exploratory methods and equipment.

BACKGROUND

Although stone has been used as a building material since prehistoric times, the use of crushed stone has been greatly accelerated in recent years. A century ago Eli Whitney Blake's invention of a mechanical stone crusher gave impetus to volume production of crushed stone. Demand for macadamized roads began to increase slowly, but highway markets for crushed stone have developed within the last half century as a result of need generated by increasing use of rubber tired motor vehicles. Rigid and flexible pavement construction required machine-produced stone in ever increasing quantities. Rapidly, other markets for crushed stone also developed, such as portland cement, railroad ballasts, fluxstone, agricultural stone, and in the metallurgical and chemical industries.

At the turn of the century, sales of stone for road-building, railroad ballast, and concrete aggregate totaled about 25 million tons, but in 1963 it reached more than 451 million tons for these same purposes. Crushed stone in 1963 for all purposes totaled more than 685 million tons valued at $972 million at the point of production.

Size, Organization, and Geographic Distribution of the Industry

There are over 3,000 commercial crushed stone plants scattered over the Nation and the number and size have been increasing in recent years. The general trend has been toward an increase in the number of plants in the larger size groups and in a larger percentage of the total production by those groups. Plants producing over 900,000 tons annually account for about 3 percent of the total number of plants and about a fourth of the total tonnage. The 328 largest plants supply 51 percent of the commercial total. The portable plant is also becoming more important within the industry. Some plants produce stone for only one purpose such as roadstone or concrete aggregate. Others, particularly limestone producers, may market products meeting physical and chemical specifications for several diverse end uses.

In contrast with strictly commercial operations, numerous noncommercial operations are reported by States, counties, municipalities, and other government agencies as being operated by themselves or by contractors for consumption by these agencies. Noncommercial producers are on the increase owing mainly to the expanded highway program and the tendency for the contractor to maintain his own portable plant.

The industry exists in every State of the Nation. As one might expect, leading industrial States with large population report the largest production and use of the industry product.

Granite rocks, used for the production of mineral aggregates, are found in widely scattered sections of the country. Production of crushed granite is greatest in the mountainous Eastern and Western States, where granite terrains are common. Basalt, and similar igneous rocks, are quarried extensively in the Connecticut Valley, New Jersey, Pennsylvania, several sections of the Piedmont in the East, the Columbia Plateau, certain sections of the western ranges, and in Hawaii. Certain siliceous rocks, such as quartzites and sandstones, are quarried extensively in Arkansas, West Virginia, California, Pennsylvania, Texas, South Dakota, Wisconsin, and Minnesota; other desirable metamorphic materials are found in the Piedmont sections in the East and in many of the mountainous regions of the country. Limestone is the most important sedimentary rock used for crushed stone. It occurs extensively throughout the Valley and Ridge province of the East, throughout the Middle West, Kentucky, Tennessee, the Ozark Plateau widely scattered areas in the Great Plains and some small areas of the Far West. Marl, shell, slate, and marble are also crushed and used to some extent in a few States where local supplies are available.

Definition of Terms, Grades, and Specifications

The term *crushed and broken stone* is applied to irregular fragments of rock crushed or ground to smaller sizes after quarrying.

The terms traprock and granite are used in the broadest sense in the crushed stone industry. *Traprock* includes all dense, dark, and fine-

grained igneous rocks such as basalt, diabase, and gabbro. *Granite* includes the coarser grained igneous rocks such as true granite and syenite. Gneisses, although classified as metamorphic, are usually included with granite. *Quartzite* is normally considered a siliceous cemented sandstone which is indurated to the extent that when fractured it breaks across the grain. However, the term is sometimes applied in the industry to less indurated materials. Ordinarily a carbonate rock is classified as *marble* by the industry if it will take a polish although in the strict geologic sense it might be classified as a *limestone.*

Riprap consists of heavy irregular rock chunks used chiefly for river and harbor work, such as spillways at dams, shore protection, docks, and other similar construction that must resist the force of waves, tides, or strong currents. It is also used to fill in roadways and on embankments.

Terrazzo consists of small chips or pieces of stone, usually marble or limestone, about one-half to three-fourths inch in diameter, made by crushing and screening. Terrazzo chips are used with portland cement in making floors, which are smoothed down and polished after the cement has hardened.

Fluxing stone used in iron blast furnaces and foundries consists of pure limestone or sometimes dolomite. Usually material below 2 inches in diameter is eliminated. The most desirable size is between 4 and 6 inches.

True whiting is a finely divided calcium carbonate prepared by wet grinding and levigating natural chalk, a variety of limestone. *Whiting substitute* is a finely ground calcium carbonate, about 98 percent pure, contaminated by magnesia, silica, iron, or alumina, and should not be confused with chalk whiting or precipitated chalk.

Refractory stone consists of sandstone, quartzite, mica schist, soapstone, or other rock that will withstand a moderately high temperature without fusing, cracking, or disintegrating. It may be used in solid blocks or crushed and mixed with a binder to form bricks.

Stucco dash and exposed concrete facing consists of various types of stones, usually white or brilliantly colored, crushed to $\frac{1}{8}$- to $\frac{3}{8}$-inch size range.

Chicken grit is commonly composed of oystershell, limestone, and marble, although other materials, such as granite and feldspar, are sometimes used.

Agricultural stone is finely ground limestone used as an alternative to lime to neutralize or reduce acidity of soils.

Increasingly rigid requirements resulting through evolution of technical design have produced many different specifications for crushed stone. In the construction field alone, many volumes have been written on specifications, testing, and test methods by such organizations as the American Society for Testing Materials and American Association of State Highway Officials. In brief, the basic physical properties of aggregates, that affect their behavior when used for various structural purposes, include hardness, toughness, resistance to weathering, shape, size, cleavage, density, composition, porosity, structure, and color. Chemical and industrial applications usually require uniform and specific chemical composition with low limits on impurities.

Quality control of aggregates is concerned with the presence of reactive materials, organic matter, iron staining agents, soft and slabby particles, adhesion properties, porosity, grading, and durability. When the extent to which the aggregate influences the quality of the concrete was realized, aggregate specifications for the various construction uses were gradually established. Specifications were held within fairly rigid limits to insure that the end product met certain prescribed standards. Acceptance tests were based upon specified procedures such as those promulgated by the American Society for Testing and Materials (ASTM), American Association of State Highway Officials, and others. The ASTM specification for concrete aggregates (*15*) illustrates the type of provision commonly included in commercial specifications. The most common tests to determine whether a stone is suitable for use as construction aggregates are those for soundness, resistance to abrasion, specific gravity, particle shape and fracture, soft particles, and gradation.

Generally, construction engineers demand stone that is clean, strong, durable, sound, and dense. This is particularly true with respect to its use as coarse aggregate. Most engineers purchase their stone on specifications based largely on physical properties. Many of these specifications differ widely, particularly with respect to the exact application of the stone and to a lesser extent to the geographical location. The presence of alkalies, soluble sulfides, gypsum, and organic matter in the stone is objectionable to most users. Other important considerations are the individual size and particle size range of the stone. As a result, many types of rock are unacceptable for one or more construction uses since they are unable to meet the requirements.

Technology

Geology

Rock, as used in engineering geology, means a compact, semihard to hard, mass of naturally occurring material composed of one or more minerals. Rocks have been, and are presently being, formed in various ways; by cooling of molten rock, by disintegration of other rocks and subsequent recombination of the resulting minerals to form new rock types, by intense action of heat, fluids and/or pressure on preexisting rock types, by precipitation from water, by deposition of shells, and by condensation of a gas containing mineral particles.

Raw materials for the crushed stone industry comprise rocks of all three groups—igneous, metamorphic, and sedimentary—and from all periods of geologic time.

The geology of a region affects the crushed stone producer in three different ways through its influence on the topography, structure, and materials of a given area.

The topography of the area, which influences the drainage, the location of transportation routes, and accessibility for mining, is directly related to the geologic history of the area.

The underground structure determines the accessibility of industrially valuable stone, the exploitation and mining methods that may be used, and the occurrence of underground water supplies.

The type, structure, composition, and hardness of rocks present may be relatively insignificant for some uses but vitally important for other.

Each stone deposit is unique and presents its own geologic problems. However, most geologic investigations of an area must include the following determinations prior to exploitation: (1) size, shape, and character of the deposit, (2) thickness and nature of overburden and the topographic conditions, (3) degree of uniformity in composition both vertically and laterally and type and nature of impurities (4) uniformity of physical properties, and (5) ground water table levels.

Mining and Processing

Though surface quarries can be operated at lower costs than underground mines, conditions do not always permit their development. The chief factors causing the development of underground operations are heavy overburden of earth and inferior rock; steeply inclined formation that results in an increasing depth of overburden in the direction of the dip; and exhaustion of surface deposits. Underground mining has the following advantages over most quarry operations: Avoidance of stripping; production of a cleaner stone free from overburden contamination; and protection of personnel from inclement wheather, permitting steadier year-round operations. Its disadvantages are it is usually more costly to mine and transport; there is a greater investment in equipment; and 20 to 25 percent of the rock must be left in supporting pillars.

A variety of mining and quarrying methods utilizing all types of equipment, both stationary and portable, are employed. In obtaining broken stone from both quarries and mines, the following series of operations is necessary: (1) stripping or driving underground entries; (2) drilling holes for explosives; (3) blasting the stone loose; (4) loading it into trucks and cars; and (5) conveying it to the crushers.

Each of these stages of production has many fundamental problems that must be solved in order to maintain crushed stone in the same low price range as competitive materials.

More detailed data on quarrying and mining stone can be found in "The Stone Industries" (*16*), the Crushed Stone chapter of the volume "Industrial Minerals and Rocks" (*24*), and in Bureau of Mines Information Circular 8184 (*17*).

The extent of processing required is governed by the use to which the crushed product is applied. For riprap, stone must be specially selected but comparatively little preparation is required. Most applications of stone require that it be prepared according to rigid specifications: Concrete and road aggregates must be crushed, cleaned, and graded to specified sizes; pulverized stone is frequently used in processes requiring a fineness of 65 to 100 percent passing a 200-mesh screen.

Shell is considered a part of the stone industry, but the mining methods are more nearly related to those used in the sand and gravel industry.

The preparation of crushed stone products involves a series of crushing, screening, and classification operations. The primary crushers normally employed are of the jaw or gyratory type; however, if the stone is relatively nonabrasive, impact crushers are sometimes used. It is common practice to install the primary crusher in the quarry or mine, conveying the crushed stone by belt to a surge pile outside the production area, which provides a source of supply in all types of weather and during quarry and mine shutdowns. Secondary crushing usually is achieved in cone crushers and high-speed gyratories. Hammer mills are also used on the less abrasive stone.

Many industrial applications of stone require an even finer gradation. Fine crushing

of the stone usually is done with gyratories, double-roll crushers, and rod mills. The swing hammer mill is also considered a fine grinder and is used to produce such products as agricultural limestone and poultry grits of relatively coarse size. The selection of grinding equipment is based upon the characteristics of the stone and the degree of fineness specified. Pulverized stone is generally produced in grinding mills—rod mill, ball mill, tube mill, or roller mill. Closed circuit grinding, along with air classification, is employed when extreme fineness is required. Owing to the low prices of stone products, the dry grinding process is preferred to the wet process and occasionally the stone is dried (in a rotary dryer) to assure better grinding operation.

Grinding or classification operations on the smaller sized stone normally employ screens of various types. Larger stone fragments are sized with bar grizzlies, steel mesh, and perforated steelplate. Air separation is employed in classifying fine particle-sized material.

Crushed and ground materials are usually transported through the plant by belt conveyor and bucket elevators; although drag, screw, and pneumatic conveyors are used occasionally.

In former years, crushed stone was seldom washed, but washing is becoming more generally practiced. A common method of washing, if the stone is merely coated with dust, is to use water jets upon the stone during its passage over the screens. Scrubbers, used to remove adhering coatings, consist of a cylindrical or conical shell fitted with lifting plates to agitate the material and carry it forward. Chains sometimes are suspended inside the shell to increase attrition.

Highly efficient portable plants, mounted on pneumatic-tired wheels, are becoming more popular in certain regions. Such plants are used in locations where freight rates on stone produced at permanently established plants make its cost prohibitive. One advantage of the portable or semiportable plant, in addition to saving transportation cost on stone, is that it can be moved from point to point on the deposit with the result that selective quarrying may be employed. Use of smaller crushers, however, requires greater fragmentation in blasting and is reflected by increased drilling and blasting costs. There is also frequently a waste in stone sizes that cannot be used on a specific project.

Uses

About 71 percent of the crushed stone produced is limestone which has a much greater variety of uses than other rocks. Large quantities are used for cement, lime, furnace flux, agriculture, and a great variety of chemical and industrial applications, such as alkali, glass, paper, and sugar manufacture. Table 4 gives quantities of stone sold by end use, in the United States, during the 1954–63 period. About 11 percent of the total consists of basalt (trap rock), about 7 percent granite, and the remainder sandstone, marble, shell, quartzite, marl, slate, and miscellaneous rocks. Concrete aggregate and roadstone are the major uses, consuming 64 percent of the total. About 14 percent was utilized as a cement raw material. Riprap, fluxing stone, and agriculture used about 4 percent each. Table 5 shows types of stone sold in 1963 by end use.

Byproducts and Coproducts

During the crushing process most crushed stone quarries produce an excess of fines that are sold as byproducts. The development of stone sand for use as fine aggregate has solved this disposal problem at many plants. Some quarries now produce fine materials exclusively. Often the weathered overlying rock that occurs at most quarry operations can be sold as "crusher run" material for use as road base. A number of dimension stone quarries and mines producing metallic ores process waste stone piles or tailings for sale as aggregates or other purposes.

The crushed stone industry is becoming more interested in diversification including concrete products, ready mixed concrete, and asphalt plants in order to sell service and to dispose of surpluses profitably.

TABLE 4.—*Crushed and broken stone sold or used by producers in the United States, by major uses*

[Thousand short tons]

Year	Concrete and roadstone	Cement	Flux	Agriculture	Calcined lime and dolomite	Riprap	Railroad ballast	Refractory	Other uses	Total

Alternate Materials

Sand and gravel and iron-blast-furnace slag are interchangeable with stone under many construction specifications; therefore, competition is very keen in areas where these occur together, and profits are usually held to narrow margins. Lightweight aggregates are moving into the field more and more, particularly where a saving in steel is desired. When high strengths are not required, a lightweight material comparable in price with stone can usually be furnished. Slag is competitive with stone in making cement and mineral wool.

Reserves

U.S. reserves are large but stone deposits of the character or quality required to meet specifications for a particular use are limited in some areas. Crushed stone is a high-bulk, low unit value commodity and its economic utility, therefore, is restricted by its ability to compete on a delivered price basis with alternate materials or sources. Availability and cost of transportation often determine whether a particular deposit is or is not a commercial reserve. For example, a new road, in addition to being a market for crushed stone aggregate, may provide a new transportation route to contiguous market areas where stone from a particular deposit could not previously compete because it was inaccessible. Local shortages in rapidly urbanizing areas exist owing to zoning restrictions imposed as build-up areas encroach upon existing quarries and because buildings occupy ground that otherwise might have been worked for stone in the future. This rapid expansion of metropolitan areas, however, is not all negative in its effect. As suburbs spread outward some quarries are forced out of business either because they are judged a nuisance or as land values spiral; but in the annular belt beyond the suburbs stone deposits, previously not economic, become profitable to operate as burgeoning markets are created by the nearby construction. The older inner core of the city presumably now built up and with less current need for aggregate must reach further out for stone supplies it is true, but with high land values in city centers, a rising cost for aggregate is not a limiting factor in determining project feasibility.

Metallurgical or chemical-grade stone is a special case with definitely restricted distribution of deposits. Discovery of new sources is becoming increasingly difficult and expensive. While no shortages exist at this time, judicious use of available stone should be practiced to ensure future supplies.

Sources of Statistical Information

Statistical data on stone are acquired by the Bureau of Mines from the individual producer and from government agencies. The smaller elements of the industry are sporadic in operation and transient in nature. Production and consumption of crushed stone are virtually synonymous, as stocks are moderate and more or less constant. Information is collected on various types of stone and the size and type of plant and productivity rates. Results of these compilations are published annually as a chapter in the Bureau of Mines Minerals Yearbook. A distinction is made between commercial and noncommercial production. Import and export data are furnished by the U.S. Department of Commerce.

Production, Consumption, and Trade

Crushed stone is a low-priced commodity and consequently most of it is shipped as it is produced, without extensive stockpiling. Some of it is stockpiled, however, to meet peak demands and to provide for the variation in demands for different sizes. There is not much variation in the total stocks carried, although the stockpiles are apt to be larger at the beginning of a construction season. There is very little difference in tonnage of stone produced and consumed during the year.

The accompany tables 4, 5, and 6 give the output of crushed and broken stone (including shell) in the United States, classified as to uses and types.

Imports of crushed stone are small. They consist chiefly of chalk and whiting from Europe and quartzite from Canada. Exports are small and consist mostly of limestone to Canada.

Tariff rates for crushed stone differ according to type and use of stone. In general, for important rock types, granite and quartzite are admitted free, limestone is subject to a duty of 20 cents per short ton, marble is 10 percent ad valorem, slate is 10.5 percent ad valorem, and stone not specially provided for is free. Rates for some types are somewhat higher if supplied by Communist nations.

Government Programs and Legislation

Federal safety standards must be adhered to by crushed stone quarry operators. Zoning legislation by State and local governments restricts the mining and processing of stone near cities.

Prices, Costs, and Productivity

Unit values are relatively low and have not advanced as much as prices of commodities in general. This is a result of the constant pressure applied by competition and the benefits from increased efficiency of production. The price of crushed stone at the plant is only slightly higher than 25 years ago and substantially below the average increase in costs of other construction materials. The average value per short ton reported in 1963 was $1.42. Depending upon type of stone, end use, and location, actual market prices varied appreciably. Prices for crushed stone used in concrete are published for individual market areas each month in Engineering News-Record.

Comparative costs of operations depend upon many variables including efficiency of management, type of deposit and character of the rock, mining method, condition of equipment, complexity of processing plant, distance from market, and volume of material sold. It is estimated that about 40,000 persons were employed by the crushed stone industry in 1963, indicating productivity in excess of 17,000 short tons per man year.

Strategic Considerations

Since crushed stone is vital to the construction, chemical, and metallurgical industries, crushed stone must be considered in mobilization planning.

TABLE 6.—*Average values per short ton of crushed and broken stone sold or used by producers in the United States, by uses*

Year	Concrete and roadstone	Cement	Flux	Agriculture	Lime and calcined dolomite	Riprap	Railroad ballast	Refractory	Other	Total
1954–58 (average)	$1.34	$1.05	$1.37	$1.64	$1.41	$1.27	$1.06	$6.60	$2.33	$1.37
1959	1.34	1.06	1.46	1.73	1.55	1.22	1.13	7.53	2.87	1.42
1960	1.35	1.07	1.45	1.72	1.56	1.36	1.15	8.12	1.67	1.41
1961	1.35	1.08	1.49	1.73	1.54	1.24	1.17	7.29	3.02	1.41
1962	1.37	1.11	1.45	1.70	1.68	1.15	1.21	8.01	2.70	1.43
1963	1.36	1.07	1.48	1.69	1.67	1.19	1.20	5.37	2.79	1.42

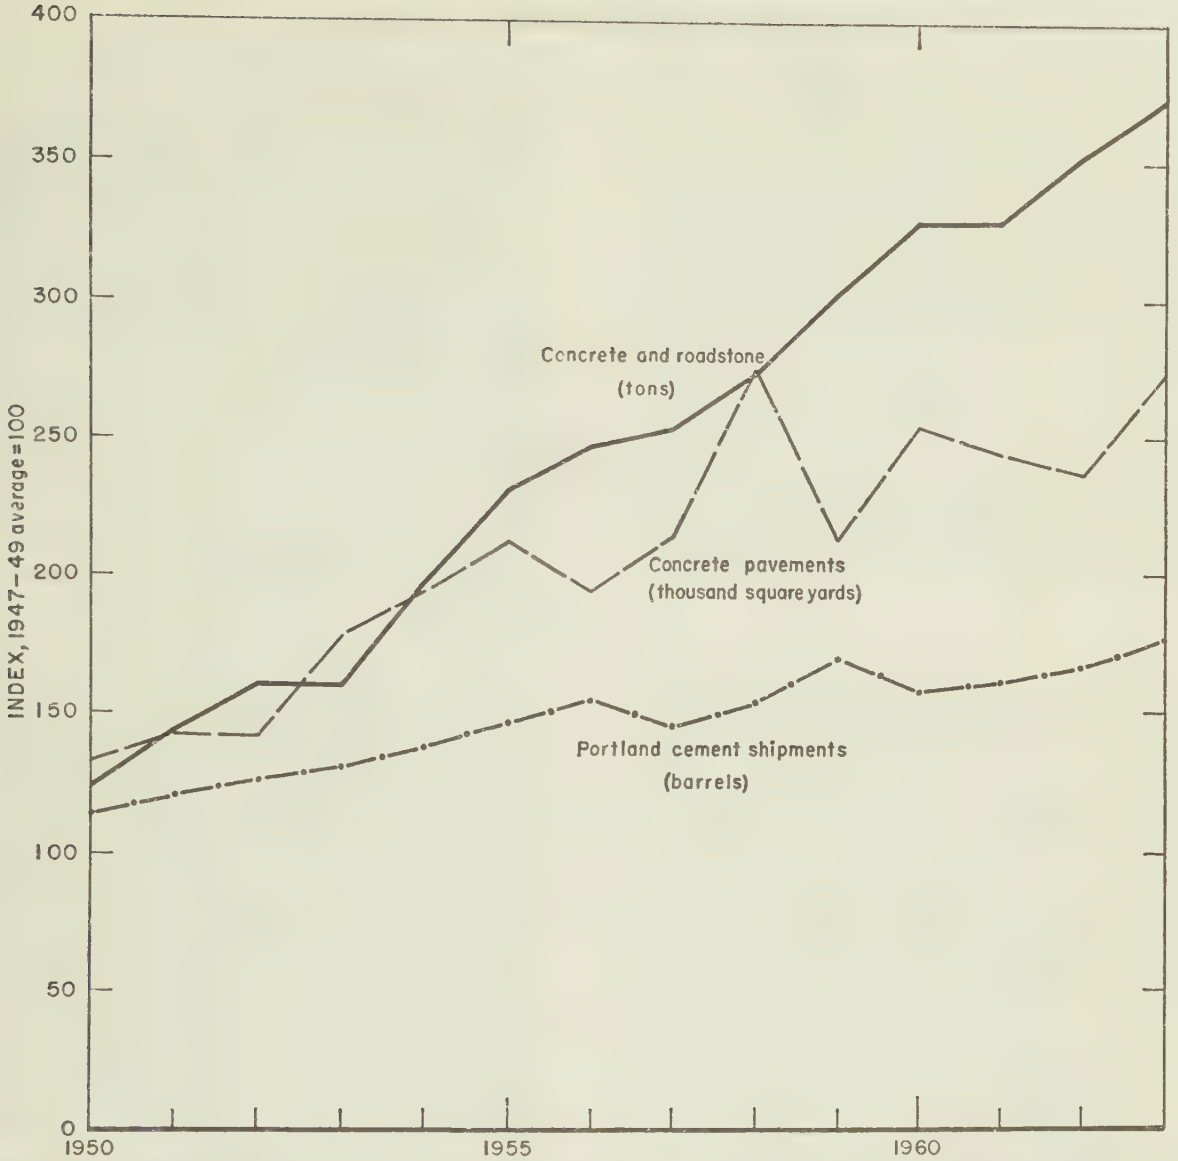

FIGURE 1.—Crushed-Stone Aggregates (Concrete and Roadstone) Sold or Used in the United States, Compared with Shipments of Portland Cement, and Concrete Pavements (Contract Awards, Thousand Square Yards).

(Data on Pavement Contract Awards from Survey of Current Business, U.S. Department of Commerce.)

The problems, however, do not evolve from raw material self-sufficiency. They are primarily in the fields of production capacity in localized areas or availability of transport and fuel to move essential stone to where it is needed.

Taxes

Crushed or broken stone is allowed a 5 percent depletion rate. Exceptions are chemical and metallurgical stone, which are granted the 15 percent rate.

Transportation

Crushed stone has a low value per ton; therefore, transportation is a major factor in the economics of the industry and sometimes makes up more than two-thirds of the delivered price. There has been a marked trend toward increased truck transportation for many years. It is conceivable that the railroads might win back some of their lost haulage as plants are removed farther from metropolitan centers. New railroad innovations such as unit trains

780-887 O—65——57

and articulated cars have lowered transportation charges in some instances and have served to help the railroads compete with highway haulage. On the other hand, the tendency toward utilization of portable plants has shortened the distance of transport. Imposed restrictions on the wheel loads permitted over highways prevent highway use of large capacity trucks used in some quarries. Water transport is of great importance in some areas, notably from the quarries of northern Michigan and in the New York City metropolitan area.

Research

Because of the basic nature and broad economic impact of the crushed stone industry, widespread research is conducted on all facets of the commodity from raw materials and mining through utilization. The industry, industry associations, equipment manufacturers, universities, and Federal and State agencies have prominent roles in various components of the overall research effort.

Among groups that deserve mention are the American Society for Testing and Materials, the American Association of State Highway Officials, The National Crushed Stone Association, The National Limestone Institute, The National Ready-Mixed Concrete Association, the National Bureau of Standards, the U.S. Army Corps of Engineers, the Bureau of Public Roads, the Bureau of Reclamation, and the Bureau of Mines.

The results of the intensive research are too numerous to mention here. But keener knowledge of the basic properties of materials, improved testing methods, more vigorous and correct specifications for various uses, better equipment and plant design, all have been among the benefits accrued from the dedicated efforts of many scientists and engineers.

OUTLOOK

Based upon anticipated or planned public and private construction and continuation of various highway building programs, the quantity of crushed stone produced may be expected to increase yearly for some time to come. Increased effort will be made by Federal road planners to speed up work in areas where construction of the Interstate Highway System appears to be lagging. Further expansion of the roadbuilding program appears to be imminent with an accompanying demand for more road aggregate. Changes in roadbuilding technology caused by heavier and faster traffic also will increase demand for roadstone; currently more stone is used for wide and heavy shoulders than for the pavement itself. The proportion of concrete work poured on the job will decrease as use of precast concrete units such as wall panels, complete with window and door openings, are produced by factory methods and brought to the building site to speed up construction and lower labor costs. Greater use will be made of lightweight concrete products, exposed aggregate panels, prestressed concrete, and aerated concrete.

Expanding use in the iron and steel industry of self-fluxing iron pellets or sinters, in which limestone is added during processing, may reduce quantity of limestone used as direct flux in the blast furnace. Expansion of Linz-Donawitz and basic-oxygen processes for steelmaking also will change previously established patterns for production and use of limestone.

Present trends in methods for producing crushed stone, which tend to improve efficiency and reduce costs, include greatly increased load capacity for off-the-road trucks; improved blasting techniques designed to avoid secondary blasting and to decrease claims for blasting damage; increased capacity, complexity, and mobility of portable plants; expanding use of tractor-drawn rippers to break ledge rock for loading; greater use of impact crushers to produce cubic road aggregate and to cut down waste owing to production of unacceptable flats and splinters; improvements in methods which are designed to reduce stockpile segregation; greater use of automatic and pushbutton controls and closed-circuit television systems to control all phases of processing; and increased concern by producers about methods for control of dust, water pollution, and noise in quarry operations.

Closer supervision of many quarry operations by various government agencies is foreseen, particularly as regards blasting, speed and weight of trucks operating on streets and public highways, and in noise, dust, and pollution abatement.

No new uses for crushed and broken stone are in prospect. New quarries to produce aggregate for local buildings are frequently opened and abandoned as programs are completed. Larger, well-established quarries will expand and modernize equipment as demand increases. Shipping radii of quarries will increase through use of innovations such as unit-trains and articulated railroad cars.

Estimated production of crushed and broken stone in 1980 is 1.5 billion tons.

PROBLEMS

There is pressing need for simplification and standardization of specifications for crushed stone aggregate. In the 50 States there are 215 dissimilar gradations specified for coarse aggregate to be used in portland cement concrete, and 58 specifications for fine aggregates. No uniform method is in actual use by the various States for designating aggregate gradation sizes. Suppliers would find it simplier and less costly if specifications for Federal, State, county, and municipal purchases, at least in similar areas, used identical specifications for the same type of construction.

There is little general understanding of the relationship between physical and chemical makeup of crushed stone aggregate and performance of concrete in which it is used.

Continuing problems are those related to (1) improving efficiency of drilling and blasting operations; (2) most efficient methods for plant layout; (3) location and rating of economically workable deposits; (4) removal of overburden; (5) control of noise, dust, and other annoyances to avoid restrictive zoning legislation; and (6) increasing insistence upon land rehabilitation.

STRONTIUM

By Paul M. Ambrose [1]

THE PRINCIPAL strontium minerals are celestite ($SrSO_4$) and strontianite ($SrCO_3$). These minerals occur in several States, and the principal deposits are in Texas, California, Arizona, and Washington. Domestic production is small and irregular. Reserves are large compared with current consumption. The market is small, and in most areas the cost of preparing the mineral for market and transporting it to the principal consumers discourages competition with strontium minerals from the United Kingdom and Mexico. Imports in 1963 totaled 16,232 short tons valued at $372,024.

Strontium minerals are usually mined by open-pit methods and beneficiated by hand picking or by simple gravity concentration. Most strontium is consumed as compounds. It is used principally in flares, fireworks, and tracer bullets because of the brilliant red it imparts when burned. Other uses are in fusees, ceramics, medicine, beet sugar, electronic tubes, purifying caustic soda, and refining zinc (*10*).[2]

Strontium mineral supplies probably will continue to come from foreign sources. Moderate increases in consumption are expected. Development of new uses and the utilization of domestic sources are problems of the industry.

BACKGROUND

Commercial production of strontium minerals and compounds began in Germany about 150 years ago. Strontianite from Westphalia was converted principally to the nitrate for use in pyrotechnics. Demand for strontium increased greatly with the introduction of the process for using the hydroxide in recovering sugar from beet-sugar molasses. Commercial production of celestite began in England in 1875, and until World War I most of it was shipped to Germany for conversion. In Germany, output of strontianite declined but production of celestite increased.

During World War I when German supplies were not available, facilities were established in the United States for processing strontium minerals from England. Domestic production increased substantially during World War I, but production of strontium minerals has been sporadic and small since then, except for a relatively large tonnage of low-grade material mined for well-drilling mud when there was a royalty on barite for this purpose. Most supplies of strontium minerals have come from England and Mexico in recent years.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Domestic production of strontium minerals in the past several years has been confined to the occasional operations of a few small firms in Washington and California. Their combined output is only a few hundred tons at most in any year, and none has been produced since 1959.

The following firms convert imported strontium minerals to various compounds: E. I. du Pont de Nemours & Co., Inc., Grasselli, N. J.; Foote Mineral Co., Exton, Pa.; and Inorganic Chemicals Division, FMC Corp., Modesto, Calif.

Strontium metal is produced in the United States by King Laboratories, Inc., Syracuse, N.Y.; however, only small quantities are made.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Two strontium minerals are important commercially. The more important of these, by reason of its greater abundance and more widespread occurrence, is celestite ($SrSO_4$), which contains 56.4 percent strontium oxide (SrO). Strontianite ($SrCO_3$), containing 70.1 percent SrO, has a higher strontium content but is less abundant and often occurs with celestite. Strontianite can be reacted directly with acids, but it often contains calcium and thus is frequently not suitable for producing high-purity strontium chemicals.

Although specifications are variable, consumers of celestite for conversion to strontium chemicals usually specify a minimum of 92 percent $SrSO_4$, a maximum of about 4 percent calcium sulfate ($CaSO_4$), and a maximum of about 4 percent barium sulfate ($BaSO_4$). Imported material is usually about 94 to 97 percent $SrSO_4$. The specifications for celestite for use in purifying zinc or in drilling mud are not so stringent as for chemical use.

The purchase specification for celestite for the national stockpile (P–10–R2, Sept. 28, 1960) provided that each lot of celestite purchased under the program should not contain more than 2 percent free moisture, not less than 95 percent strontium sulfate ($SrSO_4$), not more than 1.5 percent calcium, as sulfate ($CaSO_4$), and not more than 2 percent barium, as sulfate ($BaSO_4$). This specification states, "All celestite shall be in the physical form that is normally supplied to, and suitable for processing by, industry." The former specification (P–10–R1, Dec. 10, 1956) required that all celestite be either lump or pebble ore, all of it should be in bulk, and not more than 2 percent by weight should pass a U.S. Standard Sieve No. 4.

TECHNOLOGY

Strontium in small quantities or traces is common in igneous rocks and less abundant in sedimentary rocks. Most commercial or potentially commercial deposits of strontium minerals (celestite and/or strontianite) occur as beds, veins, veinlets, nodules, or irregular masses in or near sediments or sedimentary rocks. In Texas, celestite is found in three areas. The first and probably most important area is in Nolan, Fisher, Coke, and Taylor Counties; the second is in Somervell, Erath, Comanche, Brown, Mills, Lampasas, Burnet, Williamson, and Travis Counties; and the third is in Real and Uvalde Counties (*5*). In these areas celestite occurs as beds, veinlets, nodules, or masses in sands, clays, shales, or dolomitic limestones.

Celestite and strontianite occur together in Skagit and Whatcom Counties, Wash. (*8*). Certain limestones in Ottawa County, Ohio, contain veins and masses of celestite. Deposits of celestite occur in Maricopa County, Ariz., one in the Vulture Mountains and another a few miles south of Gila Bend. Several celestite deposits occur in arid south-central California. Celestite occurs a few miles south of Ocotillo, San Diego County; along the edge of Bristol Dry Lake in San Bernardino County; near the southern end of Death Valley; and in the Cady Mountains north of Ludlow in San Bernardino County (*2*). Strontianite occurs in the Mud Hills near Barstow.

Strontium minerals are recovered by simple methods on a small scale. The very small tonnage occasionally mined in the West is concentrated by selective mining and hand picking. The material formerly mined in Texas was broken from the deposit by horse-drawn plows, sorted, and handloaded. During World War II, a domestic firm processed this ore by grinding and tabling. The concentrate obtained was relatively low grade, and production was discontinued when higher grade foreign material became available. The Bureau of Mines conducted research on a flotation process for recovering celestite from Texas ores.

In England and Mexico, the ore is mined by simple methods in shallow open pits or from veins exposed in the stopes of metal mines. Usually the celestite is handpicked. Gravity concentration has been employed in the English operations in recent years.

Most of the strontium minerals consumed are converted to various chemical compounds. A common procedure is to digest finely powdered celestite in a hot soda ash solution to produce the less soluble strontium carbonate, which is treated with the appropriate acid to make the desired salt. Another method is to burn finely powdered coal with celestite to produce a soluble strontium sulfide, which is leached from the clinker with water and filtered. The solution may be treated with carbon dioxide to produce the carbonate; or with nitric acid to produce the nitrate. Strontium metal is produced by thermal reduction of strontium oxide with metallic aluminum and also by electrolysis of fused strontium chloride and ammonium chloride.

USES

There are uses for the minerals celestite and strontianite, strontium metal, and alloys of strontium, but much greater quantities are consumed as strontium compounds.

The characteristic brilliant crimson color that strontium imparts to a flame has many pyrotechnic applications. Most military uses of strontium depend on this property. The principal direct military uses are for strontium nitrate, peroxide, and oxalate in flares and tracer ammunition. In tracer ammunition, a charge containing one of the compounds mentioned previously or a combination of them, is inserted in the base of the bullet. On firing, this charge is ignited and burns brilliantly during the flight of the bullet permitting the gunner to see the accuracy of his aim.

The military use of strontium next in importance is in flares and signal devices. Flares are used for tactical and distress or rescue signaling and for illumination. They are various sizes, shapes, and types, and have red flames and usually some ejecting or propelling device.

Marine distress signal equipment consists of red parachute flares and a pistol for shooting the flares into the air. Larger distress rockets may be fired several hundred feet high, and some release showers of "stars." Similar red flares may be dropped or shot from aircraft or released by submarines.

The Federal Motor Carrier Safety Regulations require that "Carriers by Motor Vehicle" operated in interstate commerce have certain emergency equipment available at all times. These regulations require that the emergency equipment units include one of several combinations of warning devices for stopped vehicles. Among these devices are red fusees. Many States also require that fusees be carried on certain types of vehicles.

The familiar red color of many fireworks and pyrotechnic exhibitions is produced by strontium compounds.

Although Federal regulations do not specifically require it, for many years railroads have used red flares and fusees for emergency signaling as a safety practice. All railroad companies require that a number of 5- and/or 10-minute fusees be carried on each operating passenger or freight train. When a train slows down or stops, the flagman places these fusees so that following trains will be warned.

In Germany, sugar-beet molasses was formerly treated with strontium hydroxide (the Scheibler process) to recover beet sugar. The sugar was precipitated as relatively insoluble strontium saccharate, filtered, and treated with carbon dioxide. Strontium carbonate was precipitated and recovered with about a 5-percent loss. The sugar solution was crystallized by evaporation. This process has been supplanted by lime and barium hydroxide processes.

The major uses of strontium carbonate are in ceramics, principally in frits and glazes. Minor applications of strontium compounds are in depilatories, medicines, greases, metallurgy, corrosion inhibitors, plastics stabilizers, fused-salt baths, and optics.

Strontium metal and some of its alloys are getters for extracting the last traces of gases from electronic tubes. This minor use consumes only a few pounds annually.

In preparing high-purity electrolytic zinc, strontium carbonate removes lead from the cathode zinc. The minerals have been utilized in well-drilling mud, in purifying caustic soda (by adsorption of iron), and as a filler, but only a small quantity is used in the United States for any of these purposes.

ALTERNATE MATERIALS

There are no satisfactory substitutes for strontium compounds in most of their chemical and ammunition and other pyrotechnic uses. Many materials impart color to flame, but no substitute has the brilliance and visibility range of strontium compounds. The use of strontium minerals in the purification of certain grades of caustic soda has largely been supplanted by other methods.

RESERVES

Domestic deposits have not been explored thoroughly, but reserves in the investigated deposits have been estimated by the U.S. Geological Survey at 3.5 million tons of material containing 85 percent or higher $SrSO_4$. When considering reserves, it is important to know whether the material can be mechanically beneficiated to chemical grade. Some celestite contains calcium and barium so intimately locked within the crystal lattice that these elements cannot be removed except in a chemical process.

Little is known of reserves in foreign countries. Deposits are worldwide, and reserves in several deposits are substantial in terms of current and anticipated requirements.

SOURCES OF STATISTICAL INFORMATION

Figures on domestic and world strontium mineral production and strontium mineral imports by country of origin are published annually in the "Strontium" chapter of the Bureau's Minerals Yearbook.

PRODUCTION, CONSUMPTION, AND TRADE

Domestic production is small and sporadic. The quantity of strontium minerals sold or used ranged from 50 short tons in 1953 to over 4,000 short tons in 1956. There has not been any domestic production for 5 years.

The United States depends almost solely on imported celestite to satisfy the demand of the domestic strontium chemical industry. Imports are given in table 1.

Celestite and strontianite have always been on the list of materials that may be imported into the United States free of duty. The duty rate for strontium carbonate (precipitated), strontium nitrate, and strontium oxide is 12.5 percent ad valorem. Duty rate for other strontium compounds is 10.5 percent. The rate for strontium metal is 10 percent ad valorem, and for strontium alloys, 15 percent ad valorem.

TABLE 1.—*Strontium minerals* [1] *imported for consumption in the United States*

Country of origin	1954–58 (average)		1959		1960		1961		1962		1963	
	Short tons	Value	Short tons	Value	Short tons	Value	Short tons	Value	Short tons	Value	Short tons	Value
Italy	2	$593	11	$2,700	11	$2,700	11	$2,700	27	$6,750	11	$2,700
Mexico	2,105	28,465	2,182	39,936	2,881	56,530	2,642	48,713	4,554	98,476	6,476	104,867
United Kingdom	4,306	99,892	5,946	182,769	3,294	90,476	7,278	193,064	2,908	83,609	9,745	264,457

STRATEGIC CONSIDERATIONS

If outside strontium supplies were cut off, the United States could be self-sufficient at a higher price and perhaps at the sacrifice of plant capacity, certain processing acids and reagents, and time. It is not known how much domestic material could be beneficiated to meet the specifications of the currently available foreign material nor at what price this could be done. Economics is the principal consideration when discussing self-sufficiency in strontium minerals.

Strontium compounds are considered essential in several military and civilian uses. Our almost total dependence on foreign sources of strontium minerals (even though this may be due in great part to economic reasons) has made strontium critical in an emergency. Therefore, celestite was placed on the list of materials to be acquired for the national stockpile.

The General Services Administration offered for sale, at its warehouse in Point Pleasant, W. Va., about 12,500 short tons of celestite that was part of a below-grade stockpile of 28,816 short tons. No acceptable bids were received. On June 30, 1964, Government inventories totaled 22,045 short tons, of which 13,037 tons was in Commodity Credit Corporation stocks and 9,008 tons in the supplemental stockpile. This is 214 percent of the present maximum objective.

PRICES

Trade journal prices for strontium compounds have remained constant since 1955. The 1963 prices follow: Strontium sulfate, air-floated, 90 percent, 325-mesh, bags, works, $56.70 to $66.15 per short ton; strontium carbonate, pure, drums, 5-ton lots or more, works, 35 cents per pound; drums, 1-ton lots, works, 37 cents per pound; technical-grade, drums, works, 19 cents per pound; and strontium nitrate, bags, carlots, works, $11 per 100 pounds, and bags, less than carlots, works, $12 per 100 pounds.

TAXES

Producers of celestite are allowed a depletion allowance of 23 percent on ores from domestic deposits and 15 percent on ores from foreign deposits.

TRANSPORTATION

One of the principal factors preventing the development of a domestic mining industry is the cost of transportation. The rail freight rate on celestite and/or strontianite from San Bernardino County, Calif., to Philadelphia, Pa., or Grasselli, N.J., in 1957 was about $50 per short ton. Added to the f.o.b. mine price, this makes the delivered price higher for domestic material, with a minimum of about 90 percent $SrSO_4$, than for English or Mexican celestite (95 to 97 percent strontium sulfate) which can be delivered to the same place for about $50.

RESEARCH

Industry, institutions, and Government have conducted research on various problems involv-

ing the production, processing, and utilization of strontium minerals, metals, alloys, and compounds.

During World War II, the Bureau of Mines and a domestic firm cooperated in research on the preparation of chemical-grade celestite from Texas ore. Although fair success was achieved, this domestic source was abandoned when higher grade material from foreign sources became available again after the war.

Research by industry has resulted in a recent patent on the use of ground celestite to remove deleterious materials, principally lead, from high-purity electrolytic zinc. A magnesian limestone process and an ammonia process have been devised as substitutes for celestite in the purification of caustic soda.

The Bureau has conducted a limited investigation of the physical, chemical, and thermodynamic properties of certain strontium alloys and compounds, such as strontium titanate, carbonate, sulfate, nitride, chloride, and fluoride.

OUTLOOK

For economic and quality reasons, strontium mineral supplies are expected to continue to come from foreign sources. The major sources of supply, Mexico and the United Kingdom, apparently have resources adequate for world needs for many years. Exhaustion of these resources in the distant future could force dependence on our domestic sources, which although low grade appear to be ample and technically amenable to beneficiation. Relocation of munitions plants, shifts of population and industry, and other unpredictable factors may make it economically advantageous to develop domestic deposits of strontium minerals long before foreign sources approach exhaustion.

A vast untapped strontium reserve is the earth's hydrosphere, in which strontium is the ninth most abundant element, amounting to 13 grams per ton of sea water.

Current trends in the use of strontium are difficult to discern. They involve largely new, expensive, and untried products, such as strontium titanates, and a decline for some uses, as in the purification of certain grades of caustic soda. Some unusual physical properties of strontium titanate crystals indicate that they may have special uses in optics, jewelry, and other fields. These uses, which require a very pure product, are not expected to involve large quantities of strontium.

Pyrotechnic devices will continue to be the major outlet for strontium compounds. Their use in pyrotechnics and in glass, enamels, refractories, and ceramics is likely to increase. Strontianite, or manufactured strontium carbonate, has been suggested as a flux on stainless steel welding rods. Strontium chloride as a refrigerant and an ammonia absorbent in refrigeration is another possible use. Strontium metal will continue to be used in small quantities as a getter.

Barring unforeseen substitutes or major new uses, the outlook is for short-term requirements to remain at about the current level and for long-term requirements to increase gradually and moderately.

PROBLEMS

The principal problem of the strontium industry is its dependence on a single market—the manufacture of strontium compounds for pyrotechnic uses.

Creating new uses for strontium products is a problem of interest to the mineral producers, the chemical processors, and the strontium metal producers. However, limited demand and restricted known uses offer little stimulus to the producer for costly research. Investigations culminating in short-term uses sometimes cause overexpansion of world production (new companies and mines, both domestic and foreign) which, in turn, presents the problem of accommodating idle productive capacity when the short-term use ends.

Lack of adequate information on resources and inadequate world production and consumption statistics further inhibit research programing.

The main problem of domestic strontium mineral producers, or of potential domestic strontium mineral producers, is competition from foreign sources. In addition (1) the domestic ore concentrates are presently lower in grade than the available imported material, (2) the domestic market is only a few thousand tons annually, and (3) the cost of preparation and the cost of transportation from the principal deposits in the West to the major consumers in the East is high enough to discourage competition with foreign sources. These factors provide little incentive for developing domestic deposits.

Information is needed on the properties of strontium metal and its alloying characteristics to enable evaluation of its potential in metallurgy.

SULFUR AND PYRITES

By Paul M. Ambrose[1]

SULFUR has many uses including cellulose products, chemicals, dyes, fertilizers, iron and steel, pharmaceuticals, rubber, and water treatment, but there is a dearth of information regarding the total number of uses. New applications are being found, and any precise statement would be incorrect when made and out of date before publication. It is likely that there are thousands of uses for sulfur and sulfur containing compounds.

Per capita sulfur consumption in any country has long been a reliable index of total chemical production. Sulfur use is closely related to the industrial activity of any nation. The average annual per capita consumption in 1963 in the United States was 81 pounds, in other developed countries 56 pounds, in the entire world 21 pounds, and in less industrialized countries 3 pounds.

The United States obtains sulfur from native sulfur deposits, pyrites, other metallic sulfide ores, sour natural gas, petroleum, and coal. Imports of sulfur from Mexico and Canada are important sources of supply. Exports slightly exceed imports.

Native sulfur deposits mined by the Frasch hot-water process are the major source of supply. Sulfur from sour natural or refinery gases is growing in importance and is competitive with Frasch sulfur. Definite quantitative information on reserves of Frasch sulfur is not available. Growing recovered sulfur production and imports should gain, but ultimately other sources of supply will need to be developed.

Annual production of sulfur in all forms in the United States was 6.6 million long tons in 1963, valued at $125 million. Production averaged 6.8 million tons per year for the period 1954–63. In 1963, 74 percent was produced by 4 firms mining 10 dome deposits in Texas and Louisiana, and 62 firms at 86 plants and mines reported the remainder of the production in the United States.

The rapid growth of the Mexican Frasch, French recovered, and Canadian recovered sulfur industries since they began in 1954, 1957, and 1951, respectively, resulted in overproduction which was finally brought near equilibrium in 1963. Competition for markets was keen and prices weakened in 1961 and 1962.

The shipment, storage, and use of liquid sulfur began in 1959; the practice developed rapidly and in 1963, 85 percent of shipments were in liquid form. Oversea shipments were introduced in 1964.

The base of supply has broadened appreciably with an increase in number and size of producers. The number of brimstone producers is increasing constantly.

The industry has many problems, including competition from Canada, Mexico, and France; unequal competition between nations in restrictions; and trade barriers to exports but none to imports. Other problems involve reserves, production processes, and need of additional market research information.

BACKGROUND

Sulfur was used by the Egyptians to bleach linen textiles in 2000 B.C., but it did not become commercially important until the development of the Leblanc soda ash process in France in 1791. The sulfuric acid industry, which has consumed most of the sulfur produced, was started by John Harrison of Philadelphia in 1793. Sicily held a virtual monopoly on the sulfur trade before the beginning of the 20th century. Sulfur was mined from pits up to 500 feet deep by miners climbing circuitous steps while carrying the sulfur on their shoulders. Pay was 7 or 8 cents per day. Sulfur was recovered by burning part of the sulfur

[1] Commodity specialist.

to melt the remainder. In 1833, a depression in Sicily and the resulting hardship to producers caused the King of Sicily to grant a monopoly of the Sicilian sulfur trade to a commercial firm which raised the price of sulfur from $25 to $75 per ton. Consumers switched to pyrite as a source of sulfur, and by 1886 use of sulfur was principally for the manufacture of gunpowder, bleaching agents, and medical compounds. Dr. Herman Frasch, successfully mined sulfur at Sulphur Mine, La., by a unique hot-water melting process after several attempts to use conventional mining processes had failed. The Union Sulphur Co., which Dr. Frasch helped organize, produced the world's first Frasch process sulfur in 1895. After its deposits at Calcasieu Parish, La. were exhausted in December 1924, Union Sulphur began producing at Boling, Wharton County, Tex., in 1928.

In November 1912 Freeport Sulphur Co. began operations at Freeport, near Bryanmound, Brazoria County, Tex. On March 19, 1919, Texas Gulf Sulphur Co. began producing at Gulf, near Matagorda, Tex., using the Frasch method. The company's Boling dome, the largest producer of sulfur and also the largest salt dome ever found to that time, was started on March 20, 1929, in southeast Wharton County, Tex. In 1928 the Duval Texas Sulphur Co. began producing at Benavides, Duval County, Tex.

The United States became the world leader in sulfur production in 1913. It has maintained this lead since. In 1948–49 world demand for U.S. native sulfur exceeded mine capacity and stocks declined. A sulfur shortage in 1950, about the beginning of the Korean war, shocked the industrial world. Consumption of elemental sulfur had been greater than production since 1942. Sales restrictions and increased use of pyrite began.

In 1952 U.S. Export-Import Bank loans to the Mexican companies, the Mexican Gulf Sulphur Corp., no longer in operation, and the Pan American Sulphur Co., started Mexico to prominence as a sulfur producer. Production from both companies began in 1954, and Gulf Sulphur Co. began producing in 1956. World Frasch production grew to 6.3 million tons in 1963. Treatment of sour natural gases in Alberta, Canada, produces sulfur as a byproduct. Starting in 1951, this industry grew to 1.9 million long tons per year in 1963; future growth will be determined by natural gas sales.

Production of recovered sulfur from sour natural gas, from the Lacq field in France, began on April 21, 1957, and grew in planned stages to 1.4 million tons in 1963.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The United States is both the largest producer and consumer of sulfur in the world. Most of the production comes from 10 Frasch process mines operated by 4 firms in Louisiana and Texas. A small quantity of sulfur ore was also mined in California and Nevada in 1963. The second most important source is recovered sulfur from the purification of sour natural or refinery gas. This industry is growing. Plants are located in 19 States. Most sulfur is consumed first in the production of sulfuric acid which is then used in a great variety of ways. Pyrite and other metal sulfides are smelted and the sulfur dioxide produced is converted to SO_3 then to acid. Smelters producing acid are located in 19 States. The use of both elemental sulfur and sulfur from metal sulfides is growing. The quantity of elemental sulfur consumed in the United States is about 13 times that of sulfur from pyrites at the present time. The more rapid growth of the elemental sulfur industry than the pyrite industry has, in the past, been due to increased need for strong acid and the availability of low-price elemental sulfur. Sales of liquid sulfur began in 1959 and have grown to 85 percent of the total in 1963. Costs usually include transportation of the liquid sulfur by the sulfur companies from the mines to liquid sulfur terminals. Such transportation is by barge on inland waterways, by rail, by truck, and by oceangoing liquid sulfur carriers. The sulfur companies own or lease ships for this purpose. Shipments outside North America are made by the Sulphur Export Corp. (Sulexco). Freeport Sulphur Co. owns 37 percent of Sulexco; Texas Gulf Sulphur Co., 37 percent; Jefferson Lake Sulphur Co. (a subsidiary of Occidental Petroleum Corp.), 18 percent; and Duval Corp., 8 percent. Shipments of liquid sulfur overseas started in 1964 after two liquid sulfur carriers, the *Naess Texas* and the *Naess Louisiana*, were completed. Imports of sulfur from Canada and Mexico increased rapidly in the last decade.

Sulfur is recovered from the sweetening of sour natural gas at 15 plants in Alberta, and 1 plant each in British Columbia and Saskatchewan. A capacity of 1.9 million tons was not fully in use in 1963, but additional capacity was to be created with time as natural gas markets expand. Lowered freight rates from Canadian sulfur sources to the upper Midwest have been an important factor in expanding Canadian sulfur sales.

Mexican Frasch production has grown stead-

ily and capacity is presently being expanded from 1.9 to 2.5 million tons.

French recovered sulfur from sour natural gas is produced by Société Nationale des Pétroles d'Aquitaine from the Lacq area of France. Planned production capacity of 1.4 million tons has been reached, and expansion has been restricted for reasons of conservation. France has started to deliver liquid sulfur in Europe to meet U.S. Frasch competition there. Liquid sulfur terminals are located at Rotterdam, Holland, Immingham, England, and Rouen, France.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Native sulfur is sulfur that occurs in elemental form in nature. *Frasch sulfur* is native sulfur mined by the Frasch hot-water process.

Recovered sulfur is elemental sulfur produced from hydrogen sulfide obtained from sour natural gas, petroleum refinery gas, water gas, and other fuel gases.

Pyrites is a not-too-well-defined term which includes a number of metal sulfides usually pyrite (FeS_2), marcasite (FeS_2), and chalcopyrite ($Cu_2Fe_2S_4$).

Crude sulfur or *brimstone* is elemental sulfur that is 99.0 to 99.9 percent pure and is free from arsenic, selenium, and tellurium. Run-of-mine Frasch sulfur contains about 50 percent fines, with lumps to 8 inches in size.

Amorphous sulfur is the insoluble residue used in the vulcanization of rubber and is produced by extracting flowers of sulfur with carbon disulfide.

Colloidal sulfur is a suspension of fine sulfur particles in water.

Flowers of sulfur is crude sulfur refined by sublimation.

Precipitated sulfur is sulfur precipitated from calcium polysulfide solutions by hydrochloric acid and washed to remove all calcium chloride.

Wettable sulfur is sulfur treated so that it is easily dispersed in water.

Paste is a slurry of sulfur and water, usually containing 30 to 50 percent of finely divided elemental sulfur.

Dark sulfur is crude sulfur containing up to 1 percent oil or carbonaceous material and is dark in color. *Bright sulfur* is crude sulfur free of discoloring impurities and is bright yellow in color.

TECHNOLOGY

Geology

Sulfur is widely distributed in nature in the free and combined state. The lithosphere and hydrosphere contain approximately 0.06 and 0.09 percent sulfur, respectively, and the average content of the lithosphere, hydrosphere, and atmosphere is 0.06 percent. Meteorites from outer space and practically all animal and plant life on earth also contain sulfur. Sulfur combines directly with most other elements, both metals and nonmetals, except nitrogen and the inert gases. Concentrations of surfur or sulfur compounds of commercial importance are much more restricted in distribution. Such economic deposits mined for their mineral value include native sulfur, sulfide, or sulfate minerals. By far the most important deposits of native sulfur occur as crystals of sulfur disseminated through a limestone or gypsum host rock. The Frasch process mines along the coast of the Gulf of Mexico and the sedimentary deposits of Poland, U.S.S.R., and Sicily are of this type. The way in which these deposits were formed has not been established definitely, but the sulfur may have been produced by the chemical reduction of gypsum, possibly through biochemical reactions.

Other native sulfur deposits associated with volcanic activity are smaller in size but are more numerous and widespread. In these deposits sulfur was released when hydrogen sulfide gas was oxidized or sulfur dioxide and hydrogen sulfide gases reacted to produce sulfur and water. Metal sulfide deposits mined primarily for the metal content also are important sources of sulfur dioxide to produce sulfuric acid and in some cases elemental sulfur. The largest potential sulfur resources occur as gypsum, calcium sulfate. Gypsum is not used in the United States as a source of sulfur but has been used in England, India, and formerly in continental Europe and probably will become important in the future. An enormous deposit of sulfur occurs with the Athabasca oil sand in Alberta, Canada. The oil sands are about to be mined and some sulfur should be produced by 1970.

Deposits Associated With Salt Domes

Salt domes occur in the United States, Mexico, West Germany, Rumania, U.S.S.R., Iran, and other countries. In the United States salt domes extend from Alabama (McIntosh salt dome) on the east, westward through Mississippi, Louisiana, and Texas to near the Rio Grande River. The deposits lie within a belt which extends 75 to 300 miles inland from the gulf coast and offshore. This area has been divided into four salt basins: Gulf coast salt basin, interior domes of Texas, interior domes of Louisiana (*19*)[2] and Louisiana-Mississippi salt basin.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

A salt-dome formation consists essentially of a solid vertical column of salt, extending to great depths and forming a dome-shaped structure in the overlying sediments. The salt dome (cap and salt stock) is usually circular or elliptical in form, with a horizontal extent of a few yards to 2 miles or more. In many instances the top of the salt stock is remarkably flat and is succeeded above by a characteristic series of minerals collectively known as the cap. Sedimentary beds surrounding the core are displaced upward at sharp angles along the sides by the upward movement of the salt column. It is widely believed that the source of the salt in domes is deeply buried Cretaceous or Permian sediments, from which salt was forced upward at points of weakness. Usually the deposits are surrounded by formations that are tight enough to restrict the flow of hot water.

The cap-rock series constists chiefly of anhydrite, gypsum, and limestone. Generally, the anhydrite lies directly on the massive salt core. Limestone and gypsum occur as zones or lenses above the anhydrite.

Sulfur usually occurs as orthorhombic crystals, crystal aggregates, and disseminated particles in the lower part of porous limestone or in gypsum zones of many domes, at depths ranging from 500 to 2,500 feet. Thickness of the sulfur horizon is seldom less than 25 and sometimes reaches 300 feet. A typical deposit of commercial size may have a sulfur-bearing zone 100 feet thick containing 20 to 40 percent sulfur. Only a small proportion of the domes discovered to date have contained enough sulfur to warrant development. The porosity of the sulfur-bearing horizon is assumed to be 15 to 25 percent.

Volcanic Deposits

Deposits of native sulfur are found in most volcanic regions of the world, both active and extinct. These deposits may be formed by reaction between hydrogen sulfide and sulfur dioxide, incomplete oxidation of hydrogen sulfide, or reaction of sulfur dioxide and water. Sulfur deposits also may originate by precipitation from thermal springs, incomplete oxidation of hydrogen sulfide by oxygen, or bacterial action. The largest known deposits of this kind are in the Andes Mountains of South America. More than 100 deposits of sulfur occur at elevations to 18,000 feet in a zone 3,000 miles long parallel to the west coast of South America. These deposits are mined to a limited extent but are of interest primarily as potential resources. In Japan sulfur deposits associated with a chain of volcanoes occur on the main island. These make important contributions to the sulfur supply of Japan. Deposits from which sulfur may be recovered are also known near Lake Rotorua, New Zealand, and in Alaska, Iceland, Mexico, and elsewhere. Deposits formed by springs are found in the Western United States—Cuprite, Esmeralda County, Nev.; Rabbit Hole mines, Humboldt County, Nev.; Sulphur Bank, Lake County, Calif.; Cave Creek mine, Beaver County, Utah; and Cody and Thermopolis, Wyo., (*13*).

Sedimentary Deposits

The sulfur of sedimentary deposits comes from sulfates in rocks and from hydrogen sulfide from volcanic emanations, anaerobic bacterial decay, and bacterial reduction of sulfates in solution. These substances are transported in solution or as colloidal sulfur to sedimentation basins. The sulfur is deposited from sulfates and hydrogen sulfide in water where reducing conditions and anaerobic bacteria exist.

Two large deposits in southeast Poland are the Tarnobrzeg deposit now being mined and the Solec-Grzybow deposit as yet undeveloped. The Tarnobrzeg deposit extends from Tarnobrzeg to Piaseczno. The sulfur occurs in a Miocene sedimentary sequence with beds in order from bottom to top of clay, gypsum containing sulfur, limestone-reef, fluviatile sand, argillites, and clays. The grade of sulfur is 28 to 30 percent average with a maximum locally of 80 percent. The sulfur beds lie close to the surface. Cover is 30 feet at Piaseczno, and 77 to 87 feet at Machow. The sulfur bed is 15 feet thick at Piaseczno and 33 feet thick at Machow but is 66 feet thick in places. The second Polish deposit of interest is the Solec-Grzybow deposit in southeast Poland. This deposit is 42,000 feet east-west, and 2,100 feet north-south. Sulfur content is 20 percent at Solec where the deposit is 15 feet thick under 75 feet of overburden and 30 percent at Grzybow where the deposit is 80 feet under 550 feet of burden.

Important sedimentary deposits occur near Kuibyshev, Sukeievo, and Chekur in the U.S.S.R. These deposits are of Permian and upper Tertiary age, respectively. The deposits at Kuibyshev contain interbedded layers of pure sulfur, laminates of sulfur, and calcite or sulfur nodules in bituminous limestone between layers of gypsum.

Sicily has numerous native sulfur deposits scattered over an area 105 miles east-west by 56 miles north-south (5,880 square miles). The richer deposits were found between Gibellina on the west and Centuripe on the east, and the central one-third of the island in the north-south directions. Deposits may have existed over the entire island before erosion. The zone containing the sulfur is well defined by a Pliocene up-

lift, principally of sandstone resting on a Miocene shale. Sulfur-bearing formations lie in isolated basins up to 5 miles long and 0.5 mile wide. These formations or lenses are composed of a series of interbedded limestone and bituminous shales. Sulfur occurs as incrustations and small pockets in the limestone or as thin seams interlaminated with rock. Formations average 26 percent sulfur of brown or brownish gray color due to bituminous contamination (*2*).

Pyrites Deposits

Metal sulfides called pyrites are important sources of sulfur providing 40 percent of all sulfur produced in 1963. Leading producers were Japan, U.S.S.R., Spain, Italy, and China.

The principal minerals in the pyrites group are pyrite, pyrrhotite, marcasite, and chalcopyrite. Pyrite is widely distributed, both geologically and geographically, as it is found in rock of all types and ages. It occurs abundantly in veins, in dissemination deposits, and as masses along the contact of basic intrusives and sedimentary rocks. The temperature at which the deposits were formed is indicated by the minerals associated with the deposit. Pyrrhotite deposits and those associated with silicates are considered to have been formed at relatively high temperatures and great depths, whereas those associated with calcite, barite, and quartz are considered to have been formed at intermediate temperatures and moderate depths. The world's largest sources of pyrite have been the Alentejo region in Portugal and the Province of Huelva in Spain. Other important deposits are found in Canada, Cyprus, France, West Germany, Italy, Japan, Norway, and the United States.

Mining

Almost all the native sulfur being produced in the United States is mined by the Frasch hot-water process from salt dome deposits. Small quantities are mined by open pit from near surface deposits.

Frasch Process

The idea behind the Frasch process is extremely simple, namely, that hot water under pressure pumped through a drill hole from the surface can melt sulfur in place so that it can be carried to the surface by compressed air. In practice, the process is more difficult and has been applied successfully to only a few deposits. Of the 230 or more salt domes known in Louisiana and Texas, only 22 have been producers of sulfur of which 10 were active in 1963. To be minable by the process, the formation must have some porosity to permit entrance of hot water, but the enclosing structure must be able to restrict the molten sulfur and water from being lost to the surrounding ground.

In the development of the mine, wells are drilled through the sulfur zone to barren anhydrite below. Mining depths have ranged from 400 to 3,000 feet in the United States. The wells are drilled with a rotary rig, similar to those used in the petroleum industry for work in soft formations, and are equipped with concentric pipes ranging in size from 1 to 8 inches in diameter. A typical installation may have a 6-inch pipe to the barren anhydrite. This pipe has two sets of circumferential holes near the bottom which are separated by an internal collar. A 3-inch pipe placed inside the 6-inch pipe rests on the collar near the bottom of the sulfur formation. The collar seals the annular space between the two pipes. The 1-inch pipe inside the 3-inch pipe reaches nearly to the collar.

The water is 325° to 340° F at the plant, but this is reduced to 320° to 325° F in the field. Control of the water temperature is important because although the water should be as hot as possible for heat transfer reasons, above 318° F the viscosity increases suddenly causing sulfur removal problems. The volume of water per ton of sulfur recovered ranges from less than 1,500 gallons per ton in a highly efficient mine; 1,500 to 3,000 gallons per ton in many mines now in operation; and 4,000 to 7,000 gallons per ton in a lean, less favorable deposit. Pumps used may supply water at 250 to 350 pounds per square inch gage, but water at 125 to 200 pounds per square inch gage is normally used at the wells. The depth of the well, the length of the surface line, the porosity of the sulfur-bearing formation, and the volume of water used are related to the pressure needed. The water is transported to the ore horizon between the 6-inch and 3-inch pipes and enters the sulfur formation through the upper set of holes above the collar. The liquid sulfur, being heavier than water, settles to the bottom around the 6-inch pipe. Liquid sulfur enters the 6-inch pipe through the lower set of holes below the collar and is forced into the space between the 3-inch and 1-inch pipes by dome pressure. Compressed air entering the liquid sulfur through the 1-inch pipe decreases the density and the column rises to the surface. Air compressors delivering pressures of 500 to 600 pounds per square inch gage to the mine are used. The depth of the well, the length of air line, and the pumping rate cause pressure variations from one well to another. It requires from 500 to 900 cubic feet of air to mine a long ton of sulfur. Bleeder wells are used to remove cool water to make room for hot water being piped into the dome.

Liquid sulfur reaching the surface is discharged into steam-heated tanks at relay stations. The same relay stations also conduct the

flow of air and water to the wells. After being metered, the sulfur is pumped through steam-heated lines to storage vats, where it cools and solidifies or to liquid storage tanks. Shipments of either solid or liquid sulfur can be made by rail, road, inland waterways, or ocean. Deliveries of sulfur to U.S. markets in 1963 were 85 percent in liquid form.

The removal of large quantities of sulfur from the cap rock may affect production in two ways: (1) The formation of voids and cavities may increase the water-to-sulfur ratio and thereby increase the cost of production and (2) subsidence may distort or break the strings of pipe in the well and surface installations in the immediate area.

To reduce hot-water requirements, voids and crevices are sometimes filled by mudding. When the cavity traversed by fluid mud is large, the velocity of the fluid is decreased and solid particles settle out. In areas of low porosity the velocity is high and the solid particles tend to remain in suspension. By varying the size, percentage, and character of the solid particles in the mud, the depth of discharge, and the rate of pumping, adjustment may be made in mudflow to suit local conditions.

Subsidence resulting from the removal of large qualtities of sulfur occurs when the remaining skeleton formation does not support the weight of the overlying formations. Although collapse of this structure is disadvantageous as it may damage producing wells, it is advantageous in that it fills voids, thereby eliminating the necessity for mudding. As water circulates through the caved area with difficulty, the incoming hot water is more closely confined to the unexhausted parts of the deposit.

When sulfur is discolored by hydrocarbons, it may be treated to brighten its color; but this treatment is not necessary to permit its use for acid manufacture or for many other applications. Of the 12 active Frasch sulfur mines in the United States and Mexico, only 3—Boling, Long Point, and Ochard domes—produce bright sulfur. Freshly mined U.S. bright sulfur contains less than 0.005 weight-percent ash. Dark sulfur, although having approximately the same ash content, includes small quantities of hydrocarbons. Hydrocarbons may be removed by treating the liquid sulfur by various means. The producers have developed proprietary processes for hydrocarbon removal.

Shallow Native-Sulfur Mines

Small native-sulfur deposits are found in several Western States, including California, Colorado, Nevada, New Mexico, Utah, and Wyoming. These have been mined from time to time since 1865 in small tonnages for local use. The largest production has been from the Leviathan mine of the Anaconda Co. in Alpine County, Calif. The deposit was developed to produce sulfur to make sulfuric acid for Anaconda's Yerington, Nev., copper oxide leaching plant. Other sulfur-producing counties in California have been Alpine, Colusa, Imperial, Inyo, and Kern. In Nevada, the Western Sulphur Corp., was operating mines and plant at the Rabbitt Hole sulfur deposits, 29 miles northwest of Humboldt House (*5*).

Deposits of sulfur ore of surficial and fumerale origin or resulting from oxidation of pyrite or sulfide ores of copper, lead, and zinc are known in Colorado, New Mexico, Utah, and Wyoming.

While development efforts have been made on several of these deposits, no tonnage of any consequence was ever mined.

Recovered Sulfur

Sulfur production from sour natural and refinery gases is becoming increasingly important in supplying world sulfur needs. Production in the United States grew from 399,000 long tons in 1955 to 950,000 long tons in 1963. During the same period world production grew from 925,000 to 4.1 million tons. Canada and France became major producers of sulfur during this period and most of this production was from sour natural gas.

Important sources of sour gas occur in the Permian Basin in New Mexico, Texas, Arkansas and Wyoming; in Alberta and British Columbia, Canada; and in the Lacq area of France. Typical hydrogen sulfide (H_2S) content of sour gas in Wyoming gasfields range from 0.5 to 42 percent H_2S. The hydrogen sulfide content of gas in the Permian Basin fields was less than 2 percent with the exception of the McElroy field in Texas with 7.1 percent (*6*).

The recovery of elemental sulfur from sour natural gas and refinery gas has been very successful. Removal of the hydrogen sulfide from natural and refinery gases provides sulfur needed by the petroleum industry, sweetens the fuel gas, and reduces air pollution. The last is important near large cities where air pollution has become a civic problem.

Other industrial gases, principally from coal-burning operations, are less promising sources of sulfur supply, although their total volume is large. They are usually too lean or locally too small in quantity for economic recovery. However, considerations of air-pollution control may force the removal of sulfur oxides from

stack gases in some urban areas. In these instances, recovery of sulfur as an adjunct to the process renders the economics of removal more attractive; thus, additional supplies of sulfur become available from the consumption of high-sulfur fuels (*3*). Additionally, in certain large installations such as coal-carbonization plants, moderate quantities of sulfur are obtained.

Several processes have been developed for recovering sulfur, hydrogen sulfide, and sulfur dioxide from sour natural, refinery, smelter, and other industrial gases.

Dry processes used for removing hydrogen sulfide from gas and recovering it in the elemental form include the iron oxide process and the activated-carbon catalytic process. The iron oxide is the only dry process that has been used extensively in the United States. This process is used by utility companies for purifying coal and carburated gases and to remove the last 10 to 25 grains of H_2S per 100 cubic feet of gas following treatment by Thylox and other liquid purification processes (*18*).

In the iron oxide process, gas and air are passed downward through a series of trays containing wood shavings impregnated with iron oxide mounted within a pressure vessel. The oxygen added to the gas reacts with the ferric sulfide formed, yielding iron oxide and elemental sulfur. Disadvantages inherent to this process include intermittent operation, cumbersome equipment, high operating costs when used to remove large quantities of H_2S, and disposal problems. Offsetting these disadvantages is the ability of the process to remove H_2S to extremely low levels, at low pressures, and its selectivity for absorbing H_2S in the presence of carbon dioxide.

Wet processes, in which hydrogen sulfide is removed from a gas stream by scrubbing, utilize solutions that absorb the H_2S. The major differences in these processes are the solutions used.

In the absorber the lean solution passes downward from the top of the tower countercurrent to the upward flow of hydrogen sulfide-bearing gas. The rich solution containing the H_2S flows out of the bottom of the absorber to the top of the reactivator.

In the reactivator the rich solution passes downward from the top of the tower countercurrent to the upward flow of steam. The H_2S and steam leave the top of the reactivator and go to a steam condenser. The lean solution leaves the bottom of the reactivator and returns to the top of the absorber after cooling.

The Girbotol process is widely used for removing hydrogen sulfide and carbon dioxide from gaseous mixtures (*4, 15, 16, 21*). Various modifications of the Girbotol process permit gas purification to a degree comparable with that obtained through the use of the iron oxide process. To remove H_2S this process uses the mono-, di-, tri-ethanolamines, which are stable and relatively nonvolatile. Triethanolamine has largely been replaced by more reactive monoethanolamine for purifying natural gas, except where selective hydrogen sulfide removal is required. Diethanolamine is widely used for removing hydrogen sulfide from refinery gases.

The Shell phosphate process is a regenerative liquid purification system used for the removal and recovery of H_2S from sour natural or refinery gases and liquid hydrocarbons (*11, 17*). This process differs from the other regenerative liquid purification systems in that it employs an aqueous solution of tripotassium phosphate.

The vacuum carbonate, alkazid, and phenolate processes follow the same basic flow scheme but differ in the absorbent solutions used for recovering H_2S.

Many processes have been developed for recovering sulfur dioxide from the roasting and smelting of sulfide and sulfate ores, the refining of petroleum, and the burning of coal at power stations. Processes used to recover sulfur compounds include American Smelting & Refining Co.'s sulfur dioxide process, which recovers sulfur dioxide by use of a dimethylaniline absorber (*7*), the ammonia process (Consolidated Mining & Smelting Co. of Canada, Ltd., Trail British Columbia), the Imperial Chemical Industries basic aluminum sulfate process, the Fulham-Simon-Carves ammonia liquor process, the Orkla process, and the anhydrite process.

The principal process used for recovering elemental sulfur from H_2S is the modified Claus (*1*). In the original process developed by Claus, H_2S was admixed with air and burned in a large combustion chamber containing a ferric oxide catalyst. Owing to the large quantity of heat liberated, the operating temperatures were extremely high, resulting in only partial conversion of hydrogen sulfide to sulfur.

Two modified Claus processes are in general use today. In the one, the partial-combustion process, the acid gas is burned in a combustion furnace with sufficient air to convert all of the hydrogen sulfide to sulfur according to the following stoichiometric equation:

$$2H_2S + O_2 \rightarrow (2/x)S_x + 2H_2O.$$

The term "partial combustion" is derived from the fact that the air required by the above equation is sufficient to convert only one-third of the hydrogen sulfide to sulfur dioxide. Both unconverted hydrogen sulfide and sulfur dioxide

emerge from the reaction furnace in the gas stream along with sulfur vapor and are themselves converted to elemental sulfur in catalytic converters which follow.

In the other, the split-stream process, one-third of the hydrogen sulfide is burned completely to sulfur dioxide in a combustion furnace according to the following stoichiometric equation:

$$2H_2S+3O_2 \rightarrow 2SO_2+2H_2O.$$

The combustion gases are mixed with the other two-thirds of the hydrogen sulfide so that the following catalyzed reaction may take place:

$$2H_2S+SO_2 \rightarrow 2H_2O+(3/x)S_x.$$

The yield of sulfur, or the total conversion of H_2S to sulfur, is influenced by the amount of water vapor, the temperature in the final catalytic converter, the concentration of H_2S in the acid gas, the pressure used, the presence of hydrocarbons, and the catalyst. Modern, properly operating sulfur plants ordinarily obtain conversions between 90 and 95 percent.

USES

In utilizing sulfur at least 91 percent passes through the sulfur dioxide stage. Sulfur end uses are so varied that the consumption of sulfur is often taken as a reliable indicator of industrial activity. The major groups of uses are given in table 1 (*10*).

TABLE 1.—*Sulfur consumption by industry*

	Percent
Acid (sulfuric):	
Fertilizers (superphosphate and ammonium sulphate)	40
Chemicals	20
Petroleum	2
Pigments	8
Steel	4
Rayon and film	4
Other	7
Total acid	85
All other uses:	
Sulfite pulp	6
Carbon bisulfide	3
Ground and refined	3
Other	3
Total other uses	15

A partial list of products produced using sulfur or sulfuric acid given below indicates the widespread industrial dependence on sulfur:

Acids
Alcohols
Alum
Ammonium sulfate
Analine
Bleaching agent
Bromine
Carbon dioxide
Carbon disulfide
Carbon tetrachloride
Casein
Caustic soda
Cellophane
Celluloid
Cellulose esters
Cements
Chlorine
Coke
Copper
Dehydrating agent
Detergents
Dyes
Ebonite
Electroplating
Explosives
Fertilizers
Fire extinguishers
Fireproofing agents
Fireworks
Food preservatives
Fumigants
Fungicides
Glue
Glycerin
Impregnant
Inorganic or organic acids
Insecticides
Leather
Livestock food
Lubricants
Magnesium
Matches
Medicine
Metallurgy
Paints and pigments
Paper pulp
Petroleum products
Pharmaceuticals
Phenol
Photography
Plastics
Plate glass
Rayon
Refrigerants
Resins
Road-surfacing materials
Rubber goods
Soap
Soda
Solvents
Steel pickling and galvanizing
Storage batteries
Sugar
Sulphonated oils
Synthetic fibers
Synthetic rubber
Textiles
Tires and rubber
Water purification

A rapidly changing technology has created new sulfur demands and made others obsolete. Since sulfuric acid is an active acid well below the cost of other acids of comparable activity it is tried first in most research requiring acid. During the 1940's aviation gasoline, synthetic ammonium sulfate, ethyl acohol, and synthetic detergents became important sulfuric acid consuming industries. However, the salt-sulfuric acid process for manufacturing hydrochloric acid was displaced by byproduct recovery hydrochloric acid from organic chlorination. In the 1950's new markets were developed in processing uranium, ammonium phosphates, tall oil, and DDT, but the industrial explosives market was lost to ammonium nitrate.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Elemental sulfur and sulfuric acid are recovered as byproducts at smelters treating copper, lead, and zinc sulfide ores.

Elemental sulfur and hydrogen sulfide are recovered as byproducts in the treatment of sour natural, refinery, and other industrial gases.

Iron sinter is recovered as a coproduct in manufacturing sulfuric acid from pyritic ores.

Pyrites can be recovered as byproducts at coal-washing plants. Sulfur compounds leached from coal mines and waste dumps may contribute to stream pollution.

Cement is recovered as a coproduct in the production of sulfuric acid from anhydrite.

ALTERNATE MATERIALS

Substitutes for sulfur or sulfuric acid have been developed for only a small part of total consumption. Hydrofluoric acid may be used instead of sulfuric acid in manufacturing high-octane gasoline. Nitric acid, at a cost, could be used by the fertilizer industry where the introduction of sulfur is not required. Hydrochloric acid could be used for steel pickling. For many years the ample supply and low price of sulfur have restricted the use of alternates.

RESERVES

Reserves of sulfur and sulfur-bearing material in the United States and the rest of the world are ample to supply any probable demand, and an orderly transition can be made to alternate sources of sulfur as supplies of low-cost sulfur are depleted.

It is unlikely that any more onshore salt-dome deposits will be discovered on the gulf coast, although numerous salt-dome deposits occur offshore within 40 miles of the coast of Louisiana and Texas. One sulfur deposit in the Gulf of Mexico is being utilized and one more is known. Reserves of native sulfur recoverable by the Frasch process have been estimated to range from 50 to almost 200 million tons. Since not all the domes in the Gulf of Mexico have been explored, and since Boling dome of Texas Gulf Sulphur Co. has already yielded over 50 million tons of native sulfur, potential resources of native sulfur in the Gulf coast area might exceed 200 million tons (*12*). The salt domes being exploited in Mexico have been estimated to contain more than 50 million tons of native sulfur.

Surface deposits are unlikely to contain as much as 30 million tons.

Sulfides, other than in coal, contain from 100 million to 150 million tons of sulfur.

Sulfur in coal is the second largest reserve of this element. Some pyrites in coal can be recovered by present methods. Finely disseminated pyrite is too difficult to recover by physical means. The sulfur from finely disseminated pyrite in coal and the organic sulfur content is expected to be recoverable only from flue gases. The sulfur content of various coals in the United States normally ranges from 2 to 3 percent. Coal in minable deposits may contain as much as 5 billion tons of sulfur.

Sulfates contain more sulfur than all other reserves combined. The quantity of sulfur in gypsum, anhydrite, and as sulfates in sea water is tremendous.

The probable sulfur in known recoverable reserves of fossil fuels can be calculated from published quantity data (*20*). Assuming that minable coal contains 2.6 percent total sulfur, petroleum contains 0.6 percent sulfur, shale oil contains 0.75 percent sulfur, and natural gas averages 0.05 percent sulfur, there is 5.1 billion tons of sulfur in known recoverable fossil fuels in the United States.

Probable sulfur reserves in the United States can be summarized as follows:

Source:	*Sulfur (million long tons)*
Salt dome deposits	200.
Surface deposits	10–30.
Sulfide ores	100–150.
Coal	5,000.
Petroleum	45.
Natural gas	7.
Shale oil	50.
Anhydrite and gypsum	Enormous.
Sea water	Enormous.

Pyrites are the most abundant of the metalliferous minerals and occur in ores of great variety and number. Pyrite (FeS_2), the commonest type, is present in small quantities in many igneous and sedimentary rocks. Only occasionally is it found in sufficient quantities and pure enough to be of commercial value. Large pyrites deposits, principally pyrrhotite, occur along the Appalachian belt in St. Louis County, N.Y.; Louisa County, Va.; Great Gossan Lead, Va.; and Ducktown, Tenn. Other large deposits are found in Bingham, Utah; Shasta County, Calif.; Jerome, Ariz.; and Maine. Smaller deposits of pyrites occur in Georgia, Missouri, Pennsylvania, South Carolina, Wisconsin, South Dakota, Colorado, Arizona, Montana, and Vermont. Large quantities of pyrites are found in slates and schists in the iron districts of Iron River, Mich., and Cuyuna, Minn.

Although the reserve of pyrites in byproduct sources is large, it becomes available slowly in quantities determined by the rate at which the main product is produced. Mine dump and tailing basins at some of the older mining properties are available sources of pyrites. Additional tonnages are constantly being added at these and other mining properties as mining progresses.

The large quantity of sulfur dioxide released in the smelting of the sulfide ores of copper, lead, zinc, and nickel is potentially a much larger source of sulfur or sulfuric acid than at present, but this source must be discounted in part owing to various physical and economic factors. Frequently, the sulfur dioxide gas produced at smelters is too dilute to be used as a satisfactory feed for an acid plant unless enriched by other means. Most smelters are situated in remote areas; consequently, transportation costs to acid markets are prohibitive.

There are many principal reserves of sulfur in addition to those in the United States and the Frasch reserves in Mexico. For example

there are large reserves of sulfur recoverable from natural gas in Canada, France, and elsewhere; there are possibly 100 million tons of volcanic sulfur in the Andes and perhaps 25 to 50 million tons in Japan; and the Tarnobrzeg deposit in Poland has a measured reserve of 90 million tons.

SOURCES OF STATISTICAL INFORMATION

Annual and monthly data on the production, shipment, and stocks of sulfur in the United States are obtained from producers by the Bureau of Mines. World production data are compiled by the Bureau from foreign service dispatches and official publications of foreign countries, and figures on foreign trade are obtained from the Bureau of the Census. Selected special information is obtained by contacting sulfur producers and distributors.

PRODUCTION, CONSUMPTION, AND TRADE

In 1963 the United States supplied about 60 percent of the world production of native sulfur, 46 percent of the elemental sulfur (including native), and 4 percent of the world pyrite production.

The production of sulfur and sulfur-containing raw materials in the United States and the world production of elemental sulfur by countries are shown in tables 2 and 3, respectively.

The United States is the world's largest consumer of sulfur. Consumption was 34 percent of the free world total in 1963. This was an alltime high.

Imports of elemental sulfur from Mexico and Canada increased rapidly in the last few years and reached 863,000 tons and 480,000 tons, respectively, in 1963. The development of large-scale sulfur production in Mexico, Canada, and France since 1956 changed the foreign trade patterns with the United States losing some markets in these and other countries but gaining new markets elsewhere. Imports and exports are shown in table 4. Imports of pyrites are shown in table 5.

Most of the sulfur exported from the United States is the so-called crude run-of-mine Frasch sulfur (99.5 percent pure) from Texas and Louisiana. Sulfur was also exported in the crushed, ground, refined, sublimed, and flowers forms. In 1963 major exports went to India, 16 percent; the United Kingdom, 15 percent; Canada, 9 percent; Brazil, 8 percent; and Australia, 8 percent.

Transocean shipments of sulfur were all in solid form until May 1964 when liquid-sulfur deliveries to Rotterdam, Netherlands, were started.

The United States does not levy a tariff on sulfur.

STRATEGIC CONSIDERATIONS

The United States continues to be self-sufficient in sulfur and has a surplus of elemental sulfur for export. In addition, Canada and Mexico are two of the world's largest producers and both are growing in sulfur production capacity. Recovered sulfur from domestic sour natural and refinery gas and imports from Canada and Mexico have been growing and have satisfied increased domestic needs while Frasch production has remained stable. Frasch reserves are adequate for the foreseeable future.

Sulfur is not stockpiled by the Government, but producers' stocks of Frasch and recovered sulfur could satisfy domestic needs for 9 months at the 1963 rate of demand.

Because the Frasch sulfur industry is concentrated in the Gulf Coast States of Texas and Louisiana and on the Isthmus of Tehuantepec in Mexico shipping sulfur by the usual maritime routes makes it vulnerable to submarine attack. Inland shipments by barge and recovered sulfur from scattered producers in the United States and Canada shipped by rail would be less vulnerable.

PRICES

The price of sulfur has remained relatively stable over a long period of time because of the inelastic nature of demand. Posted prices have differed from contract prices with the latter containing a competitive allowance as required by current marketing conditions. Prices have changed somewhat in the last few years as a result of the development of liquid sulfur deliveries to consumers in the United States and to oversea markets. Delivered prices from regional liquid-sulfur terminals include transportation, handling, and storage costs.

Historically, posted prices remained at $18 per long ton, f.o.b. mines, from 1926 to 1938. Prices dropped to $16 for the period 1938–47; rose to $18 for 1947–50; and rose to $21 to $22 in 1950. The Office of Price Stabilization froze the price of sulfur at $21 to $24 per long ton f.o.b. mine for domestic sales in 1951. Export prices were $25 to $27 per long ton f.o.b. port. Price controls were removed on March 17, 1953. Prices rose to $25.50 to $27.50 f.o.b. mines for domestic sales and $28 to $30.50 f.o.b. port for export. Domestic prices remained at this level until 1957 when prices were reduced $3 per ton

to $23.50 and $22.50 per long ton f.o.b. mines for bright and dark sulfur, respectively, when competition from Mexican Frasch sulfur began. Export prices were $25 and $24 f.o.b. port for bright and dark sulfur, respectively. In 1959 Freeport Sulphur Co. initiated a $3.50-per-ton competitive allowance for water shipments to east coast ports and a $1 per ton discount for barge shipments on the Mississippi River and other inland waterways but posted prices remained unchanged. In 1961 competitive allowances along the east coast of the United States were reduced to adjust for a $2-per-ton increase in price of Mexican Frasch sulfur in these markets. In 1961 prices along the east coast and the oversea markets increased. In 1962 a competitive allowance of $1.50 to $3 to the upper Midwest was provided to offset competition from increasing Canadian sulfur imports.

TABLE 2.—*Production of sulfur and sulfur-containing raw materials by producers in the United States*

[Long tons]

	Gross weight	Sulfur content	Gross weight	Sulfur content	Gross weight	Sulfur content
	1954–58 (average)		1959		1960

Source: Bureau of the Census.

In 1964 price increases on new business came first in the oversea markets. A domestic price increase of $2 per ton became effective on new business on July 1 and as of January 1, 1965, on business under contract. Published prices at beginning January 1, 1965, were $27.50 per long ton f.o.b. gulf ports for bright sulfur to be exported; $25.50 per long ton f.o.b. mines and $27 per long ton f.o.b. gulf ports for domestic markets. The published price for acid grade or dark sulfur at any point or for any market was $1 less than that for bright sulfur.

The Mexican Frasch producers, Pan American Sulphur Co. and Gulf Sulphur Co., increased prices $2 per long ton to all markets.

TAXES

The sulfur industry has the usual taxation problems faced by all industry and in some States pays severance taxes. In Texas and Louisiana, severance taxes of $1.03 a long ton are imposed. Domestic producers are granted a depletion allowance of 23 percent on income from domestic and foreign production.

TRANSPORTATION, STORAGE, AND HANDLING

In 1963, 85 percent of the elemental sulfur used in the United States was delivered to consumers in liquid form. United States and Mexican Frasch producers shipped liquid sulfur to 27 producer-controlled regional storage and transshipment terminals in 1963. The location and capacity of these terminals are listed in table 6. The terminals were supplied by tankers along the coast and by barges on inland waterways. The widespread acceptance by the U.S. consuming industry was followed by the development of liquid-sulfur service overseas. The Sulphur Export Corp. (Sulexco) which sells for the four U.S. Frasch producers overseas contracted for two oceangoing liquid-sulfur carriers of 25,000-ton capacity each and for a liquid-sulfur terminal at Rotterdam, Holland. The first liquid-sulfur delivery overseas was made by the *Naess Texas* during May 1964 to Sulexco's Rotterdam, Netherlands, terminal. A sister ship, the *Naess Louisiana*, began service in the second half of 1964 after launching in

[1] Completed in 1963 but not in operation. [2] Began operating in 1963.

June in England. Pan American Sulphur Co. of Mexico, a Frasch producer, and the Société Nationale des Pétroles d'Aquitaine of France, a recovered-sulfur producer, built liquid-sulfur terminals at Immingham, England; Rotterdam, Netherlands; and Rouen, France.

Sulfur is an excellent heat insulator and is readily kept liquid by steam coils while in shipment or storage. If solid, the same coils can act as remelters. Advantages in using liquid sulfur include reduction in labor costs, wind losses, contaminations, and melting costs.

Liquid sulfur may be handled in iron and steel equipment if moisture is absent. Aluminum containers are satisfactory for storing liquid or dry solid at normal temperatures. Special stainless steel containers, pipes, etc., are required at elevated temperatures (above 444.6° C).

Safety considerations require the removal of hydrogen sulfide and carbon disulfide, if they occur, by ventilation to outside air. Both are potentially explosive; carbon disulfide has exploded in contact with steam pipes (*9*).

Most of the sulfur exported from the United States is crude Frasch sulfur from Texas and Louisiana. Sulfur was also exported in the crushed, ground, refined, sublimed, and flowers forms. United Kingdom, India, Canada, Brazil, Australia, and the Netherlands were the chief recipients of crude sulfur in 1963.

Freshly broken sulfur weighs approximately 84 pounds a cubic foot. This weight may be increased to 90 pounds per cubic foot after several handlings, owing to the tendency of sulfur to settle and pack. Its angle of repose is normally about 35°, although vertical faces may develop in removing sulfur from a stockpile.

The equipment used for handling bulk sulfur depends on the quantity to be moved and may range from hand shovels or wheelbarrows to power shovels or conveyor systems.

In the broken state, sulfur, particularly under humid conditions, may become corrosive; consequently, sulfur companies recommend the use of corrosion-resistant materials such as aluminum, stainless steel, rubber, and wood in conveyors, hoppers, chutes, cars, and other pieces of equipment.

Shrinkage resulting from mechanical spillage, windborne loss during transfer, and wind and rain erosion of outside storage averages about 0.5 percent, but sometimes is substantially higher.

RESEARCH

In a sense, every chemist who tries sulfuric acid first in an experiment is doing research for the sulfur industry. A search of the patent files reveals a very large number of patents dealing with sulfur or its compounds. In addition, all large producers do some research and several outside groups have been formed. The Sulphur Institute with offices in Washington, D.C., and London, England, is supported by producers of

Frasch and recovered sulfur and pyrites. It operates on a grant-in-aid basis in the United States, Europe, Australia, and New Zealand. The research is done in universities or by industrial groups. The Institute distributes literature in the field of interest. Primary interest is on agricultural uses for sulfur. Freeport Sulphur Co. opened a central Research and Development Laboratory at Belle Chasse, La., in 1962. Its research includes increasing the knowledge of the manufacture of sulfuric acid among other things. Texas Gulf Sulphur Co. recently published a sulfur manual.

In Canada, two groups are active, the Research Council of Alberta and a newly formed group, the Alberta Sulphur Research, Ltd.

Several reports by the Bureau of Mines have been issued or are nearing completion on the sulfur industries of regional areas of the United States.

OUTLOOK

World demand for sulfur is expected to grow as underdeveloped countries become industrialized, and the production of sulfuric acid for fertilizer manufacture is increased to reduce food shortages. By 1970, consumption of sulfur in all forms may be 25 million long tons per year of which 15 million tons is expected to be elemental.

The dependence on U.S. Frasch sulfur has been reduced by the rapid development of sulfur industries in Mexico, Canada, and France. Mexican Frasch capacity is being increased from 1.9 to 2.5 million tons per year while Canada, prior to 1964, did not use fully her 1.9-million-ton capacity. Larger Canadian capacity is expected, but this is related to sales of natural gas using pipelines not yet authorized or constructed. French production presently uses all of a 1.45-million-ton-per-year capacity and sales are not expected to increase because of the planned rate of production of natural gas. Poland is planning to produce 1.0 million tons of sulphur per year from the Machow deposits by open-pit mining by 1975.

U.S. Frasch production has remained relatively stable and will grow by utilizing full capacity of present mines and opening new ones as demand exceeds supply. Offshore sulfur deposits offer the best promise of new reserves. Frasch potential resources should last until the year 2000 at the present rate of production. Recovered sulfur from sour natural and refinery gas will become an increasing important source of sulfur in the United States. Development of the huge Athabasca oil sand deposits in Alberta, Canada, may eventually contribute large tonnages, but only 200,000 tons per year is forecast for 1970. Ultimately, greater use will need to be made of pyrite and gypsum as sources of sulfur, but greatly expanded use of sulfur in smelter gases is not predicted in the United States in the near future, and it will be a long time before gypsum and anhydrite will be sources of domestic sulfur.

Elemental sulfur sold in the United States is now 85 percent in liquid form. Movement overseas of liquid sulfur is developing and will increase, but most oversea deliveries will be solid sulfur.

Sales groups, such as the Sulphur Export Corp. (Sulexco) of the United States, and Cansulex of Canada will expand foreign markets. Sulfur utilization research should become more intense and will ultimately be a factor in increasing sales.

Prices, historically quite stable, will increase and may approach the peak prices of 1956. Price increases will bring about the development of additional reserves.

More sulfur may be recovered from sulfur-bearing gases produced at metallurgical plants, but this source will not expand rapidly unless there is some major development in the recovery of elemental sulfur from hot, dilute gases.

The ratio of production of elemental sulfur to pyrites, usually fairly constant, is expected to increase.

For the foreseeable future, the North American Continent will continue to supply the major quantity of world sulfur, unless a substantial source of easily recoverable sulfur is discovered elsewhere. There does not appear to be any source that will replace Frasch sulfur in its dominant position. Production of recovered sulfur will increase and continue to supplement that produced from Frasch mines. It may be recovered from high-sulfur crude oil in the Middle East.

It has been estimated that, exclusive of by-product sulfuric acid, the demand for sulfur in the United States will be 12.5 million tons per year by 1975 (*14*).

PROBLEMS

The principal problems of the sulfur-producing industry are economic rather than technical. Technical improvements in most sulfur-producing and utilization processes will occur just as technical progress is being made in most industries.

While reserves appear to be adequate for perhaps 40 years, the present and future producers of sulfur must do sufficient exploration and development work to permit timely production from new sources. Since 11 years passed between discovery and production at Grand Isle it is apparent that offshore exploration should be 6 to 10 years ahead of production. Enough know-how and experience has been gained so additional new deposits could be brought in faster unless more difficult oceanographic conditions prevail.

Privately financed sulfur producers in the United States must compete, for both domestic and overseas markets, with sulfur from Mexico produced from mines that were subsidized during the development period and whose products may be exported to U.S. ports in ships at rates below those available for U.S. producers to ship their sulfur to the same ports.

Preferential freight rates that are available for sulfur produced in Canada and marketed in Midwestern United States creates unequal marketing problems in the industrialized north-central part of the country.

Unequal competitive practices which put U.S.-produced sulfur at an economic disadvantage in world markets could result in the closing of some Frasch mines before the maximum quantity of sulfur had been removed. This problem of conserving sulfur resources through maximum extraction would become more acute whenever sulfur prices decrease.

Trade barriers in the form of high import duties, required licenses, quotas, complete embargos, special taxes, or required deposits all make marketing of U.S.-produced sulfur more difficult to users in some countries. Long-term credit insurance is essential to the exporting of sulfur to countries where the political or economic conditions are unfavorable for prompt payment for material received.

Lack of adequate information on the location and quality of undeveloped or unknown reserves, new market areas, and costs of producing sulfur or sulfur compounds hampers development of output from local resources.

Similarly, the lack of efficient and economical processes restricts the use of non-Frasch resources and sulfur-bearing waste products of other industries. This is a limiting factor in the recovery of both primary and secondary sulfur. The hazards and nuisance situations involved in producing and handling sulfur and its compounds, especially those to be recovered from hot dilute sulfurous gases, are continuing problems to the industry.

Accurate and current statistics on the use pattern of sulfur and sulfuric acid is a serious information problem to industry and government organizations concerned with these commodities.

All sulfur producers encounter many serious individual problems in the mining and production of their products. In addition, there are numerous common problems, such as taxation, freight rates, competition with substitutes, and need for basic commodity information.

TALC, SOAPSTONE, AND PYROPHYLLITE

By J. Robert Wells [1]

TALC, soapstone, and pyrophyllite are used in a multitude of ways and enter into practically every aspect of modern living, although no more than a small fraction of the total quantity used appears in such easily recognized forms as marking crayons or toilet powders. A much greater amount, over 90 percent of the total U.S. consumption, finds its way into ceramics, paints, fillers, and refractories.

The earliest recorded uses of soapstone were for carved ornaments, building stone, and cooking utensils. Ground talc was first produced in New York in 1880, and since that year New York consistently has produced more talc than any other State. In recent years North Carolina and California have also been major producers of talc and pyrophyllite.

Deposits occur in many States and in most foreign countries; the greatest production usually comes from those areas where industrial development is greatest. The United States produces about 25 percent of the world total. Since 1930 the value of talc, soapstone, and pyrophyllite consumed annually in the United States has increased at a rate about 1½ times that of gross national product in constant dollars. Domestic production in 1963 totaled 804,000 short tons, sales were 794,000 tons valued at $18 million, and apparent domestic consumption was 763,000 tons. Strategic block talc is imported from India and Italy; high-grade ground talc is imported from India, Italy, and France. Imports have declined in recent years.

Talc, soapstone, and pyrophyllite deposits are believed to have been formed during periods of intense dynamic disturbance through hydrothermal alteration or contact metamorphism of preexisting rocks. The whiter, purer talcs were derived from sedimentary magnesium carbonate rocks, the less pure from ultrabasic igneous rocks, and pyrophyllite from acidic igneous rocks.

The physical and chemical properties of talc vary with its genesis, and its uses often depend on specific properties. Talcs from different deposits are not always interchangeable in industrial applications. Although few, if any, minerals surpass talc in multiplicity of uses, the ceramic, paint, rubber, insecticide, roofing, and paper industries consumed 79 percent of the 1963 output of talc and soapstone. The remainder was used in toilet preparations, asphalt filler, foundry facings, refractories, and a large number of minor applications.

The United States is self-sufficient in all grades of talc, soapstone, and pyrophyllite except block steatite talc and block pyrophyllite, the requirements for which are small. Block steatite talc is on the list of strategic and critical materials for stockpiling, but phosphate-bonded talc is a satisfactory substitute. In an emergency, conversion to the phosphate-bonded material could be accomplished quickly.

Except for industrial research to control quality and expand the uses of these commodities, little money or time is expended on research. Some work was done by the National Bureau of Standards on talc synthesis. The Bureau of Mines and others have conducted beneficiation research on talc and pyrophyllite and on the chemical bonding of ground steatite talc.

The short- and long-term supply outlook for talc, soapstone, and pyrophyllite is good, and consumption should continue to increase at a rate greater than that of the gross national product.

There is need for additional research to find new uses for the plentiful grades of talc, soapstone, and pyrophyllite, to lower mining and processing costs, and to improve quality.

[1] Commodity specialist.

BACKGROUND

The earliest known uses of soapstone, which depended upon the ease with which it could be cut, were for amulets, and building stone.

Soapstone was first used on this continent by the American Indians, who early availed themselves of its heat-retaining and easy cutting qualities for making bowls, pots, cooking stoves, and other utensils. These uses suggested the term "potstone," which is still applied to soapstone in some localities. The early European settlers on the North American Continent used heated blocks of cut soapstone extensively as warming stones in carriages, sleighs, and beds, a practice that survived until recent times. Beginning between 1870 and 1880, tubs, sinks, hearthstones, mantels, fireless cookers, griddles, firebrick, and various utensils were manufactured from soapstone. The first talc grinding mill was established at Gouverneur, N.Y., about 1880, and the product was used principally for paper filler (*1*).[2]

From 1880 to 1900, inclusive, the annual output of the talc and soapstone industry of the United States was about 88,000 short tons valued at about $1 million. These figures include manufactured soapstone items.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF INDUSTRY

In 1963 there were 34 talc, 12 soapstone, and 11 pyrophyllite producers. One company produced talc and pyrophyllite, and one company produced talc and soapstone; all others produced only one commodity. Operations ranged from individuals mining less than 100 tons a year of crude ore, mainly in California, to companies producing several tens of thousands of tons from either a single deposit or several deposits. In 1963 sales of talc, soapstone, and pyrophyllite in the United States totaled 794,000 tons valued at $18 million.

The larger producers were grinders of talc, soapstone, and pyrophyllite in mills either adjoining or near the deposits or at sites convenient to the major markets. All talc produced in Nevada, however, was shipped to California, part of the California and Montana output was shipped to Nebraska and Utah, and part of the Washington output was shipped to Oregon for grinding. One company in North Carolina produced talc crayons in 1963 in addition to ground material. One company in Maryland produced sawed talc for ceramic purposes in addition to crushed material.

Substantial quantities of crude ore were sold by producers to merchant grinders, especially in California. Part of the crude and prepared talc, soapstone, and pyrophyllite was sold directly to consumers by the producers; the remainder was sold to brokers. Some brokers also imported high-quality talc.

Most of the block steatite talc used for electronic tube spacers in the United States was processed by firms in Englewood, N.J., and Chattanooga, Tenn.

Talc is a relatively abundant mineral, and deposits of talc and soapstone occur in most countries. Pyrophyllite deposits are distributed less widely. Commercial production has been confined mostly to the countries having the highest industrial development. The United States produced 26 percent of the world output of talc, soapstone, and pyrophyllite in 1963; Europe, excluding Russia, 21 percent, and Japan, 23 percent. Almost all Japanese production was pyrophyllite. The free world sources of block steatite talc are India and Italy.

In 1963 talc was produced in Alabama, California, Georgia, Maryland, Montana, Nevada, New York, North Carolina, Texas, and Vermont. Soapstone was produced in Arkansas, California, Maryland, Nevada, Texas, Virginia, and Washington. Pyrophyllite was produced in California and North Carolina. Sericite schist, closely resembling pyrophyllite in physical and chemical properties, was produced in Pennsylvania and included with pyrophyllite statistics.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Talc, in its broader definition, is an inclusive term covering all gradations from the pure mineral to impure, massive talcose rocks (soapstone) that may contain as little as 50 percent of the mineral talc.

Talc, the mineral, is a hydrous silicate of magnesium, $3MgO \cdot 4SiO_2 \cdot H_2O$, theoretically containing 63.4 percent SiO_2, 31.9 percent MgO, and 4.7 percent H_2O. These constituents vary within rather wide limits. Steatite was originally an alternative mineralogical name, often restricted to massive talc (*14*). It also was used to refer to any massive talcose rock. In recent years steatite has been used to designate a grade of talc suitable for making electronic insulators. Specifications for steatite talc state

[2] Numbers in parentheses refer to items in the list of references at the end of this chapter.

the allowable maximum impurities, shrinkage, dielectric properties, and fired color (*13*).

Steatite ceramics are dielectric bodies compounded from ground steatite talc and a suitable flux and binder, formed by dry pressing or extrusion and subsequently fired at relatively high temperatures to form strong finished products. Frequently, these steatite ceramics are improperly referred to only as steatite.

Block talc is any massive talc or soapstone from which products can be obtained by machining.

Block steatite talc is block talc that meets specifications for electronic insulators. Block steatite talc has been designated as strategic; thus, the two grades of block talc are referred to as strategic block talc and nonstrategic block talc.

Lava is a term frequently used in the trade to designate block talc or even the finished product made from block talc.

French chalk is a soft, massive variety of talc used for marking cloth.

Soapstone originally was synonymous with steatite. Now it includes all massive gray to bluish or greenish talcose rocks, which, with a few exceptions, feel soapy and can be carved easily with a knife. Virtually all commercial soapstones are highly ferruginous metamorphic rocks composed of 50 to 80 percent of the mineral talc, intimately mixed with varying proportions of chlorite, amphibole, pyroxene, and mica, as well as pyrite, quartz, calcite, or dolomite. Soapstone, therefore, is a rock rather than a mineral, although the term may be used accurately to refer to massive talc, however pure. Soapstone grades imperceptibly into talc.

Pyrophyllite is a hydrous aluminum silicate similar to talc in properties and in most applications. Its formula is $Al_2O_3 \cdot 4SiO_2 \cdot H_2O$, with 66.7 percent SiO_2, 28.3 percent Al_2O_3, and 5.0 percent H_2O.

Agalmatolite and pagodite are terms applied to massive pyrophyllite from China and Korea, used to produce carved ornaments.

Wonderstone is a term applied to a massive block pyrophyllite from the Republic of South Africa.

Grades of talc usually are identified with the end use; for example, Cosmetic grade, Ceramic grade, Pharmaceutical grade, or crayon stock. Some talcs are distinguished by their crystal shape or structure as acicular, fibrous, or massive; by their mineralogical impurities, as tremolitic; or by such terms as hard or soft, white or offcolor. Similar appropriate terms are applied to grades of soapstone or pyrophyllite.

National Stockpile Specifications P–53 Talc (Steatite) Block and P–53a, Talc (Steatite) Lump, cover the physical, chemical, and electronic requirements for grades of talc designated as strategic or critical.

TECHNOLOGY

Geology

Commercial talc deposits are of two classes, those derived from or associated with ultrabasic igneous rocks and those derived from sedimentary magnesium carbonate rocks. Although there is a considerable variation in each class, talc associated with sedimentary carbonate rocks tends to be whiter and purer than that derived from ultrabasic igneous rocks. High-quality steatite talc usually is associated with sedimentary carbonate rocks and occasionally with quartzites and granites.

Talc ordinarily is formed either under conditions of intensive dynamic disturbance, where the magnesian host rock has undergone severe deformation and squeezing with attendant heat and pressure or where the host rock has been subjected to contact metamorphism or hydrothermal alteration as a result of igneous activity.

Commercial talc deposits contain quartz, calcite, dolomite, magnetite, limonite, and many other impurities. In certain instances some impurities are acceptable and do not preclude commercial use of the talc. For example, the St. Lawrence County, N.Y., commercial talc may contain 30 percent or less of mineralogically pure talc. The tremolite, serpentine, and anthophyllite, although mineralogical impurities, are considered to be part of the talc, but other mineralogical impurities, such as hematite, limonite, and pyrite, are deleterious.

Pyrophyllite occurs in irregular, lenticular, or bedded deposits, usually in areas of intense metamorphism. According to Spence (*19*), it is believed to have been formed by hydrothermal alteration of acidic rocks (andesites, rhyolite, tuffs, slates, schists, etc.). Stuckey (*20*) states that the North Carolina deposits were formed through replacement of acid tuffs and breccias. Minerals associated with pyrophyllite are quartz, sericite, pyrite, chloritoid, chlorite, epidote, zircon, titanite, rutile, zeolites, apatite, certain feldspars, and iron oxides. The North Carolina deposits range from a few feet to 500 feet in width, up to 1,500 feet in length, and more than 500 feet in depth.

Mining

More than 60 percent of the domestic talc, soapstone, and pyrophyllite production is ob-

tained by underground methods. Underground entry may be by adit, inclined shaft, or vertical shaft. When underground openings are entirely in ore and support is necessary, extra care must be taken in placing timbers because of the slippery nature of talc. Some deposits are mined by open-stope and pillar methods, with rock bolting used where necessary; recovery ranges from less than 50 to as much as 65 percent.

Mechanization of underground mines is not extensive, although in recent years diesel-operated mining and transportation equipment has been used in one of the larger California mines, which has a vein of talc approximately 15 feet thick with a 13° dip.

When the talc is to be used in block form or for cutting into crayons, explosives are used sparingly to minimize shattering, and blocks as large as practicable are broken out with bars.

At the quarry of Alberene Stone Division, the Georgia Marble Co. at Schuyler, Va., which closed in 1962, cuts averaging 4 feet in width were made along two benches, each about 7 feet high. About 75 percent of the soapstone removed was waste, partly because of hard spots that made sawing difficult, but chiefly because of small cracks that might cause the slabs to break.

Frequently, different grades of talc are mined selectively or hand sorted. One company in Gouverneur, N.Y., mines several grades of talc by selected loading from various stopes or development openings.

Milling

Talc, soapstone, and pyrophyllite have no end uses in the crude form and usually receive some treatment before being sold, although a few consumers prefer to buy crude talc and prepare it to their own specifications. A small quantity (less than 0.25 percent of the total sales) is sawed into rectangular prisms for marking crayons.

A Vermont firm recovers a flotation product from a mixture of talc, high-iron magnesite, and other impurities. Although talc is one of the most flotable minerals, the occurrence of deposits of talc with satisfactory properties for almost all industrial applications has discouraged widespread interest in beneficiation. The cleanest talc is obtained with pine oil and alcohol frothers alone, but the additional use of such reagents as petroleum sulfonate or short-chain amines is usually required to effect satisfactory recovery (*2*, *8*, *11*). Ore from some deposits is dry screened or washed in trommel screens to remove fines and is then passed over belt conveyers to facilitate the elimination of the larger pieces of waste or low-grade material by handpicking.

Primary crushing in jaw or gyratory crushers is followed by secondary crushing in rotary or disc crushers or in rolls. Hammer mills, with or without air separation, are used for further reduction of particle size to the 40- to 100-mesh range.

Roller mills, in closed circuit with air separators, are the most satisfactory for finer grinding (100- to 325-mesh) of soft talcs or pyrophyllites. Roller mills are sometimes equipped with combustion chambers, permitting simultaneous drying and grinding, or with magnetic separators, or with both.

For more abrasive materials, such as New York talc and North Carolina ceramic-grade pyrophyllite, this stage of the grinding is effected in quartzite- or silex-lined pebble mills, with quartzite pebbles as a grinding medium. These mills are ordinarily in closed circuit with air separators but sometimes are used as batch grinders, especially if reduction to finer particle sizes is required.

Fluid-energy grinding mills, popularly called micronizers, are used to make products of finer particle size than are attainable with standard mills. In a micronizer, the granules of feed drop through a central opening into a steel chamber and are there subjected to an intense mutual bombardment by the impulse of high-pressure air or steam introduced through nozzles around the chamber periphery. Standard particle sizes from 20 microns to less than 1 micron are attained; the product is known as micronized talc.

Talc marking crayons are cut from selected, medium-hard, massive talc or soapstone by circular saws similar to those used in woodworking. The lumps of crude talc are squared with large saws, 18 to 24 inches in diameter, and the resulting blocks are sawed into slabs equal in thickness to the desired width of the crayons. Saws, 6 to 12 inches in diameter, are used to cut the slabs into finished crayons, which are then sorted and packed for shipment. For greatest strength, the crayons are cut lengthwise of the grain of the talc.

USES

Properties that make talc, soapstone, and pyrophyllite desirable for a wide variety of industrial uses include the following: Extreme softness (No. 1 on Mohs' scale), whiteness, good hiding power, good luster, good retention for filler purposes, chemical inertness, high slip, high fusion point, high dielectric strength, high specific heat, varying degrees of oil absorption, low moisture, and low electrical and heat con-

ductivity. Talc is used for marking crayons because it makes a mark on either hot or cold metal that remains visible when the metal is cooled or reheated. All of these properties are not necessarily found to the same favorable degree in an ore from a specific deposit. The ceramics, paint, rubber, insecticides, roofing, and paper industries consumed 79 percent of the talc, soapstone, and pyrophyllite sold or used by producers in the United States in 1963.

Table 1 shows the percentage distribution by uses of talc, soapstone, and pyrophyllite sold by producers in 1959–63 and illustrates the differences in the use patterns of the materials.

Because most talc, soapstone, and pyrophyllite is marketed within a few hundred miles of the source, the use pattern for material from an individual deposit is usually confined to the needs of local industry rather than to the wide range of uses for which it is suitable. Customers, however, frequently insist on certain materials regardless of transportation costs. Table 2 shows the differences in use patterns of ores of each commodity from selected States.

Talc has diverse minor and special uses such as in white-shoe polishes and white-glove cleaners; as a dusting powder for salami; to prevent sticking of bottle, rubber, and candy molds; to impart a finish to wire nails and leather; as a filler in plastics; as an admixture for certain concretes; as a polishing medium for peanuts, gunpowder grains, and turned wooden articles, and as a component of some cup greases.

Nonstrategic block talc is used for gas-burner tips, insulators for electrical appliances, and marking crayons. Strategic-grade block talc is used for tube spacers and insulators for vaccuum power tubes.

Block pyrophyllite is used as a pressure transfer medium in ultra-high-pressure devices and for welding-torch tips, airplane instrument-panel bushings, and components of warheads for guided missiles, among other applications.

ALTERNATE MATERIALS

Talc, soapstone, and pyrophyllite are subject to competition from each other, from kaolin, fuller's earth, limestone, and other nonmetallic fillers, and from feldspar for ceramics as determined partly by price and partly by performance. For example, although pyrophyllite is more suitable as a neutral diluent for organic insecticides, talc, soapstone, fuller's earth, kaolin, diatomite, or other substances may be used in areas where pyrophyllite costs much more or when other properties of the filler are more important. Another example is the substitution of kaolin for New York and Vermont talcs as paper filler.

Phosphate-bonded talc is used in place of block steatite talc; potential substitutes are magnesium oxychloride-bonded talc, phosphate-bonded synthetic mica, and hot-pressed syntheic mica.

RESERVES

Quantitative data on domestic talc and soapstone resources are not complete, but about 90 million tons of reserves has been estimated on the basis of available information (*9*). Additional large deposits will probably be discovered in some of the major producing areas for which reserve data are now lacking. The largest known ore bodies, containing over 50 percent of the known reserve, are in New York. The Vermont deposits comprise 30 percent of the reserve, and the remaining 20 percent is distributed between California, Georgia, Montana, Nevada, North Carolina, and Texas.

Essentially all of the domestic talc is of nonstrategic varieties, but deposits in Montana and Nevada contain a few thousand tons of lump steatite similar to the lump material from India. Large quantities of nonlump high-quality talc suitable for electronic applications are also known to exist in those States.

Pyrophyllite reserves in North Carolina total at least 12 million tons (*21*). The pyrophyllite belt is about 75 miles long, extending in a Northeast-Southwest line from Granville County to Montgomery County (*10*). Pyrophyllite deposits in California are located in Mono, Inyo, San Bernardino, and San Diego Counties. Reserve data are not available.

Talc and soapstone deposits are widespread throughout the world with the notable exception of Japan, where there is very little talc. Japan has, however, large deposits of pyrophyllite, a suitable substitute for most applications. The reserve is more than 70 million tons. Only two countries, India and Italy, have significant reserves of strategic-quality lump or block steatite, and only the Indian material is suitable for ultra-high-frequency electronic applications. In India, one of the two adjoining mines was essentially exhausted several years ago; reserves of the other deposit are not known. The Italian strategic block talc is found in Sardina; reserves are large, but quantitative data are not available. Large deposits of nonstrategic talc and soapstone are being exploited in France, Austria, Norway, India, U.S.S.R., and other countries.

SOURCES OF STATISTICAL INFORMATION

Annual data on the quantity and value of production and on sales of crude, sawed, manufactured, and ground talc, soapstone, and pyrophyllite are obtained from a canvass of all domestic producers and are published by the Bureau of Mines. In addition, data on the estimated end use of these materials are obtained from domestic producers in lieu of canvassing the large number of ultimate consumers. No data are published on stocks.

Figures on the quantity and value of imports of crude talc and soapstone and exports of talc, soapstone, and pyrophyllite are compiled by the Bureau of Mines from data obtained by the U.S. Department of Commerce. World production and exports data are compiled from State Department dispatches and official publications of foreign countries.

PRODUCTION, CONSUMPTION, AND TRADE

Table 3 shows world production of crude talc, soapstone, and pyrophyllite, by countries, 1954–58 (average) and 1959–63. Table 4 shows the apparent consumption of these materials in the United States for the same period. From 1930 to 1963, consumption of talc, soapstone, and pyrophyllite increased at a rate about 1½ times that of the gross national product in constant dollars, and no slackening of the rate of increase is apparent. The domestic per capita consumption of these commodities increased from 2.9 pounds a year in 1930 to 8.1 pounds a year in 1958 and remained at about that average level

TABLE 3.—*World production of talc, soapstone, and pyrophyllite, by countries*

[1] Data not available; estimate included in total except for North Korea.
[2] Includes Colombia (1960–63); Kenya (1954); Greece, Mexico, Paraguay, Peru, Portugal, Swaziland, Uruguay (1954–63); Yugoslavia (1954–58).

in the 1959–63 period. Italy, Canada, and France provided 95 percent of the United States imports from 1949 to 1953, inclusive, and 97 percent from 1954 to 1963, inclusive. Exports from the United States began to rise markedly in 1955 as a result of increased shipments of ceramic-grade talc from Texas to Mexico and amounted in 1963 to nearly 2½ times the 1954 volume.

Tariff rates effective August 31, 1963, on talc and soapstone were: Crude and not ground, 0.05¢ per pound; ground, washed, powdered, or pulverized, 12 percent ad valorem; cut or sawed, or in blanks, crayons, cubes, disks, or other forms, 0.5¢ per pound; other not specifically provided for, 24 percent ad valorem.

TABLE 4.—*Apparent consumption of talc, soapstone, and pyrophyllite in the United States*

[Thousand short tons]

Year	U.S. total sales	Imports for consumption				Exports	Apparent consumption
		Italy	Canada	France	Other countries		
1954–58 (average)	688	17	3	3	1	40	672

1962	777	19	2	4	1	47	756
1963	794	18	2	5	1	57	763

STRATEGIC CONSIDERATIONS

Block steatite talc is on the list of strategic and critical minerals for stockpiling. The free world supply is concentrated in one deposit in Italy and two adjoining deposits, one now practically depleted, in Madras Province, India. The supply of Italian material exceeds the demand, but Italian block steatite talc is not suitable for ultra-high frequency applications such as power-tube insulators. Indian material can be used for all applications, but production is erratic. The stringency of the block-steatite supply situation has been virtually eliminated by stockpiling and by development of phosphate-bonded talc, which is made from ground steatite talc and phosphoric acid, both in ample domestic supply. Evaluation tests made under contract with the U.S. Army Signal Corps Supply Agency showed that the phosphate-bonded material, although somewhat more difficult to fabricate into tube insulators, is equal in performance to the Indian natural block steatite talc normally employed. The block-talc processing facilities in the United States are concentrated in two plants, one in New Jersey and one in Tennessee. In an emergency the processing facilities could be dispersed readily, because only standard woodworking equipment, such as lathes and drill presses, is required.

Talc, soapstone, and pyrophyllite mines and grinding plants are distributed throughout the United States so that there are no strategic problems in production, but shortages of transportation for such bulk commodities could develop in an emergency.

The United States is self-sufficient in all grades of talc, soapstone, and pyrophyllite except block steatite talc and block pyrophyllite. Annual requirements of these materials are about 2,000 tons. Ceramic-grade pyrophyllite, produced only in North Carolina, is in short supply, but no other world sources of comparable material are known.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration, U.S. Department of the Interior, will advance 50 percent of approved costs on exploration programs for block steatite talc.

PRICES

Prices are negotiated between buyers and sellers on the basis of a wide range of specifications. Quotations only indicate the range of prices. For example, crude soapstone is delivered in Los Angeles for about $5 a ton, California talcs are valued in the general range of $8 to $15 a ton, f.o.b. mines, and ground and bagged material is priced about as follows: Soapstone and grades of talc used mostly as fillers, $17 to $20 a ton; ceramic and paint talcs, $30 to $32; steatite-grade talc, $35 to $40; cosmetic and pharmaceutical talcs, $35 to $50; and micronized talcs, $50 to $100 (*23*). Although a greater variety of grades is produced in California than in most States, the same general price range prevails in other producing areas.

Talc prices quoted in E&MJ Metals and Minerals Markets for December 30, 1963, were as follows: Per short ton, carlots, f.o.b. works, including containers unless otherwise specified: Georgia, 98 percent through 200-mesh, gray, $10.50 to $11.00 and white, $12.50 to $15.00; New Jersey, mineral pulp, ground, bags extra, $10.50 to $12.50; Vermont, 100 percent through 200-mesh, extra white, bulk basis, $12.50 and 99.5 percent through 200-mesh, medium white, $11.50 to $12.50; Virginia (soapstone), 200-mesh, $10 to $12, 325-mesh, $12 to $14, and crude, bulk, $5.50.

Quotations in Oil, Paint and Drug Reporter, December 30, 1963, were as follows: Per short ton, carlots, in bags, f.o.b. works: California,

$34.00 to $39.50; New York, fibrous, ground, $28.00, 99.5 percent through 325-mesh, $31.00, 400-mesh (micronized), $38.00, and 625-mesh (micronized), $80.00; Vermont, offcolor, $19.40; Canada, $20.00 to $35.00.

Pyrophyllite prices have not been published since 1954, when they were given as follows: Per short ton, bulk, carlots, f.o.b. mines: Standard grade, 200-mesh, $12.50, 230-mesh, $13.50, 300-mesh, $16.75; No. 3 grade, 200-mesh, $10 to $12, 325-mesh, $12 to $14, and crude, $5.50.

TAXES

No special taxes are imposed on the talc, soapstone, or pyrophyllite industries. Producers of block steatite talc are granted a depletion allowance of 23 percent on domestic production and 15 percent on foreign production. Producers of all other grades of talc and of all grades of soapstone and pyrophyllite are granted a depletion allowance of 15 percent on either domestic or foreign production.

TRANSPORTATION

Many of the grinding mills in the California-Nevada area are 100 or more miles from the mines. Some California and Montana crude talc is shipped to Utah and Nebraska, and Texas crude talc is shipped 300 to 400 miles for grinding. With these exceptions, grinding mills are near the deposits and have access to the major marketing areas. The better grades of ground talc, however, may be shipped from one coast to the other, despite the relatively high transportation costs.

RESEARCH

Most producers of talc, soapstone, and pyrophyllite have laboratory facilities for controlling the quality of their products, and some of the larger companies conduct research to correlate physical properties with end uses and to evolve new applications. Through research, producers develop specifications for various uses.

The National Bureau of Standards, under contract with the Office of Naval Research, carried out research on the synthesis of fluoro talcs, in which hydroxyl groups are replaced by fluoride ions (*22*).

Improved blending results from a new procedure in which ground talc is introduced upward from the base of the storage silo as a fluidized air suspension. Continuous agitation is thus assured as the filling progresses, and subsequent withdrawal of the stored talc through several ports around the bottom of the silo simultaneously delivers a product of superior uniformity (*16*, *17*).

A new application was announced in which ultrafine micronized talc is used to reinforce synthetic rubbers, ethylene propylene copolymers (EPR) and ethylene propylene terpolymers (EPT) (*15*).

The difficulty of obtaining adequate supplies of block steatite talc during World War II stimulated research by the Bureau of Mines and others that resulted in the development of phosphate-bonded talc as a suitable substitute (*7*). Subsequently, the Bureau of Mines developed a process for producing block talc from ground material with magnesium oxychloride as a bonding agent (*12*).

OUTLOOK

Consumption of talc, soapstone, and pyrophyllite has increased in amount by an average of 20 thousand tons annually for the past 20 years, a rate of increase that is expected to continue. The year-to-year consumption pattern is erratic and difficult to predict.

New uses for talc are expected to develop as finer grinds, precise sizing, and quality stabilization become standard for the producing industry. Recent research has indicated the possibility of improving EPR–EPT rubbers by incorporation of micronized talc. This use alone could require several thousand tons annually within a few years.

Recent consolidations by several talc producers may have pointed the way for similar moves by others in the field to obtain the advantages of national sales, advertising, and managerial organizations.

PROBLEMS

Many of the uses for talc and pyrophyllite can be filled either by other natural materials such as clays, feldspar, kyanite-group minerals, mica, quartz, and wollastonite or by manufactured or processed materials. Competition from these materials imposes limits beyond which it is difficult to develop new talc markets or even to maintain or expand those already existing.

The development of standardized specifications for talc has been hindered by the diversity of physical and chemical properties of the talc and pyrophyllite from different parts of the country.

While the larger producers have developed improved processing methods and can turn out high-quality products with little variation from year to year, the small operators do not have the facilities or capital to achieve and maintain such quality and are therefore at a disadvantage in marketing their products.

Little information is available concerning the influence upon the suitability of fillers for various purposes of such properties as particle size, particle shape, and sorption characteristics. Each deposit has its characteristic properties, so that the application of industry-wide specifications is difficult, but better basic data would be helpful to industry in applying them to any particular deposit.

Many underground talc mines are not well laid out, impeding the use of modern equipment in the irregular haulage drifts, shafts, and stopes.

TANTALUM

By Richard F. Stevens, Jr.[1]

ALTHOUGH discovered in 1802, tantalum did not assume commercial or strategic importance until the 20th century with the development of the nuclear and space-age requirements for material having elevated-temperature strength properties and with the development of tantalum capacitors for the rapidly growing electronic industry. The demand for tantalum is expanding, but the rate of growth may be limited by an uncertain ore supply. New methods of extractive metallurgy have been developed by the Bureau of Mines which simplify the separation of tantalum and columbium. A process originally developed for titanium and zirconium has been successfully used to reduce tantalum and columbium chlorides to metal. The reduced tantalum metal can then be arc-cast into ingots using consumable electrodes. Electron-bombardment melting, which significantly reduces the impurity content of the metal, also is used to produce high-purity tantalum metal ingots.

The presently known tantalum resources are insufficient to supply the demands of an expanding technology. Exploration for and development of domestic tantalum ores and minerals should be conducted so that the United States will not be completely dependent upon imports. The development of less expensive and more efficient separation processes is required to recover tantalum from its low-grade ores. Physical metallurgy research is required to develop high-temperature tantalum-base alloys.

BACKGROUND

Tantalum was not used commercially until 1903 when Siemens-Halske A.G., Germany, began producing tantalum incandescent-light filaments. The following year production of tantalite for export to Germany started in South Dakota. By 1912 tungsten had replaced tantalum in filaments.

In 1922 Fansteel Products Company marketed a battery charger featuring a tantalum rectifier. By 1927 technological advances largely eliminated the use of radio storage batteries, lowering the demand for tantalum rectifiers; but chemical plants began using tantalum equipment. The use of tantalum expanded slowly through the 1930's, and sintered tantalum capacitors were introduced in 1940.

Ore shortages and increased demand for tantalum during World War II and the Korean war resulted in temporary allocation controls. In 1952 a Government-guaranteed purchase program was instituted to encourage increased production of tantalum concentrate. Termination of Government purchases of foreign tantalum concentrate in May 1955 and of domestic tantalite in December 1958 resulted in lower ore prices. Industrial demand for the minerals, however, increased as new firms began producing the metal. This was encouraged primarily by burgeoning demand for capacitors.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Tantalum mining is predominantly a foreign industry. The Congo (Leopoldville), Brazil, Mozambique, Rhodesia and Malawi (formerly Nyasaland), and Portugal were principal sources of tantalum ore in 1963. World output in 1963 totaled 5,330 tons of columbium-tantalum concentrate. Domestic mine output has consisted of intermittent and highly variable production from many low-grade pegmatite deposits in South Dakota, Colorado, New Mexico, Maine, New Hampshire, and North Carolina, with minor production from a few other States. Euxenite, a columbium-uranium-rare earth

[1] Commodity specialist.

mineral concentrate produced in Idaho, contains potentially valuable quantities of tantalum.

Installed annual domestic production capacity is estimated to be more than 300 tons of tantalum and is expanding. This is many times the installed capacity of the rest of the free world nations combined. U.S. capacity for producing ferrotantalum-columbium is estimated to be about 1,000 tons and capable of rapid expansion if necessary.

Tantalum metal, compounds, or alloys were produced during 1963 by the following domestic firms: Fansteel Metallurgical Corp., North Chicago, Ill., and Muskogee, Okla.; Kawecki Chemical Company, Boyertown, Pa.; Kennametal Inc., Latrobe, Pa.; National Research Corp., Newton, Mass.; Union Carbide Metals Co., Niagara Falls, N.Y.; and Wah Chang Corp., Albany, Oreg. Tantalum metal, compounds, or alloys were produced by the following foreign firms: Murex Limited and Blackwell's Metallurgical Works, Ltd., England; Fansteel-Hoboken S.A., Belgium; Herman C. Starck A.G., Gesellschaft für Electrometallurgie, and Heraeus Quarzschmelze, Germany; Metallwerke Plansee, Austria; Kovametalli Oy, Finland; Société des Produits Pharmaceutiques Ciba, Switzerland; and Kobe Steel Works, Ltd., Japan Vacuum Engineering Co., Ltd., Shin-Etsu Chemical Industry Co., Ltd., and Taiyo Metal Industries Co., Ltd., Japan.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Tantalum is characterized by high melting point, resistance to corrosion, and ease of fabrication. At elevated temperatures the metal is an excellent interstitial absorber of common gases. It is a relatively good conductor of heat and electricity and an excellent thermionic emitter of electrons in vacuum tubes. The metal exhibits a rectifying or electronic valve action in an electrolyte. It is twice as dense as steel and has a moderately high thermal-neutron-capture cross section of 21 barns.

Tantalum metal is sold in several grades from 95 to 99.9 percent purity. Tantalum concentrate is nominally sold on the basis of 60 percent contained Ta_2O_5 but substantial lower grade concentrate is used. Stockpile specifications for tantalum minerals require a content of at least 40 percent Ta_2O_5 and that Ta_2O_5 be equal to or in excess of Cb_2O_5.

TECHNOLOGY

Geology

Tantalum is recovered mostly from pegmatite deposits and weathering products of pegmatite or granite. The current production from bedrock is of minerals of the columbite-tantalite series and minor amounts of microlite. The residual and placer production is all columbite-tantalite except in Idaho, where the principal mineral, euxenite, contains some tantalum.

The amount of tantalum in the crust of the earth has been estimated at 0.00021 percent. Characteristic geochemical associations are most often with columbium, rare-earth elements, titanium, zirconium, and tin (*2*).[2]

The principal tantalum minerals are microlite, fergusonite series, stibiotantalite series, tapiolite-mossite series, columbite-tantalite series, euxenite-polycrase series, eschynite-priorite series, betafite series, samarskite, and struverite.

Mining and Concentration

Depending upon labor and power supply and upon the geologic nature of the deposit, mining methods extend from hand labor through giant dredges to highly mechanized open-pit mining operations. Underground mining is restricted to relatively shallow inclines and shafts which have followed rich ore shoots beyond the practical limit of opencut mining techniques. Tantalum concentrates are produced by hand separation or by various combinations of gravity, magnetic, and electrostatic separation.

Metallurgy

Columbium and tantalum are extracted from mineral concentrates by fusion with hot sodium hydroxide followed by leaching with water and then with hydrochloric acid to remove impurities. The insoluble columbium-tantalum residue is dissolved in anhydrous hydrogen fluoride, potassium hydroxide is added, and the batch is cooled to precipitate potassium-tantalum fluoride, leaving the more soluble potassium-columbium oxyfluoride in solution.

Solvent extraction, a process by which a metallic salt is selectively transferred from one to the other of two immiscible liquids, is used by some companies to produce separated tantalum and columbium oxides. A new plant in California separates columbium and tantalum by fractional distillation of their chlorides. Other methods of extractive metallurgy have been developed by the Bureau of Mines to separate tantalum and columbium (*3*, *6–7*). Physical metallurgy research conducted by the Bureau has evaluated tantalum-base alloys for elevated-temperature applications.

Tantalum reduction is usually done by electrolysis of potassium-tantalum fluoride. Tan-

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

talum metal is produced at the cathode as a fine crystalline aggregate which disperses in the molten electrolyte.

A less widely used commercial method of tantalum reduction consists of mixing dried potassium-tantalum fluoride with metallic sodium and heating the mixture in an evacuated vessel. Some metal is produced in Europe by hydrogen reduction of tantalum chloride. Tantalum metal also is prepared by heating a mixture of pentoxide and tantalum carbide in a vacuum.

Tantalum powder or sponge can be converted into massive metal by vacuum sintering, by melting in a consumable or nonconsumable electric arc furnace, or by electron-beam melting.

Fabrication

Tantalum, when hot, readily absorbs gases that cause embrittlement, and all forming, stamping, and drawing is done cold. The metal seizes and tears easily and requires caution during machining operations. Tantalum work-hardens at a much slower rate than most other metals and thickness reduction of 60 percent or more without an intermediate anneal is standard practice. Rolling tantalum to half-mil or quarter-mil foil for capacitor use is accomplished on a precision Sendzimir rolling mill.

Tantalum can be welded to itself and a number of other metals by either resistance welding or inert-gas arc welding.

USES

Ferrotantalum-columbium (approximately 40 percent Cb and 20 percent Ta) is added to certain steels or high-temperature alloys.

An alloy of 92.5 percent tantalum and 7.5 percent tungsten maintains its elasticity at high temperatures and is used to manufacture electronic tube components such as filament and grid coil springs. Other tantalum-tungsten alloys are used in experimental rocket-engine parts.

Tantalum capacitors are characterized by high capacity in a small volume, stability of the oxide film, workability over a wide temperature range, long shelf life, and low reverse current (back leak). The tantalum anode acquires its dielectric property from a thin tenacious oxide film formed by anodic oxidation before assembly. This field is the largest consumer of tantalum metal.

Tantalum rectifiers are used in low-voltage applications such as railway signals, highway crossing devices, and battery charges.

Tantalum is a preferred material for use as a getter and electron emitter in electronic tubes. The metal also offers a high melting point, ease of fabrication, and efficient thermionic electron emission.

A new type of miniature electronic valve, the cryotron, consists of a tiny strip of tantalum around which a fine columbium wire is wrapped. The combination becomes superconductive at about −270° C. Such a component has a considerably lower power consumption than a thermionic valve, and a hundred such devices will fit into a thimble. They offer revolutionary possibilities for computer design and great improvement in radar devices.

The remarkable inertness of tantalum and its other properties make the metal suitable for equipment used in handling acids. Its corrosion resistance and strength permit thinner gage metal to be used in heat exchangers resulting in higher heat-transfer efficiency. Tantalum crucibles are the best available for melting certain metals.

Tantalum, because of its resistance to attack by body acids and its compatibility with body tissue, is used for sutures, for sheet and plate for cranial repair, to mend broken bones, and in both surgical and dental prosthetics.

Because it is insoluble in plutonium, tantalum was used as the fuel-container material in the Los Alamos Molten Plutonium Reactor Experiment. It is being considered for use as the fuel container in other fast reactors where resistance to corrosive action of the fuel is of extreme importance and the thermal cross section is unimportant. It may also prove useful in reactor heat-exchanger systems.

Tantalum carbide can be used separately or blended with other carbides in forging dies, cutting tools, jet-engine turbine blades, valves, valve seals, valve guides, and rocket nozzle coatings.

Tantalum oxide was used during World War II as a catalyst to produce butadiene from alcohol. The process has since been replaced by a more economical one, which does not require the use of tantalum-bearing catalysts.

Tantalum 182 radioisotope is produced at Oak Ridge National Laboratory for use as a radioactive tracer element. Tantalum is also used in spinnerets for synthetic fiber production, surgical and dental instruments, laboratory ware, anode baskets for electroplating devices, extrusion rings for the manufacture of synthetic sausage casings, special optical glass, and high-voltage surge arresters.

BYPRODUCT AND COPRODUCT RELATIONSHIPS

Columbite-tantalite ores are usually coproducts and in some cases are associated with other valuable minerals such as cassiterite, mica, feldspar, beryl, and spodumene. In more intimate

association, columbium and tantalum may share a crystal lattice with rare-earth metals, tin, uranium, zirconium, titanium, thorium, phosphorus, and calcium. The particular suite of valuable constituents in a given deposit often determines whether or not it can be profitably worked.

Tin smelter slags and tin mine tailings are sources of columbium-tantalum. Although current practice is to separate most of the columbium-tantalum concentrate by magnetic means at the mine while the remainder of the columbite-tantalite reports with the tin concentrate, some tailing piles contain significant quantities of columbium-tantalum minerals.

ALTERNATES AND SECONDARY SOURCES

In electronic uses, alternate rectifier materials include aluminum, silicon, germanium, and selenium. Zirconium, titanium, and misch metal are substitutes as getters in vacuum tubes. Possible replacements for tantalum corrosion-resistant equipment are platinum, columbium, and zirconium.

Data are not collected on utilization of tantalum scrap. A substantial quantity, such as worn tantalum chemical equipment, is reclaimed.

RESERVES AND RESOURCES

Reported free world tantalum resources total less than 100,000 tons of contained Ta_2O_5 (*2*), much of which is economically unrecoverable. Whether there are sufficient ore resources to supply an expanding long-term demand is questionable.

Deposits of tantalum ore, primarily associated with columbium, have been reported in North America, South America, Europe, Africa, and Oceania. Over 80 percent of the economically recoverable tantalum is obtained from Africa and South America, making the United States almost completely dependent upon overseas supplies for tantalum.

The principal foreign sources of tantalum metal are columbite-tantalite and microlite from pegmatites, and residual deposits associated with pegmatites, placers, tin tailings, and smelter slags.

SOURCES OF STATISTICAL INFORMATION

Data on domestic production and consumption of tantalum concentrates and production of the metal, alloys, and compounds are obtained by the Bureau of Mines through industry canvasses. Satistical data on imports and exports of concentrates and products are obtained from the Bureau of the Census. Data on world production of concentrates are compiled by the Bureau of Mines from the information supplied by foreign service dispatches and by official publications of the Departments of Mines of various foreign countries and from other sources.

PRODUCTION, CONSUMPTION, AND TRADE

Since 1940, the United States has been the leading consumer of tantalum ores, but domestic mine production of tantalite has been negligible. Virtually all of the U.S. tantalite supply is imported; 73 percent of 1963 imports were from the Eastern Hemisphere and 27 percent were from South America. Salient tantalum statistics are presented in table 1.

Tantalum ore and concentrates and columbium-tantalum-bearing tin slags are imported duty free. Duties on tantalum-bearing metal scrap have been suspended by Public Law 869 (1950) as amended and extended. Duty on the metal and its alloys is 10 percent, ad valorem, effective August 31, 1963, under the "Tariff Schedules of the United States, Annotated (1963)." For Communist nations, the statutory rate of duty of 25 percent, ad valorem, remains in force.

STRATEGIC CONSIDERATIONS

The domestic tantalum industry is almost entirely dependent upon imports for its ore supply. Because of the dependence upon Eastern Hemisphere and South American supplies, it was necessary during the peak of World War II submarine attacks to airlift high-grade ore to the United States for military uses. Dependence will continue on overseas sources of tantalum ores. Tantalum ore reserves are not large and if the demand for such ore should increase drastically, the search for new ore supplies would have to be greatly accelerated.

Although a new tantalum stockpile objective of 3.4 million pounds was announced on March 20, 1964, the quantities of tantalum concentrates, compounds, and alloys stockpiled by the Government are considered to be satisfactory for all potential emergency requirements. Foreign acquisitions, except through barter, have been terminated, and no further domestic contracts are planned. On June 30, 1964, Government stocks totaled 3.1 million pounds, of which 1.6 million pounds was in the national (strategic) stockpile, 1.5 million pounds in Defense Production Act stocks, and 35 pounds in the supplemental stockpile.

TABLE 1.—*Tantalum salient statistics*

[Pounds]

	1954–58 (average)	1959	1960	1961	1962	1963
United States:						
Imports:						
Tantalum mineral concentrate	1,213,255	652,839	709,936	1,004,151	1,211,757	944,459
Tantalum metal, compounds, and alloys	[1] 3,029	[2] 1,565	[2] 5,123			2,025
Exports:						
Tantalum mineral concentrate	[3] 4,263	10,337	32,406		36,322	56,010
Tantalum metal, compounds, and alloys [4]	[1] 5,866	6,495	21,469	28,930	34,761	58,666
Tantalum metal powder	[3] 5,950	1,988	1,174	5,585	7,445	14,146
Industrial consumption:						
Contained metal [5]	424,800	466,000	578,000	828,000	946,000	502,000
Ferrotantalum-columbium	[1] 252,800	116,000	130,000	74,000	104,000	34,000
Industrial production:						
Metal	[6] 200,000	244,000	300,000	484,000	514,000	418,000
Ferrocolumbium and ferrotantalum-columbium [7]	[8] 558,000	709,947	847,968	1,156,051	1,573,915	1,575,943
World: Production of columbium-tantalum concentrate [9]	7,990,000	6,040,000	7,020,000	7,540,000	9,210,000	10,660,000

[1] Average of 1955–58 only.
[2] Columbium and tantalum metals and alloys. Separate statistics for tantalum are not available.
[3] Average of 1956–58 only.
[4] Columbium and tantalum metals and alloys in crude and semifabricated forms, and scrap. Separate statistics for tantalum are not available.
[5] Tantalum content of all raw materials consumed, includes columbite, tantalite, and tin slag.
[6] Data for 1958 only; data for previous years unavailable.
[7] Individual production statistics for ferrotantalum-columbium are not available.
[8] Average of 1957–58 only.
[9] Separate statistics for tantalum ore are not available. Does not include tin slags.

The Office of Minerals Exploration encourages exploration for tantalum ores in the United States and its territories and possessions by advancing 50 percent of approved costs of exploration.

PRICES

Although tantalite prices were quoted in the trade papers during 1963 at $6 to $7 per pound of 60 percent tantalite, actual sales were a matter of negotiation in the market. They were primarily determined by the variation in tantalum-columbium ratio and the total tantalum oxide content.

Tantalum was quoted (per pound) at $30 to $49 for powder, $47 to $60 for sheet, and $52 to $65 for rod.

TAXES

Depletion allowance for domestic producers of tantalum ore is 23 percent, and for U.S. producers with production in foreign countries, 15 percent.

TRANSPORTATION AND STORAGE

Transportation and storage of tantalum ores or concentrates present no special problems. For stockpiling, they are packed in 55-gallon galvanized steel drums, but commercially shipments are made in cotton or burlap bags, wooden kegs, or steel drums.

Tantalum powder and pellets are usually packed in sealed polyethylene bags in steel drums. The fluoride of the metal is soluble in water and will hydrolyze to hydrofluoric acid. The containers must be kept dry at all times to prevent production of the highly corrosive acid fumes. Satisfactory containers for the fluoride include rubber-lined drums or coated fiber containers.

RESEARCH

Research on tantalum has greatly accelerated in the past 15 years. The Bureau of Mines has been evaluating resources and studying extraction, separation, and reduction of the metal, including sampling and evaluation of potential domestic resources, beneficiation studies of columbium-tantalum-bearing minerals in alluvial deposits in the Northwest, extraction of columbium and tantalum from low-grade ores and tin slags, separation by solvent extraction, anhydrous separation, reduction techniques, analytical techniques, and preparation of high-purity metal and alloys (*1*, *3*, *6–7*, *10*). Other government agencies engaged in or sponsoring tantalum research include the Atomic Energy Commission on nuclear applications, the Defense Department and National Aeronautics and Space Administration on high-temperature and electronic uses, and the Geological Survey on mineral deposits. Research sponsored by the U.S. Air Force has been primarily concerned with the development of oxidation-resistant coatings for tantalum (*4*, *11*, *12*). Industry and institutions have numerous research programs underway, including research on high-purity metal production, improved high-temperature alloys, and other problems.

OUTLOOK

Tantalum consumption in electronic and high-temperature applications is increasing. Tantalum and tantalum-base alloys will find increasing use as high-temperature cladding and structural material in fast nuclear reactors. Since it is insoluble in plutonium, tantalum is one of the few metals which can be used to clad this extremely reactive metal.

Unless additional sources of supply of tantalum are discovered the presently known deposits of tantalum ore will be insufficient to meet the growing demands of the nuclear and space age.

PROBLEMS

The primary problem associated with tantalum is that of supply. Although the supply of tantalum is adequate for the immediate future, the long-term supply required to meet the projected high-temperature demands of the nuclear and space industries will be inadequate under the present conditions of extractive technology.

The lack of data on domestic and world ore reserves, the dependence of the domestic metals industry upon water-borne imports of tantalum ores, and the lack of extractive methods to recover tantalum economically from low-grade domestic ores will prevent the wider use of tantalum owing to the inability to assure material for future requirements.

Present processes of extraction, separation, reduction, and purification of tantalum metal and of analytical techniques are expensive and hampered by incomplete basic metallurgical and chemical data on tantalum metal, alloys, and compounds.

TELLURIUM

By Arnold M. Lansche [1]

ONE of the rarest elements, tellurium has never been found in large quantities, nor is its distribution widespread. Its occurrence is comparable to that of gold, with which it is frequently associated. In chemical and physical properties, the element is similar to selenium and sulfur; in its common form, it resembles antimony.

Domestic production of tellurium in 1963 was 201,000 pounds valued at about $1 million. This quantity was 64 percent of world output. It was obtained as a byproduct of base metal refining. The United States is the major producer in the free world.

Thermoelectric devices, metallurgy, and the chemical, rubber, and ceramic industries use tellurium. Great interest is centered on the use of metallic tellurides to convert heat to electricity and to utilize electricity for cooling or heating. There is increasing usage of tellurium in the preparation of the important free-machining steels.

The most important tellurium problem is the need for definitive knowledge of the tellurium resource base. Tellurium needs uses that will annually require constant significant quantities.

BACKGROUND

Tellurium was discovered in 1782 by J. F. Müller von Reichenstein while examining auriferous ores from Siebenbürgen, Transylvania. It had been believed by early chemists that this ore contained an alloy of bismuth and antimony. When he found no trace of either, von Reichenstein published his conviction that the ore contained a new element. His work was later confirmed independently by Bergmann and Kitaibel. In 1792 Klaproth demonstrated conclusively that the new element existed when he extracted it and determined some of its properties. Tellurium was named after the Latin word "tellus," meaning earth, the genitive of which is "telluris."

Commercial production of tellurium began in the United States in 1918. Output was not reported, however, until 1926 when 917 pounds valued at about $1,850 was produced. In 1963 production was 201,000 pounds.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The world's tellurium industry is organized mainly around the electrolytic copper refineries as a byproduct material. Companies reporting tellurium production in 1963 were American Metal Climax, Inc., Carteret, N.J.; American Smelting and Refining Company, Baltimore, Md.; International Smelting & Refining Co., Perth Amboy, N.J.; Penn Rare Metals, Inc., Revere, Pa.; Phelps Dodge Refining Corp., New York, N.Y.; and United States Smelting, Refining, and Mining Co., East Chicago, Ind. In January 1964 it was announced that Kawecki Chemical Co., Boyertown, Pa., bought Penn Rare Metals, Inc.

The geographic distribution of the free-world tellurium industry closely follows the pattern of the world's electrolytic copper and lead (*1*)[2] refineries, as well as of the fire refining of lead. The United States produced 64 percent of the tellurium output of 1963. Canada, Japan, and Peru accounted for the remainder. The U.S.S.R. is believed to have produced significant quantities of tellurium as a byproduct from sulfide-ore processing.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Tellurium is normally marketed as a steel-gray, minus 200-mesh powder. The pulverized

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

tellurium is packed in cartons and cans. The powder is 99.5+ percent pure. Tellurium of similar quality is also marketed in slabs, tablets, and sticks.

A typical analysis of commercial-grade tellurium is 99.7 percent tellurium, 0.003 percent lead, 0.02 percent selenium, 0.004 percent silica, and 0.015 percent copper.

High-purity tellurium, 99.999+ percent, is marketed in 1- and 2-pound plastic containers as crystals usually less than 1 inch long. Cakes about 5 pounds in weight are also available in sealed plastic bags. Maximum level of impurities, copper and iron, is less than 1 part per million. Total halogens, sulfur, and selenium do not exceed 5 parts per million. Silicon, lead, or magnesium also may be present as minute impurities.

Other tellurium materials include 99.99+ percent metal, a powder containing 94 to 95 percent tellurium dioxide, ferrotellurium containing 50 to 58 percent tellurium, and a tellurium-copper alloy containing 40 to 50 percent tellurium.

Tellurium and its compounds have a toxicity similar to but less than that of selenium. When very small quantities of volatile tellurium are absorbed by the human body it imparts a strong garlic odor. This characteristic odor leaves no permanent ill effects and is caused by the formation of organic methyl telluride in the human system. Several drugs, including ascorbic acid and chlorophyll, prove very effective in combating this offensiveness, but the treatment is a prolonged one generally requiring many months. The hazard is controlled by removing tellurium fumes by mechanical ventilation or hooding and the use of respirators.

Thermoelectricity is electricity produced by direct conversion of heat to electricity, but the term is used broadly to denote the interconversion of heat and electricity. The conversion of heat to electricity, known as the Seebeck effect, was discovered in 1822. The inverse, or Peltier effect, whereby electricity can be converted to heat or cold, was discovered in 1834. Tellurium and certain of its compounds have the highest thermoelectric performance characteristics over the medium temperature range.

Seebeck effect.—Seebeck discovered that a voltage was developed in a loop containing two dissimilar metals, providing the two junctions were maintained at different temperatures. This is the basic principle of thermocouples, which have been used for many years. Now the principle is being considered for the production of electric power.

Peltier effect.—Peltier discovered that the junction between two dissimilar metals acted as a heat sink or as a heat source, depending on the direction of the electric current. This is the basis of thermoelectric refrigeration.

TECHNOLOGY

One of the least abundant elements, tellurium is about 1×10^{-6} to 1×10^{-9} percent of the earth's crust. Tellurium minerals may be formed in almost any stage of the ore-forming processes. Its occurrence is similar to that of gold, with which it is often associated, although it is seldom found in the native form. More than 40 distinct tellurium minerals are known, but at present none of these is exploited for tellurium alone.

The major tellurium minerals follow:

Name	Composition	Percent tellurium
Tellurium, native	Te	92–100
Calaverite	$AuTe_2$	56–58
Petzite	$(Ag, Au)_2Te$	32–35
Sylvanite	$(Ag, Au)\ Te_2$	60–63
Hessite	Ag_2Te	35–38
Rickardite	Cu_4Te_3	59–60
Altaite	PbTe	37–39
Tetradymite	$Bi_2(Te,S)_3$	33–49

Of lesser importance are the minerals montbrayite, krennerite, empressite, weissite, emmonsite, nagyagite, coloradoite, joseite, tellurbismuth, and wehrlite.

Tellurium has also been detected in the eruption products of Mount Vesuvius, Italy, in the orange-red sulfur of Japan, and in pyrite from Spain. The most noteworthy occurrences of the element at gold camps are at Cripple Creek, Colo.; Great Boulder Reef, Kalgoorlie, Western Australia; Kirkland Lake, Ontario; and Angel Camp, Calif. High tellurium values have been reported in bismuth deposits of Bolivia. Goldschmidt reported 0.1 gram of tellurium per ton in meteorites, but not any in the sun (*4*).

Tellurium is mined, beneficiated, and smelted along with the coproducts copper and lead. Its presence in gold ores is a serious handicap in recovering the gold because it hinders amalgamation and cyanidation. Such gold ores usually must be concentrated and/or roasted to remove the tellurium as early as practicable from the extraction circuit.

Modifications in tellurium-refining methods are closely guarded trade secrets, and modifications which different companies make in the standard flowsheet are not disclosed. Processing begins with a tellurium-bearing anode slime from the electrolytic refining of copper and lead, which is usually minus 200-mesh. About 8.3 pounds of solids containing recoverable quan-

tities of copper, lead, selenium, tellurium, gold, and silver are obtained from a ton of anode.

The anode slime is leached in acid solution for copper removal and then fused with sodium bisulfate to convert residual copper to copper sulfate and volatilize part of the selenium. The fused cake is granulated and leached with water to remove the copper sulfate. A subsequent leach with caustic soda solution extracts the tellurium. Residue from the double leach is refined in a doré furnace for recovery of precious metals. The tellurium is recovered from the caustic solution by acidulation to precipitate a tellurium oxide sludge that is subsequently refined to metal.

USES

Tellurium and tellurium compounds are used in thermoelectric devices and metallurgy, and by the chemical, rubber, and ceramic industries.

There is increasing interest in combining tellurium with other materials to make use of the phenomenon of thermoelectricity. Lead telluride, bismuth telluride, cadmium telluride, bismuth - tellurium - selenium - antimony alloy, silver telluride, and germanium telluride are some of the alloys successfully used in thermoelectric devices. These alloys perform excellently in converting heat into electricity and in utilizing electricity to cool or to heat. In these devices, the generation of heat depends on the direction of electron flow rather than on ohmic resistance to electricity, as generally known.

Tellurium is added to nonferrous metals to modify certain physical characteristics. Tellurium increases the ductility of aluminum, imparts extreme hardness with a high maximum stress to tin, and improves the machinability of copper without seriously impairing conductivity. Tellurium-lead alloys are tougher, stronger, and more resistant to fatigue, corrosion, abrasion, and vibration than ordinary lead and are widely used for linings of tanks, for heating coils, and for other special equipment for the chemical industry. Lead-base tellurium alloys are widely used in Europe for cable covering and sheathing. Tellurium also increases the corrosion resistance of some magnesium-base manganese alloys.

Addition of a small quantity of tellurium to chilled cast iron acts as a powerful carbide stabilizer and markedly increases the depth of chill. This chilled cast iron is preferred for applications such as railway car wheels, gears, and camshafts. Added to special steels, in quantities reported to range from 0.023 to 0.057 percent, tellurium acts as a degasifier and also improves machinability. It reduces the annealing time of large malleable-iron castings. Other metallurgical uses of tellurium include staining silver. Tellurium-bearing slime is used as a catalyst for removing cobalt in the Tainton process for producing electrolytic zinc.

The uses of tellurium in the chemical industry are comparable to the uses of sulfur and selenium, but both of these elements are superior to tellurium for most chemical uses, and few significant applications have materialized. Consequently, the chemical uses of tellurium and its compounds are often only temporary outlets involving relatively small quantities. One use for tellurium and its compounds is in the field of chemical coloring as a component in the manufacture of the highly competitive organic and inorganic dyestuffs. Tellurium is used for making ultramarine, black, blue, red, and brown colorants used in coloring glass, ceramics, and lithopone. Tellurium is also a chemical catalyst.

Tellurium and its compounds are secondary vulcanizing agents in the processing of both natural and GR–S synthetic rubber. Tellurium diethyldithiocarbamate is the fastest accelerator for butyl rubber manufacture. The normal percentage of tellurium added is generally less than 0.5 percent. The tellurium additives increase the vulcanizing rate, improve aging and mechanical properties, eliminate porosity, and increase the resistance to heat and abrasion. Specific applications include its use in rubber-jacketed cables in the mining, dredging, and welding industries and for conveyor belts.

Colloidal tellurium is an insecticide, germicide, and fungicide. Soluble tellurium compounds are used in photography in toning baths. Tellurium vapor will emit light similar to sunlight under appropriate excitation.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Anode slime produced during electrolytic refining of copper is the chief source of tellurium. Coproduct materials include gold, lead, selenium, and silver. Tellurium and selenium are separated from each other after the other elements have been removed. It is uneconomical to recover tellurium from anode slime without recovering the precious metals also.

ALTERNATE MATERIALS

Selenium often is used in place of tellurium in metallurgy, ceramics, rubber materials, and thermoelectric devices.

SECONDARY SOURCES AND RECOVERY

Production of tellurium from secondary sources is negligible. The use of the element in old scrap-source products, such as thermocouples, will not generate secondary source materials in significant quantities for several years.

RESERVES

The estimated domestic indicated and measured copper reserve is 32.5 million tons of refined copper. The quantity of recoverable tellurium, theoretically contained in the domestic copper reserve based on the rate of 0.20 pound of tellurium per ton of copper, is 6.5 million pounds. The quantity of tellurium recoverable from lead reserves raises the total to 7.2 million pounds of tellurium. Estimates of tellurium resources outside the United States are not available. There is an unmeasured potential resource of tellurium in gold-silver ores, base metal ores, and minor metal tellurides.

CONSERVATION PRACTICES

The value, rarity, and useful properties of tellurium stimulate efforts to recover it from source materials rather than discard it as waste.

SOURCES OF STATISTICAL INFORMATION

Statistics on production, shipments, and stocks are received quarterly and annually by the Bureau of Mines from producers of tellurium and tellurium compounds. These data are on company confidential basis, and the data of the individual companies are combined to provide the published totals. Six companies supplied data in 1963. Records of imports of tellurium are available from the Bureau of the Census, U.S. Department of Commerce.

Statistical coverage for the United States is relatively complete.

PRODUCTION, CONSUMPTION, AND TRADE

In 1963 domestic output of tellurium was 201,000 pounds, valued at about $1 million, general imports 2,000 pounds, producers' stocks 141,000 pounds, and shipments to consumers 134,000 pounds. In 1959 total supply (production, stocks, and imports) almost balanced the large tellurium demand as expressed by shipments to consumers. Total supply in 1959 was 251,000 pounds compared with 257,000 pounds of shipments. That was the first time since 1939 that tellurium supply and demand have so nearly balanced.

Annual free world production was reported in Canada, Japan, Peru, and the United States in 1959–63. The rank, in descending order, was the United States, Peru, Canada, and Japan. Free world output in 1963 was 315,800 pounds of which about 75,000 pounds was produced in Canada, 26,600 pounds in Peru, and 13,300 pounds in Japan.

Imports in 1959–63 totaled 38,250 pounds and came from Australia, Canada, Japan, Peru, Switzerland, the United Kingdom, and West Germany. Imports were sporadic; in 1961 and 1962 there were none. Canada and Peru exported to the United States during 2 years of the period while each of the other countries sent tellurium during only 1 year.

The tariff was adjusted on August 31, 1963, the metal at 8 percent and the compounds at 10 percent. The statutory rate is 25 percent for both metal and compounds.

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in tellurium, and Canada has an adequate supply. Neither the metal nor its compounds are included in the "National Stockpile List of Critical and Strategic Materials." Most producers are in the highly industrialized eastern part of the United States; in Maryland, New Jersey, New York, and Pennsylvania. One producer is at East Chicago, Ind.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration includes tellurium among minerals and mineral products eligible for government financial participation up to 50 percent of approved costs.

PRICES

The price of commercial-grade powder tellurium increased sharply in the period 1959–62 from $1.65 to $6 per pound, or 264 percent. Throughout 1963 the price was $6 per pound. The high-purity grade, 99.999 percent, was $25 per pound in 1959–60, $21.50 to $30 per pound in 1961–62, and $21 to $30 per pound in 1963.

TAXES

There are no special taxes on tellurium. Producers are granted a depletion allowance of 15 percent on domestic and foreign production.

TRANSPORTATION

There are no shipping regulations for tellurium metal or its compounds. High-purity tellurium is shipped and stored in sealed plastic bags.

RESEARCH

A bibliography with abstracts of current literature on tellurium research is compiled and issued monthly by Battelle Memorial Institute for the Selenium-Tellurium Development Association, Inc. (*5*).

A process for converting waste heat into a valuable asset by means of a lead telluride thermoelectric element has been developed (*3*). Lead telluride, as strip or wire, in contact with another metal forms a thermoelectric element capable of converting heat directly into electricity. This system is far superior to ordinary thermocouples in converting heat to electricity in two ways: (1) much larger currents are developed and (2) conversion efficiencies are more than 20 times higher.

Experimental work has been performed on many metallic tellurides to determine the Seebeck coefficient, the resistivity, and the thermal conductivity (*2*). Some of the more promising materials examined were gold-antimony-bismuth teluride, lithium-manganese telluride, bismuth-selenium telluride, antimony-selenium telluride, silver-germanium-antimony telluride, silver-antimony telluride, bismuth-tellurium sulfide.

OUTLOOK

Some economic uses for tellurium have been developed. Several metallic tellurides, which are desirable for use in thermoelectric devices have been produced. Tellurium is used in produring free-machining steels which have been a welcome addition to the steel-shaping industry. The short-term and long-term outlooks are for an adequate supply and a slowly accelerating consumption. Competitive materials will continuously challenge any uses of tellurium because of its scarcity, high prices, and apparent lack of superior or unique properties. However, in an expanding economy where all kinds of commodities are in demand, it is anticipated that there will be a place for tellurium despite competition.

PROBLEMS

Tellurium problems are directly proportional to the level of demand. The most important problem concerns the need for greater knowledge of the potential resources of tellurium because the element has applications in which large quantities would be consumed if available. The problems related to detection, exploration, and extraction are expected to be routine. Substitution is a perennial problem for tellurium because of price and inelastic supply. Tellurium needs uses that will annually require reasonably constant significant quantities. The odor and toxicity of tellurium are problems with which industry must contend.

THALLIUM

By Harold J. Schroeder [1]

THALLIUM, a relatively rare element in the earth's crust, was discovered about 100 years ago by Crookes. It is found associated with many minerals, but not in deposits of sufficient size and tenor to be processed for thallium alone, and its sole domestic source is as a byproduct from flue dusts at zinc smelters. It is best known for its odorless, tasteless, and very poisonous sulfate, which is used as a rodenticide. In addition to this use, small quantities are used in electronics and in alloys for bearings, solders, and fusible alloys.

The domestic resource of thallium in zinc sulfide deposits alone is substantial, although at present most of the resource from zinc-smelting operations is wasted because there is little demand for thallium. The United States is self-sufficient in thallium, and it is not stockpiled by the Government.

Present prices of thallium are $7.50 per pound for the metal and $5 per pound for thallium sulfate; 99.999 percent thallium is available at a higher price.

Research on thallium by industry, institutions, and government has been limited. There is a need for research to develop more uses for the element before the outlook for thallium can be considered good.

BACKGROUND

Sir William Crookes, an English scientist, discovered thallium in 1861 while making spectroscopic examinations for tellurium on a residue from a sulfuric acid plant in Germany. Crookes named the new element thallium from the Latin word thallus, meaning budding twig, because its spectrum resembled the color of young vegetation. Shortly thereafter Crookes produced a few grains of the metal. During the following year, A. Lamy, a French scientist, found thallium in a residue from roasting Belgian pyrite for sulfuric acid and recovered several hundred grams of the metal to study its chemical and physical properties.

SIZE AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Thallium metal and compounds are produced in the United States by the American Smelting and Refining Company at its Globe, Colo. refinery.

Countries presently producing thallium are Belgium (Societe des Mines & Fonderies de Zinc de la Vieille Montagne, S.A.), West Germany (Duisburger Kupferhütte, Duisburg, and Unterharzer Berg- und Hüttenwerke G.m.b.H., Goslar), and the U.S.S.R.

Small amounts of thallium have been produced by Cerro de Pasco Corp., at its smelter in La Oroya, Peru, and by Hudson Bay Mining and Smelting Co., Ltd., Flin Flon, Manitoba, Canada.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS

Thallium is bluish white, malleable, and softer than lead. A freshly cut surface of thallium dulls to a bluish grey tinge when exposed to air, and in a few weeks a thick oxide crust forms. Thallium has an atomic number of 81 and an atomic weight of 204.39. The metal has a density of 11.85 grams per cubic centimeter at 20° C and 11.25 grams per cubic centimeter at 330° C. The element melts at 303° C and boils at 1,457° C. Other physical properties of thallium include (*1*, *5*) [2] latent heat of fusion, 5.04 calories per gram; latent heat of vaporization, 189.9 calories per gram; volume contraction on solidification, 3.23 percent; and tensile strength 1,300 pounds per square inch. Thallium has valences of 1 and 3.

[1] Commodity specialist.
[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Thallous compounds include the water-soluble acetate, nitrate, perchlorate, hydroxide, sulfate, carbonate, and ferricyanide; the moderately hot-water-soluble halides; and the insoluble sulfide and chromate. Thallic compounds are less numerous and mostly unstable, being readily reduced to thallous salts by stannous chloride, sulfurous acid, metallic thallium, ferrous sulfate and sodium arsenite, or boiling water. Thallium metal dissolves slowly in hydrochloric acid, readily in sulfuric acid, and even more readily in nitric acid.

Thallium forms alloys with antimony, bismuth, cadmium, indium, lead, magnesium, mercury, potassium, sodium, and tin, but most of these alloys are unstable in air. Brittle alloys are obtained with antimony, bismuth, gold, and platinum, and malleable alloys are obtained with copper, lead, and silver.

Thallium metal and compounds have long been known to be toxic (*2–3, 9*). Thallium can be absorbed into the human body by skin contact, by inhaling dusts, fumes, and mists, or by ingestion. The element is not quickly eliminated from the body, and absorption of subtoxic quantities eventually may accumulate to a toxic level. Symptoms of poisoning from thallium compounds include actions similar to those of intoxication, loss of sleep, and various pains throughout the body. Overexposure may result in loss of hair, serious gastrointestinal and nervous system disorders, and sometimes death. A specific antidote for thallium poisoning is not known, but industrial poisonings from thallium are rare because safety procedures have been well established.

Thallium metal is normally sold as sticks or rods with a purity ranging from approximately 99.90 to 99.98 percent thallium. High-purity thallium with a guaranteed analysis of 99.999+ percent is also sold.

TECHNOLOGY

Widely divergent estimates of the abundance of thallium in the earth's crust have been published. In 1947 Ahrens' estimate of 3 grams per ton increased previous estimates by a factor of 10; in 1958 Mason assigned a value of 1 gram per ton to thallium and placed it 58th in a listing of relative abundance of the elements.

Traces of thallium have been found in many minerals, including berzelianite, carnallite, chalcopyrite, dufrenoysite, galena, feldspars, micas, hematite, jordanite, manganite, pitchblende, pyrite, pyrolusite, and sphalerite. Crookesite [$(Cu,Tl,Ag)_2Se$], hutchinsonite [$PbS\cdot(Tl,Ag)_2S\cdot 2As_2S3$], vrbaite [$Tl_2S\cdot 3(As,Sb)_2S_3$], and lorandite [$Tl_2S\cdot As_2S_3$] contain 16 to 60 percent thallium, but these minerals are rare. Thallium is known to occur in arsenical gold ores at Mercur, Utah. Owing to its association with many minerals, thallium is found in tailings, liquors, residues, and dusts resulting from milling and chemical and metallurgical processing of various ores (*11*). The element is also found occasionally in commercial products such as arsenic, bismuth, cadmium, platinum, tellurium, zinc, and sulfuric acid. The trace amounts of thallium found in zinc-bearing ores, along with the normally associated cadmium, indium, and germanium, are concentrated in certain flue dusts and residues which provide the principal commercial source for production of thallium.

Several methods have been developed to extract thallium from ores, flue dusts, and other materials (*1, 4–6, 11*). In one process applied to cadmium- and thallium-bearing flue dust resulting from the smelting of lead-zinc sulfide ores, the dust is leached with sulfuric acid, and cadmium and thallium sulfates are formed. After precipitating most of the impurities as sulfides and hydroxides, the purified solution containing cadmium and thallium sulfates is electrolyzed for deposition of cadmium. When the ratio of thallium to cadmium in the electrolyte reaches 1 to 10, new cathodes are introduced. The electrolysis is continued, and a cadmium-thallium alloy containing 5 to 20 percent thallium is deposited. This alloy is converted to hydroxides by treatment with hot water and steam, and sodium carbonate is added to precipitate the cadmium. The cadmium-free filtrate containing thallium carbonate is then treated with hydrogen sulfide to precipitate thallium sulfide. The washed thallium sulfide is dissolved in sulfuric acid and boiled free of hydrogen sulfide, and the resulting solution of pure thallous sulfate is electrolyzed to recover pure metallic thallium sponge. The sponge is then pressed, melted, and cast.

Thallium metal also can be prepared from thallium sulfate solution by precipitation on zinc plates arranged vertically around the sides of a vessel. After heating for several hours thallium sponge is deposited on the zinc. The spongy mass is separated from the plates, thoroughly washed with water, and compressed or fused into sticks.

Another method uses zinc dust cementation of thallium, cadmium, and indium from a leached solution of pyrite cinders. The cementite is redissolved and converted into a zinc-free mercury amalgam; then by fractional distillation it yields an indium-containing thallium fraction which is further refined to thallium metal.

Production of sulfate, the main commercial product, is obtained by the relatively easy con-

version from the metal. Another method employs leaching and cementation of impurities followed by fractional crystallization of the thallium sulfate.

High-purity thallium is produced by two or more stage electrolysis, amalgam electrolysis, or fractional dissolution and precipitation. Purification can also be obtained by the zone-refining process.

USES

Many uses have been suggested for thallium metal, alloys, and compounds, but there are few applications with a sustained substantial consumption (*1*, *5*, *10–11*). Since 1920 thallium has been best known for its odorless, tasteless, and very poisonous sulfate which is used to exterminate rodents and ants. On rats it acts slowly and cumulatively, principally as a killer; in small doses it halts reproductive processes and thereby restricts the rat population.

There are small but important uses for thallium in electronics. Thallium-activated sodium iodide crystals mounted on photomultiplier tubes are an integral part of certain portable scintillation counters for detecting gamma radiation. The ability of thallium bromoiodide crystals to transmit infrared radiation and of thallium oxysulfide crystals to detect light of this wavelength has been employed extensively in military communications systems.

Low-melting glasses containing arsenic, thallium, sulfur, and selenium are used to coat semiconductors, capacitors, and other electronic devices to protect them from atmospheric oxidation, contamination, and humidity.

Thallium compounds impart black or brown colors and increase the density and index of refraction in glass used in optical instruments and for synthetic gems. Thallium pigments in artists' paints are resistant to hydrogen sulfide. Water solutions of thallous formate or thallous formate-malonate can be used as heavy liquids in the sink-float separation of minerals in laboratory work. Thallium salts absorb traces of oxygen and can be used to increase the life of tungsten filaments in incandescent lamps. Burning thallium salts produce a bright-green flame and have some application in rockets and flares. Thallium salts also have been used as additives to fuels to prevent knocking in internal combustion engines. Thallium has been a constituent in some medicines to treat dysentery, tuberculosis, and scalp diseases, but the narrow margin between toxicity and therapeutic benefits limits its use in this field. It has been used in the catalytic reduction of nitrobenzene by hydrogen.

Thallium alloyed with mercury has been used in low-temperature thermometers; with copper and copper-lead in bearings; with silver in contacts, in bearings, and for articles requiring high resistance to acids and hydrogen sulfide; with lead in solder and fuse metal; with tin and lead as anodes for the electrowinning of copper; and with vanadium as a catalyst in the manufacture of sulfuric acid.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Commercial thallium, along with cadmium, gallium, indium, and germanium is obtained from processing zinc ores for zinc and pyrites for sulfuric acid.

ALTERNATE MATERIALS

Alternative materials are available for most uses of thallium. In exterminating rodents, thallium sulfate can be replaced by other chemicals that are safer to humans and less harmful to desirable animals and birds.

RESOURCES

Resources of thallium are sufficient for this little-used minor metal. Estimates of its principal commercial reserves in sulfide ores have not been published. Mill tailing and unmined arsenical gold ores at Mercur, Utah, are reported to contain large quantities of thallium. Potash deposits contain significant quantities of thallium but are not of commercial importance at present.

SOURCES OF STATISTICAL INFORMATION

Data on domestic production and consumption of thallium are obtained annually by the Bureau of Mines through industry canvasses but are kept in confidence and not published, at the company's request.

PRODUCTION AND CONSUMPTION

Data on domestic production and consumption of thallium are company confidential. Only Belgium, West Germany, the United States, and the U.S.S.R. are known to produce primary thallium metal or sulfate.

TARIFF

Thallium in concentrates can enter the United States duty-free, but the metal and its salts are dutiable at 10.5 percent ad valorem, effective June 30, 1958.

PRICES

The price of thallium metal was $10 per pound prior to 1944, then gradually rose to $20 in 1947. By 1949 the price descended to $12.50 per pound and remained there until December 1957, when it dropped to $7.50 per pound. This price prevailed in 1963 for orders of 25 pounds or more.

The price of thallium sulfate in 1963 ranged from $5 per pound for orders of 100 pounds or more to $10 per pound for orders of less than 10 pounds.

High-purity thallium is priced at $3 per 25 grams.

TAXES

No special taxes are imposed on the thallium industry. Depletion allowance for domestic producers of thallium metal is 15 percent.

RESEARCH

Production research has been conducted by companies to develop metallurgical procedures for the recovery of thallium from zinc-processing operations. A spectrochemical method for determining thallium in source materials was developed by the Bureau of Mines. In response to the increased demand for thallium in military and peaceful applications, the Bureau made a nationwide search for sources of thallium in 1947–49. White arsenic and Cottrell preciptator dusts from the American Smelting and Refining Company plant at Murray, Utah, were found to be the most promising sources of thallium (*8*). A Bureau report on determining thallium in source materials was published (*7*).

Through research, the U.S. Department of Agriculture found that the possibility for secondary poisoning of birds and animals through eating carcasses of rodents killed by thallium sulfate was very small.

Contributing to utilization research, the Bureau of Mines investigated the use of thallous silver nitrate and thallous formate in water to separate minerals by sink-float methods for use in mineralogical analysis, and also developed methods of preparing and cleaning thallium-base liquids used in sink-float testing of minerals. Thallous formate and thallous malonate-formate were among the materials studied.

Recent development in lamps that produce radiation in the erythemic (suntan) range has included investigation of thallium-activated alkaline earth silicates and phosphates which provide the desired radiations. Use of thallium in mercury vapor lamps to produce a very white light has been investigated. Substantial research has been conducted on improved methods of producing thallium-containing crystals and their electronic applications.

OUTLOOK

Thallium consumption is expected to remain fairly constant, and thallium will be used predominantly for rodenticides. Some of the lesser applications may show increased consumption but this will not greatly affect the total. Should demand increase for thallium, resources and productive capability are available to quickly expand the supply.

PROBLEMS

The principal problem for thallium is lack of uses and demand for the metal and its alloys and compounds. Many of the chemical and physical properties of thallium are known; but fuller knowledge of the properties may lead to development of larger usage of the element. The principal use as a rodenticide is vulnerable to substitution by other chemicals that are less expensive or less dangerous to humans and desirable birds and animals.

In some uses that have been developed for thallium, either its toxicity or its relatively high price is a deterrent.

Resources are ample for anticipated demand, but should a sudden large use for thallium develop, a problem of economic supply could result because thallium is a byproduct of base metals and the supply is therefore inflexible.

THORIUM

By Charles T. Baroch [1]

THORIUM has the nuclear property shared with uranium 238 of being transmuted under neutron bombardment into uranium 233 which is fissionable in a chain reaction. Thus it is a potential fuel for the generation of nuclear energy.

The element thorium is widely distributed, comprising from 0.001 to 0.0015 percent of the earth's crust. It is usually associated with uranium or the rare-earth elements and is obtained commercially principally from monazite, thorianite, and thorite. Large deposits of monazite occur as beach sands in India, Brazil, Malaysia, and the southeastern coast of the United States. Thorianite and thorite occur with uranium in Idaho, Colorado, Ontario, and the Malagasy Republic, and increasing amounts of thorium are being derived as coproducts of uranium.

Monazite is recovered from beach sands by gravity concentration and electrostatic and electromagnetic methods. The concentrates are processed by wet chemical methods using either hot sulfuric acid or strong sodium hydroxide solution to decompose the monazite. Other chemical processing with selective precipitation and filtration yields a crude thorium nitrate solution that is purified by solvent extraction.

Thorium contained in dilute solution from the uranium treatment plant of Rio Tinto Dow, Ltd., at Elliot Lake, Ontario, Canada, is recovered by solvent extraction. The crude precipitate, containing 15 to 20 percent thorium, is refined to metallurgical-grade thorium oxide. Thorium metal is produced by the reduction of thorium halides or oxide by alkali or alkaline-earth metals, by thermal decomposition of the iodide, or by electrolytic methods.

Thorium nitrate is used for producing incandescent gas mantles, and the oxide is used as a refractory, as a catalyst, for producing a dispersion-hardened nickel alloy, and in nuclear breeder reactors for the production of uranium 233. Thorium metal also is used in nuclear breeder reactors and as an alloying agent, particularly with magnesium.

Thorium has a great potential use as a source of energy if a successful breeder reactor can be developed in which surplus neutrons in the fission of either plutonium, uranium 233, or uranium 235 are captured by thorium to produce uranium 233. Substantial research on the thorium-uranium 233 fuel recycle technology has been done, but much more remains. Until a breeder reactor is developed, only experimental quantities of thorium will be used for nuclear purposes.

The principal technical problems are the development of new uses and of process improvements that would lower the cost of thorium products. The main economic problem is the development of a larger market commensurate with the abundance of thorium resources.

BACKGROUND

Thorium was discovered by the Swedish chemist Baron Jons Jakob Berzelius in 1828 in a mineral now called thorite. Little use was found for thorium until 1885, when Dr. Carl Auer von Welsbach of Vienna discovered that thorium oxide became incandescent when heated. From this discovery he developed the Welsbach mantle which was widely adopted in gaslighting and later for gasoline and kerosine lamps.

Thorium derived from monazite was produced as early as 1893 in the Carolinas; however, this production was soon eclipsed by production from Brazil which started in 1895. Production from India began in 1911. At the same time, German manufacturers soon built up almost a complete monopoly of the thorium nitrate industry. World War I cut off German supplies and enabled domestic production of thorium nitrate to expand, although monazite

[1] Commodity specialist.

supplies still came from India and Brazil at prices so low that domestic producers could not compete. In the early 1920's electricity began to supplant gas for general lighting purposes and the need for thorium mantles declined; however, rare-earth elements began to be used increasingly, and thorium became a byproduct of the rare-earth elements.

The discovery of the principles of fission and the development of the nuclear bomb was followed by the discovery in 1946 that Th^{232} could be transmuted into U^{233}, a fissionable isotope. India in 1947 and Brazil in 1951 nationalized the production of monazite for their own use, and this jeopardized the domestic supply. Large domestic resources were found, and the rich monazite mine at Steenkampskraal, Republic of South Africa, began production in 1953 and became a major producer, stabilizing the market. This mine was closed in 1963, when developed ore was depleted.

Meanwhile, a new source of thorium began production in 1959 when the Elliot Lake plant of Rio Tinto Dow, Ltd., in Ontario, Canada, began recovering thorium from waste uranium-plant solutions. If demand increases, additional thorium could be recovered as long as uranium production is maintained. About 1960, the French Atomic Energy Commission also began producing thorium for its own use from both uranothorianite and monazite in Malagasy Republic.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Prior to the production of thorium in Canada as a byproduct of uranium, most of the thorium was derived from monazite and was coproduced with the rare-earth elements. Some monazite was recovered as a byproduct from Florida beach sands by Titanium Alloy Manufacturing Division, National Lead Co., but most monazite was imported from the Republic of South Africa. More recently some monazite has been imported from Malaysia, Ceylon, and Australia.

Processing of monazite was pioneered by Lindsay Light Co., established in 1902, which was changed to Lindsay Light & Chemical Co. in 1935, and which merged in 1958 with American Potash & Chemical Corp. as the Lindsay Chemical Division. This firm, with its plant at West Chicago, Ill., retains its dominant position as a processor of thorium-bearing ores and concentrates and produces high-purity rare-earth and thorium compounds. Other processors of ores and concentrates are Nuclear Fuel Services, Inc., formerly Davison Chemical Division of W. R. Grace & Co., Erwin, Tenn.; and Vitro Chemical Co., Chattanooga, Tenn. Nuclear Fuel Services specializes in thorium metal and oxide, and Vitro produces thorium-magnesium master alloy, and thorium nitrate and hydroxide.

Rio Tinto Dow, Ltd., was formed by The Rio Tinto Mining Company of Canada, Ltd., and Dow Chemical of Canada, Ltd., a subsidiary of the Dow Chemical Co., for recovering crude thorium sulfate cake from Rio Algom's Nordic mill at Elliot Lake, Ontario, Canada. Part of the cake is refined to metallurgical-grade thorium oxide at the Quirke plant nearby, and the rest goes to Dominion Magnesium, Ltd., at Haley, Ontario, for the production of pure thorium-metal pellets, thorium powder, and thorium-magnesium master alloy. This group of Canadian operations has a designed capacity for 150 to 200 tons of thorium annually.

Westinghouse Electric Corp., Bloomfield, N.J., manufactures thorium metal and a special grade of thorium oxide from metallurgical-grade thoria, for use in lamp filaments and emission material. Fabricators of uranium reactor fuels also have capabilities for processing thorium fuels. Among these are The Babcock & Wilcox Co., Lynchburg, Va.; General Atomic Division, General Dynamics Corp., San Diego, Calif.; Kerr McGee Oil Industries, Inc., Cushing, Okla.; Metals & Controls, Inc., a division of Texas Instruments, Inc., Attleboro, Mass.; National Lead Co., Albany, N.Y.; Nuclear Fuel Services, Inc., Erwin, Tenn.; Nuclear Materials & Equipment Corp., Apollo, Pa.; United Nuclear Corp., Hematite, Mo.; and Westinghouse Electric Corp., Pittsburgh, Pa.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The element thorium, chemical symbol Th or isotopic symbol Th^{232}, has an atomic weight of 232.05, atomic number 90, and lies in the fourth subgroup of the Periodic Table with titanium, zirconium, and hafnium. It is mildly radioactive with a half-life of 1.39×10^{10} years, decaying through 12 intermediate radioactive isotopes, finally yielding a stable isotope of lead, Pb^{208}.

Th^{232} is not fissionable in itself but is a *fertile material;* that is, by irradiating it with slow neutrons, it is converted into Th^{233} which is highly radioactive with a half-life of 23 minutes and decays to protactium, Pa^{233}, with a half-life of 27.4 days, which in turn decays to uranium 233 (U^{233}). U^{238} is a similar fertile material that will produce plutonium, Pu^{239}, by neutron bombardment. Both U^{233} and Pu^{239} are artificial elements and are fissionable. The production of fissionable material from fertile material is

known as *breeding*, and a nuclear reactor that produces more fissionable material than it consumes is called a *breeder reactor*.

When the atomic nuclei of fissionable atoms are struck by neutrons of proper energy (speed), the nucleus splits into two atoms of nearly equal size. This reaction is called *fission* and results in the release of a large amount of energy.

The products of fission are *fission fragments*, and an average of 2.5 neutrons are produced for each atom fissioned. These released neutrons make a *chain reaction* possible, as these new neutrons can cause fission in other nearby fissionable atoms. A *nuclear reactor* is a device containing fissionable materials and control devices that can absorb excess neutrons, yet permit sufficient neutrons to fission other nuclei at a controlled rate.

No general specifications for thorium metal or compounds have been established. Producers manufacture various grades of their products that are suited for the various uses, and they will further refine materials as needed for special purposes.

Metallurgical-grade thorium oxide is better than 99.8 percent ThO_2. For nuclear uses, a better grade product is usually required by specifications established by each reactor manufacturer. Reactor-grade material, either oxide or metal, must be 99.9 percent pure and must be especially low in high-neutron-absorbing elements, such as boron, cadmium, gadolinium, samarium, dysprosium, and europium, which must be well below 1 part per million; most other metallic impurities must be below 50 parts per million.

Thorium-magnesium master alloy, sometimes referred to as magnesium-thorium hardener, is used for producing magnesium alloys, and contains from 20 to 40 percent Th.

Thorium nitrate as made by modern solvent-extraction methods is a very pure material and is used as an intermediate product for the production of oxide or metal. One large manufacturer produces four grades of thorium nitrate, in addition to the mantle-grade which contains from 0.5 to 1.0 percent sulfate, SO_3, intentionally added because it gives a very hard, dense ash and strengthens the mantle.

TECHNOLOGY

Mineralogy and Geology

Thorium is widely distributed in nature and is usually associated with uranium and the rare-earth elements. Its geochemical abundance is estimated to be between 10 to 20 parts per million in the earth's crust, about three times that of uranium.

Monazite has been the most important thorium-bearing mineral in the past. It is essentially a phosphate of the rare-earth elements but contains up to 12 percent ThO_2 and up to 1 percent uranium oxide (U_3O_8). Typical analyses of monazite sands from different sources are as follows, in percent (*13*) :[2]

	ThO_2	Rare-earth oxides	U_3O_8
India	8.9	59.4	0.35
Brazil	6.5	59.2	.17
United States	3.1	40.7	.47
South Africa, Republic of	5.9	46.4	.12
Malagasy Republic	8.8	46.2	.41

Monazite has a specific gravity of 5.0 to 5.3 and a hardness of 5 to 5.5 on the Mohs' scale. It occurs widespread as small accessory grains and crystals in granites, gneisses, and syenites, occasionally in large masses and crystals. Weathering of these rocks and water action concentrates the monazite in placer deposits along river beds and beaches. The most important deposits occur in India and Brazil, and others are found in Australia, Ceylon, Indonesia, Malagasy Republic, Malaysia, Republic of South Africa, Canada, and the United States. Important domestic deposits have been worked in Florida and South Carolina where monazite was recovered as a byproduct of ilmenite, and in Valley County, Idaho, where it occurs with euxenite. Other deposits are known in North Carolina, Michigan, and California. Pegmatite occurrences are at Amelia, Va.; Spruce Pine, N.C.; Gunnison and Chaffee Counties, Colo.; Portland, Conn.; Glorieta, N. Mex.; and the Aquarius Range, Ariz. (*6*).

The Steenkampskraal deposit, 50 miles north of Van Rhynsdorp, Cape Province, Republic of South Africa, is a hydrothermal vein of fine-grained quartz and monazite in Precambrian granitic rocks. The vein is from a few inches to 6 feet thick and was exposed for 600 feet. Ore as rich as 75 percent monazite was found, but most of it was only 20 percent. Ore contained up to 5 percent copper.

The two principal India beach deposits are in Travancore at Malavalakurichi and near Chavara on the southwest coast extending from Quiton to Cape Comorin. Other lower grade deposits are in the Malabar district north of Travancore and on the east coast in Madras and Orissa. The black sands constitute less than 1 percent of the beach sand, and they contain from 40 to 50 times more rutile and ilmenite than monazite (*10*).

The Brazilian beach deposits are in the States of Bahia, Rio de Janeiro, and Espirito Santo.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Heavy minerals range from a few percent to 75 percent of the beach sand and the black-sand portion from Prado, Bahia, contained 18 percent monazite, 59 percent ilmenite, 2 percent rutile, and 21 percent zircon.

Monazite occurs in beach and dune deposits near Fort Dauphin, Malagasy Republic. The sands average 2 to 2.5 percent monazite and total about 50 percent heavy minerals.

Thorianite, ThO_2, and thorite, $ThSiO_4$, are the only two true thorium minerals and both may have varying amounts of UO_2 and UO_3 replacing ThO_2. Thorianite is isomorphous with uraninite and may contain up to 90 percent ThO_2 and up to 33 percent U_3O_8. When U_3O_8 content is above 15 percent, the mineral is called uranothorianite. Thorite may contain up to 80 percent ThO_2 and up to 25 percent U_3O_8. When it contains more than 5 percent U_3O_8 it is called uranothorite.

Important thorianite deposits occur in pyrometasomatic veins in the Bancroft Region, Ontario, Canada, and near Fort Dauphin, Malagasy Republic. It has been found in small quantities in sand and gravel deposits in Alaska, California, Ceylon, Montana, New Zealand, and other places. Uranothorianite in the Malagasy Republic is in masses and lenses of pyroxenite which contains from 0.3 to 0.4 percent uranothorianite ranging from 57 to 83 percent ThO_2 and 8 to 26 percent U_3O_8.

Thorite is found in pegmatites, carbonatites, veins, and placers, also as an accessory mineral in many igneous rocks. Notable deposits of thorite occur in the Wet Mountains of Custer County, and other places in Colorado, as veins in a Precambrian complex of gneisses and quartzite; and in the Lemhi Pass district along the Idaho-Montana line as quartz-hematite-copper fissure veins from a few inches to 10 feet wide and as much as 500 feet long. Thorite also occurs in beach sands in New Zealand and central California and in gold placers along the Tuolumme, Cosumes, and other rivers. Lesser deposits are found in North Carolina, Texas, Australia, Norway, and Japan.

Mining, Milling, and Processing (3)

Monazite is recovered from river and beach sands by placer mining methods, most often using bucket or suction dredges, but sometimes using shovels or draglines and, in primitive mining operations, hand shovels. Tables, jigs, and Humphreys spirals are used to make a bulk concentrate of the heavy minerals, known as black sands. This concentrate is usually transported to another plant for intensive treatment to separate the various components into marketable products. Monazite is usually a minor component and other heavy minerals present may include magnetite, ilmenite, rutile, zircon, cassiterite, garnet, staurolite, and others.

Black sands, after drying, are separated by magnetic separators and electrostatic separators, varying combinations being used for sands with different constituents. In the Malagasy Republic, for instance, ilmenite is removed first with a low-intensity magnetic separator, and the monazite is removed with high-intensity magnetic separators, leaving the nonmagnetic zircon. A plant in Brazil uses first an electrostatic separator that separates the electrical conducting minerals, ilmenite and rutile, from the nonconductors, monazite and zircon. Electromagnetic separators then separate the magnetic ilmenite and monazite from the nonmagnetic rutile and zircon.

Monazite is treated by a fairly complex series of chemical-processing methods to separate thorium from a predominant quantity of rare-earth elements and phosphate. Initial treatment is either with hot concentrated sulfuric acid or hot concentrated sodium hydroxide solutions.

Sulfuric acid digestion produces a sulfuric acid-phosphoric acid solution of the rare-earth elements, thorium, uranium, and other impurities, which is filtered from the gangue, primarily silica. Thorium usually is separated from this solution by precipitation, but fractional crystallization also has been used. Partly neutralizing the acid to pH 1.0 with ammonium hydroxide gives almost complete recovery of the thorium as phosphate, and only about 5 percent of the rare-earth elements as sulfates. The rare-earth elements are recovered by further alkalization of the solution. The crude thorium phosphate precipitate is dissolved in nitric acid and the thorium is recovered by solvent extraction (7).

Digestion of monazite with sodium hydroxide (50 percent NaOH at 140° C) solubilizes the phosphate, leaving hydrous oxides of thorium, uranium, and the rare-earth elements after filtration. This residue is dissolved in hydrochloric acid, and then the solution is neutralized carefully with sodium hydroxide. All thorium and uranium are precipitated with only a small quantity of the rare-earth elements. This crude thorium hydroxide is dissolved in nitric acid and purified by solvent extraction, as with the crude thorium phosphate precipitate from the acid process.

A modification of the acid process was developed at Ames Laboratory, Iowa State College. Thorium and the rare-earth elements were precipitated from the diluted sulfate solution with sodium oxalate, leaving uranium to be recovered on an anion exchange resin. The oxalate precipitate was treated with sodium hydroxide,

leaving a hydroxide precipitate and regenerating sodium oxalate. The hydroxides were calcined to decompose residual oxalate and produce oxides which could then be dissolved in nitric acid for purifying the thorium by solvent extraction.

Solvent extraction is an efficient method of separating and purifying thorium, and it has superseded all other methods. Several variations of the method have been developed for different conditions. Typically, the nitric acid solution of thorium, containing rare-earth elements, uranium, and other impurities, is brought vigorously into contact with an organic solvent, such as kerosine or xylene, which is insoluble in water. The solvent contains an organic compound, like tributyl phosphate (TBP), which forms a complex compound with thorium. The thorium complex dissolves in the solvent phase leaving the impurities in the aqueous phase. After separating the two liquids, the thorium is stripped from the solvent by mixing violently with a dilute 0.02-normal nitric acid solution, thereby bringing the thorium back into a new aqueous phase. The high-purity thorium nitrate product may be crystallized from this aqueous phase or precipitated as an oxalate for further processing (*4*).

The thorium-recovery plant of Rio Tinto Dow, Ltd., near Elliot Lake, Ontario, receives the waste solution from the uranium mill of Rio Algom Mines, Ltd. This contains about 1 pound of thorium per thousand gallons and was formerly discarded to the tailings pond. Thorium is extracted by solvent extraction, and the organic extractant is stripped to form a precipitate containing from 15 to 20 percent Th. The precipitate is either refined into metallurgical-grade thorium oxide or is used to produce thorium metal or thorium-magnesium master alloy.

Thorium and yttrium are recoverable from thorite ores by leaching with sulfuric acid. Thorium was removed from the leach solution by solvent extraction using a kerosine organic phase containing 10 percent primary alkylamine and 10 percent isodecyl alcohol. The thorium was stripped from the organic solvent by a 2-molar ammonium carbonate solution. Yttrium was recovered from the thorium-free acid leach solution by solvent extraction in a solvent containing 0.24-normal di-2-ethylhexyl phosphoric acid (EHPA) in kerosine. The organic solvent was stripped of yttrium with 6-normal hydrochloric acid (*2*).

Thorium oxide is prepared by calcination of thorium oxalate precipitated from the pure nitrate solution derived from solvent extraction.

Reduction and Refining (*8*)

The production of pure thorium metal is very difficult as it is very reactive and has a high melting point (1,840° C). It is prepared by reduction of the halides with calcium or magnesium, reduction of thorium oxide with calcium or sodium, fused-salt electrolysis, or thermal decomposition of thorium tetrachloride by the Van Arkel-de Boer process (*14*).

The U.S. Atomic Energy Commission (AEC) plant at Fernald, Ohio, operated by National Lead Co. used a process developed at the Ames Laboratory for producing about 20 tons of thorium per month. Thorium fluoride, prepared from ThO_2 with anhydrous hydrofluoric acid, was mixed with anhydrous zinc chloride and reduced with metallic calcium in a steel bomb. The bomb was heated to about 650° C when the reaction proceeded by its heat of reaction. Part of the zinc chloride was reduced along with the thorium fluoride, producing a zinc-thorium alloy with a low melting point. After separating the calcium chloride slag, the alloy was heated in a vacuum to remove the zinc, leaving a thorium metal sponge. The sponge was melted to a solid ingot by arc melting in a water-cooled copper crucible using a consumable electrode of the thorium metal sponge.

Thorium also has been produced by metallothermic reduction of thorium tetrachloride by sodium, potassium, calcium, and magnesium. Magnesium reduction is similar to the Kroll process for producing titanium and zirconium (*5, 11*).

Westinghouse Electric Corp. produced thorium powder by reacting thorium oxide with a slight excess of calcium in a refractory-lined steel bomb heated to 950° C. The product was leached with dilute acetic or nitric acid, and the thorium powder was dried in a vacuum, followed by compacting and sintering. Metal produced in this manner had a purity of 99.8 percent.

Thorium is too reactive to be deposited electrolytically from aqueous solutions, but it has been prepared on a small scale by electrolysis of the oxide, fluoride, and chloride in molten-salt electrolytes. The oxide can be electrolyzed in either a potassium-thorium fluoride mixture and in a sodium-potassium-thorium chloride bath. The fluoride was electrolyzed in an electrolyte of a double fluoride of thorium and potassium and sodium chloride in a pilot plant in 1952, but fluoride accumulated in the bath and it could not be run continuously. Electrolysis of thorium tetrachloride proved to be better, as chlorine was released at the anode continuously. Electrolysis produces thorium powder.

USES

The most important use for thorium metal is in magnesium alloys. A typical alloy contains 96.3 percent magnesium, 3 percent thorium, and from 0.5 to 0.7 percent zirconium. Heat treatment gives the alloy extraordinary resistance to creep and excellent strength up to 750° F. Their light weight and high-temperature strength make these alloys particularly suitable for structural use in high-speed aircraft and missiles. They can be rolled, deep drawn, extruded, spot welded, and fusion welded by the inert-arc process. Standard sheet and plate are available.

Thorium nitrate is of great importance in the fabrication of incandescent gas mantles, millions of which were used by the Armed Forces during World War II and which are still used in large quantities. For camping and outdoor use, gas mantles provide efficient and portable light from kerosine or gasoline lamps. Mantles are made from cotton, ramie, or synthetic fibers woven into cloth and impregnated with thorium nitrate (25 to 50 percent) solution containing 1 to 2 percent of cerium nitrate, then dried and denitrated with ammonia, hydrofluoric acid, or alkali fluoride solution, converting the thorium and cerium to insoluble hydroxides or fluorides. When the cloth burns away a skeleton of thoria remains, which when heated gives a brilliant white light. Mantle manufacturers prefer thorium nitrate containing about 0.6 percent sulfate, SO_3 which, it is claimed, strengthens the ash skeleton of the mantle (*9*).

Thoria has a melting point of 3,220° C, is the most stable of the refractory oxides, and has a low dissociation pressure. However, it has poor resistance to shock and it does not have high strength. These disadvantages and its high cost permit it to be used only in some very specialized crucibles, such as for the melting of molybdenum, columbium, nickel, and similar metals or alloys.

Nickel containing about 2 percent thorium oxide dispersed throughout produces an alloy that has superior strength and corrosion resistance at temperatures as high as 2,400° F. It will outperform columbium and most other superalloys at long-time low-load service. Made and sold under the trade name, TD Nickel, it consists of a very fine-grained nickel-thoria powder produced by chemical methods and compacted by powder-metallurgy methods. It can be worked with conventional metal-forming machinery and is finding applications in rockets, space vehicles, and chemical and furnace parts (*12*).

Thorium oxide is used as a catalyst in the petroleum and chemical industries, particularly to convert ammonia to nitric acid and sulfur dioxide to sulfur trioxide and sulfuric acid. A small amount of thoria is compounded with tungsten to produce filaments for incandescent lamps. From 0.8 to 1.2 percent thorium oxide makes the filaments more ductile and inhibits crystallization of the tungsten, thereby keeping the filament from getting brittle. Thoriated tungsten also shows an improved thermionic emission, making such filaments highly desirable in electronic tubes. Metallic thorium also requires comparatively little energy to produce high electron emission and serves well as electrode material in gaseous discharge lamps and mercury arc lamps. As metallic thorium emits strong monochromatic radiation, it is used as target material in X-ray tubes. Thorium oxide is used in fabricating thoriated tungsten electrodes for inert-arc welding and as nonconsumable electrodes in arc melting of transition metals. From 1 to 2 percent thoria offers the advantage of instant starting and arc stability.

Thorium is a fertile material and probably will become an important nuclear fuel. It can be converted in a nuclear reactor to uranium 233, which is fissionable and can sustain a chain reaction. In a breeder reactor, the system thorium-uranium 233 gives promise of complete utilization of thorium in the production of nuclear power. The energy available from the world supply of thorium has been estimated to be greater than the combined energy available from uranium, coal, and oil resources.

Thorium test reactors have been designed using thoruim as metal, dioxide, fluoride, and carbide. The trend appears to be toward ceramic elements that favor ThO_2 or ThC pellets, except in the molten-salt reactor concept, which uses ThF_4 in mixed lithium and beryllium fluoride. Thorium oxide also has been used as a coating for spherical UO_2 pellets for use in either fixed- or fluidized-bed reactors (*8*).

Initially, breeder reactors will require either U^{235} or Pu^{239} to provide the neutrons necessary to transmute Th^{232} to U^{233}, but once sufficient U^{233} becomes available, reactors can operate on a Th^{232}–U^{233} cycle and will need only thorium for the replacement of consumed fuel. While the thorium-uranium cycle produces a higher breeding ratio than the uranium-plutonium breeder, it has the disadvantage of also producing uranium 232 which is not fissionable and which decays into a series of short-lived daughter products. These emit penetrating gamma rays and necessitate remote-control of all fabrication.

The following three power reactors have been designed and operated with thorium:

1. The Consolidated Edison Co. of New York pressurized-water reactor at Indian Point, N.Y.,

has an electrical capacity of 255 megawatts. The original reactor core contained 38,000 pounds of ThO_2 mixed with 2,600 pounds of UO_2 enriched to 93 percent U^{235}. The second core was redesigned to use enriched uranium and U^{238}, largely because of its lower cost.

2. The Elk River Reactor, Elk River, Minn., cooperatively built by AEC and Rural Cooperative Power Association, started up in 1963 and has a capacity of 20 megawatts. It is of the boiling-water type, and its core consists of about 8,500 pounds of thorium and 800 pounds of enriched uranium.

3. The Peach Bottom, Pa., reactor of Philadelphia Electric Co., capacity 40 megawatts, was put in full operation in 1964. It is a gas-cooled, graphite-moderated reactor designed to operate at the high temperatures of 660° F inlet and 1,380° F outlet, whereas the other reactors operate at 490° to 550° F. The fuel elements are UC_2, ThC_2, and graphite made into rods.

Among smaller test reactors that have been considered for thorium reactor-fuel experiments are the Sodium Reactor Experiment (SRE), Santa Susana, Calif., an aqueous homogeneous type (HTR) at Oak Ridge National Laboratory, the Liquid Metal Fueled Reactor with a suspension of thorium in a liquid metal (bismuth), the aqueous homogeneous reactor concept using a slurry of UO_2 in heavy water surrounded by a blanket of ThO_2 pellets, and the molten-salt reactor with enriched UF_4 in LiF-BeF_2-ZrF_4 salt with a blanket of ThF_4 in the same type of salt.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Monazite from sand deposits is largely a byproduct of ilmenite, rutile, and zircon production. Further processing of monazite yields rare-earth elements and thorium as coproducts, together with lesser quantities of uranium and yttrium. Copper was a coproduct of monazite from the vein deposit in South Africa. Thorium and uranium are coproducts in many uranothorite and uranothorianite ores, and thorium occurs in small amounts in many uranium ores, often in recoverable quantities such as in the Blind River area of Ontario.

ALTERNATE MATERIALS

No satisfactory alternative materials are suitable for the larger nonenergy uses of thorium, particularly in gas mantles and in alloys. Zirconium and titanium are superior to thorium as a getter in electronic tubes. Beryllia and yttria can often be substituted for thoria as a refractory above 2,000° C.

Uranium breeder reactors are competitive, to a certain extent, with thorium breeder reactors. Neither has been sufficiently developed to predict which will find greatest use.

RESERVES

Known thorium resources of the types that have been mined recently are listed in table 1. In almost all cases individual deposits have been only partially explored and evaluated, and the totals embrace deposits of several distinct kinds, the grades of which cover a wide range. Hence, the data are classed as resources, rather than as reserves. The economic mining of many of the deposits is dependent on recovering and marketing of coproducts, such as ilmenite, rutile, and zircon.

Domestic reserves consist of thorite vein deposits in Idaho and Montana, that have been evaluated by some at 100,000 tons of ThO_2 recoverable, and monazite sands in the Southeastern and Western States.

Canadian reserves are associated mostly with uranium ore in the Blind River and Bancroft region.

Brazilian beach sands were once a source of imported monazite until Brazil imposed an embargo on its exportation. These are in the districts of Espirito Santo, Bahia, and Rio de Janiero. In addition to the figure shown, about 130,000 tons of thorium is estimated to be present in the low-grade (0.07 per cent ThO_2) pyrochlore carbonatite at Araxa in Minas Gerais, which might be recoverable as a byproduct in the recovery of the columbium.

TABLE 1.—*World resources of thorium*

Country	Content, thousand tons ThO_2	Principal types of deposits [1]
India	250	P
Canada	200	S, R
United States	100	V, P
U.S.S.R. and Eastern Europe	100	
Brazil	30	P, R
West Africa	15	P, R
Australia	10	P, R
Malagasy Republic	10	P, R
Nyasaland	10	P
South Africa, Republic of	10	V

Source: U.S. Geological Survey Bulletin 1204.

India was another source of monazite for the United States until exports were prohibited. The estimated thorium reserve shown in table 1 is probably conservative. An additional 250,000 tons of ThO_2 may possibly be found in the unexplored inland placers of Bihar and West Bengal.

The uranothorianite deposit at Belafa is the only one being exploited in the Malagasy Re-

public. Even though exploration of this ore body is not complete, reserves are estimated to total 2,500 to 5,500 tons of mineral containing 1,300 to 3,250 tons of ThO_2 and around 1,000 tons of U_3O_8. The balance of the reserve shown in table 1 is in monazite sands at Antete and Fort Dauphin. Another estimate of these sands accounts for about 150,000 tons of monazite at 7.8 percent or about 12,000 tons of ThO_2.

The quest for radioactive materials begun in 1944 included thorium as well as uranium, and all known domestic resources of thorium were examined and evaluated. The magnitude and sources of the reasonably assured total domestic resources are listed in table 2. While most of this thorium is far beyond utilization under present economic conditions, the eventual development of thorium breeder reactors and a strong demand could bring many of these resources into production. Even group 4 has to be regarded as a potential energy source for the far distant future when fossil fuels and uranium can no longer supply the demand.

TABLE 2.—*Magnitude and sources of thorium in the United States*

Group [1]	Price range per pound of ThO_2	Reasonably assured resources of ThO_2 (thousand short tons)	Estimated total resources of ThO_2 (thousand short tons)
1	Under $10	100	400
2	$10–$30	100	200
3	$30–$100	7,000	35,000
4	$100–$500	1,000,000	3,000,000

[1] Group 1. Measured, indicated, and inferred ores, plus geological estimate of potential discoveries; mainly Idaho vein and Altantic States placer deposits.
Group 2. Mainly low-grade placer and vein deposits.
Group 3. New Hampshire (Conway) granite (to a depth of 2,000 feet).
Group 4. Other granites (to a depth of 2,000 feet) extending over large areas of other States.

Source: AEC, Civilian Nuclear Power, a Report to the President, 1962, as presented to the Joint Committee on Atomic Energy, 88th Cong., Feb. 20 and 21, 1963.

Thorium content of the earth's crust is three to four times that of uranium; however, uranium deposits have been formed in higher concentrations, and unit cost would have to increase appreciably before thorium would be equal in availability to uranium. Practically all granites contain thorium and uranium that can be recovered. The Conway granite in New Hampshire represents one of the largest, and it has been examined quite thoroughly, even to metallurgical tests. The outcrop areas total about 300 square miles, and the rock averages about 50 parts per million ThO_2, of which from 60 to 85 percent is recoverable; uranium content averages about 11 parts per million, of which about 56 percent on the average can be recovered. Estimated recovery costs of combined uranium and thorium from different areas of the Conway granite range from $38 to $75 per pound.

The fourth group consists largely of granites in Colorado, California, Idaho, Montana, Texas, and Washington which contain from 40 to as low as 12 parts per million thorium and less than 10 parts uranium. These can be processed at an estimated cost of from $120 to $470 per ton of combined thorium and uranium.

Fuel Value of Thorium Resources

The total energy contents of the domestic thorium resources listed in table 2 are shown in table 3. For comparison, the known recoverable and marginal and undiscovered marginal resources of coal were estimated at 4,220 billion tons with an energy value of 88.6 Q and the energy value of petroleum, natural gas, natural gas liquids, oil in bituminous rock, and shale oil were estimated at an additional 41.5 Q, or a total energy value for all fossil fuel of 130.1 Q.

The total Q value shown in table 3 for reasonably assured resources of thorium is 63,712 Q and for total resources is 192,238 Q. This compares with comparable Q values for uranium of 30,696 Q and 121,490 Q, respectively. Domestic energy consumption in 1963 was about 0.048 Q and world energy consumption was about 0.17 Q. Domestic future use of energy in 1980 is estimated at about 0.082 Q and for the year 2000 it is expected to double this figure.

TABLE 3.—*Energy content of domestic thorium resources* [1]

Group	Thorium resources price range per pound ThO_2	Fission energy content, Q [2]	
		Reasonably assured resources	Total resources
1	Under $10	6	25
2	$10–$30	6	13
3	$30–$100	700	2,200
4	$100–$500	63,000	190,000

[1] See table 2 for quantities of fuel.
[2] Q=1 quintillion British thermal units, or 10^{18} Btu. 1 short ton ThO_2 will produce 6.3×10^{13} Btu on conversion to U^{233} and its complete fissioning.

SOURCES OF STATISTICAL INFORMATION

Annual data on production, stocks, and shipments of thorium minerals are obtained from producers by the Bureau of Mines. Annual

data on consumption and production of thorium products and their field of use are obtained from processors and consumers. However, much data must remain confidential because of the limited number of producers. World production of monazite is obtained through the Department of State and is reported in the Bureau of Mines Minerals Yearbook, volume I, in the Rare-Earth Minerals chapter; however, the thorium content is not reported. U.S. imports and exports are obtained from the Bureau of the Census, but again the thorium content of monazite is not known.

PRODUCTION, CONSUMPTION, AND TRADE

Thorium is classified as a fissionable source material in the Atomic Energy Acts of 1946 and 1954, and thorium production was classified information from 1945 to 1955. Recognizing its fissionable potential, India banned exports of monazite concentrate in 1946, and Brazil did the same in 1951. Shipments of thorium-bearing materials from Australia and the Republic of South Africa are under Government control.

World production of monazite concentrates by countries is shown in table 4. The thorium content of monazite production is not recorded and varies widely from about 4 percent to 8 percent, usually, with occasional shipments analyzing as high as 12 percent.

Thorium is produced in Canada as a byproduct of uranium processing, but production data are confidential because there is only one producer. Imports until 1962 were classified with barium, boron, strontium, and vanadium metals. In 1963, 5,420 pounds of thorium metal valued at $55,187 was imported into the United States from Canada. Other imports included about 1,300 pounds of thorium nitrate from Canada and the United Kingdom.

Thorium exports were classified by the Bureau of the Census in 1960 into class 6255.0, thorium ores, concentrates, and compounds, and class 6257.0 thorium metal and thorium-bearing alloys including semifabricated and fabricated forms, except special nuclear materials. Data for 1961–63 are shown in table 5.

Ores and concentrates are duty free. The duty rate established August 31, 1963, for metal was 12.5 percent ad valorem, for alloys it was 15 percent, and for nitrate and other compounds 35 percent.

Year	Class 6255.0			Class 6257.0	
	Number of countries	Pounds	Value	Pounds	Value
1961	16	102,352	$378,916	260	$16,693
1962	19	1,094,566	357,563	980	46,513
1963	22	40,340	264,235	1,316	50,506

STRATEGIC CONSIDERATIONS

The Office of Emergency Planning established on March 13, 1964, a new stockpile objective of 500,000 pounds for thorium. The inventory of strategic and critical inventories on June 30, 1964, contained 848,354 pounds of residues in the Defense Production Act inventory and 3,965,441 pounds (ThO_2 equivalent) in the Supplemental Barter inventory.

The President may direct AEC to acquire such quantities of special nuclear material as he deems necessary in the interest of national defense. It is known that AEC purchased thorium in the past, but the quantities were not disclosed until 1959. To fulfill the military requirement as well as for their own research program, AEC has an inventory of thorium, just as is the case with the military stockpile of uranium and its byproducts. A summary of AEC activity in thorium is shown in table 6.

Resources of thorium in the United States assure complete self-sufficiency for any conceivable contingency, even though at present these resources cannot be exploited economically. In addition, the large potential resources in the Blind River and other areas of Canada provide assurance of self-sufficiency for the North American Continent. Brazil's large reserves of monazite form a third source of supply within the Western Hemisphere. The sudden large-scale development of thorium breeder reactors would not suffer from lack of resources. Processing facilities are capable of a manyfold increase in demand, and could be expanded quickly.

TABLE 6.—*Thorium activity of AEC, fiscal years 1959–64*

[Thousand pounds]

GOVERNMENT PROGRAMS

Thorium was included in the list of minerals eligible for financial assistance in the national minerals-exploration program of the Defense Minerals Exploration Administration (DMEA) instituted under the Defense Production Act of 1950, as amended. DMEA expired June 30, 1958, and a similar program continued under the Office of Mineral Exploration (OME). A total of nine exploration contracts, solely for thorium, were made in nine States, for $206,244, of which Government participation was $167,158. Thorium often appeared as a secondary commodity in many applications for DMEA aid for uranium and rare-earth mineral prospects. At present, up to 50 percent of the allowable cost of authorized exploration is contributed by the Government.

AEC is charged with the control of all fissionable material and any source material used to produce fissionable materials. More explicitly, source material means any material, except fissionable material, which contains 0.05 percent or more of uranium, thorium, or any combination thereof. Unless authorized by a license isued by AEC, no person may transfer, deliver, or export any source material after removal from its place of deposit in nature. Application for license is available from AEC and, upon determination that an application meets the requirement of the Atomic Energy Acts of 1946 and 1954 and of the regulations of AEC, a license will be issued in the form and upon the conditions deemed appropriate and in accordance with law. The conditions imposed include the filing of reports and restriction upon the use of source material.

As of October 1964, nine States—Arkansas, California, Florida, Kansas, Kentucky, Mississippi, North Carolina, New York, and Texas—have assumed cooperatively some of AEC licensing and other regulatory authority over the uses of radioactive materials within the State. About 20 other States have passed enabling legislation to permit negotiations with AEC. State responsibility is usually vested in the State board of health (or agency or department, as the case may be). Criteria for issuance of licenses will be the same as used by AEC. Provisions are made for exemption of certain quantities and concentrations of radioactive material, and any person may receive, possess, or use products or materials containing radioactive material in amounts or concentrations not in excess of those listed in the published exempt schedule.

In August 1964, the Atomic Energy Act of 1954 was amended to permit private ownership

of nuclear materials. By January 1, 1971, all new distributions of nuclear materials must be by sale, rather than by lease as at present, and by June 30, 1973, all leased material must be purchased by the leasing firm or returned to AEC. AEC will still retain its licensing and regulatory functions.

PRICES AND COSTS

Quoted monazite prices have been relatively stable for several years and have been quoted nominally, depending on the grade, at 13 to 20 cents per pound for material containing 55 to 68 percent total rare-earth oxides, including thoria. Metallurgical-grade thorium oxide (99.8 percent ThO_2) was quoted by Rio Tinto Dow, Ltd., of Canada at U.S. $4.63 per pound and metallurgical-grade thorium fluoride was U.S. $3.93 per pound.

Domestic thorium oxide, ceramic-grade (99 percent), was offered at $7 per pound in lots of 10 to 49 pounds, and the high-density grade (also 99 percent), was $10 per pound. Thorium nitrate, wire-grade, ranged from $2.50 to $3 per pound, and the mantle-grade ranged from $2.65 to $3.15 per pound. Thorium-magnesium master alloy containing 30 to 40 percent Th was quoted at $9.18 to $10 per pound of contained thorium, plus the contained magnesium at $0.3625 per pound. All prices were quoted f.o.b. destination, continental United States, and the range in prices depended on the quantity per shipment.

Thorium metal, reactor grade (99.9+ percent), was $20 per pound, and metal pellets were $15 per pound. The new high-temperature alloy, TD Nickel, containing about 2 percent ThO_2 dispersed in the nickel, was offered at $30 per pound in sheet form and $20 per pound in bars.

TAXES

Depletion allowances for the mining of thorium minerals, under the Internal Revenue Code of 1954, is 23 percent for domestic operations and 15 percent for foreign operations.

RESEARCH

As part of its nuclear research program, AEC has conducted extensive investigations to advance the use of thorium in reactors. Phillips Petroleum Co., AEC principal contractor at the National Reactor Testing Station in Idaho, has conducted reactor physics studies on the irradiation of Th^{232} in the production of U^{233}. This work has given much fundamental data on the production rate of U^{233} under neutron bombardment, as well as the buildup of other nuclides.

AEC began a long-range program in 1959 at the Oak Ridge National Laboratory, Oak Ridge, Tenn., known as the Thorium Utilization Program. Technology related to the use of thorium-based fuel in fluid-fuel, thermal breeder reactors, and much information have been developed on the Th^{232}-U^{233} fuel-cycle. Some of this work has been conducted with the Brookhaven National Laboratory, where a wide range of U^{233}-Th lattices will be studied. A former program on the Liquid Metal Fuel Reactor concept was conducted at Brookhaven. While this particular type of reactor had many disadvantages and work on it was abandoned, it yielded much information on the use of thorium in reactors.

AEC plans a further long-range program at a new installation to be called the Thorium-Uranium Cycle Development Facility. This facility should demonstrate various fuel recycle processes for the several reactor types that operate best on thorium-uranium fuel.

The Sodium Reactor Experiment began operation in 1957 as an experimental nuclear power plant (5,000 kilowatts) to develop technological data. The core was fully enriched uranium-thorium alloy and the coolant was liquid sodium which enters the reactor at 530° F and leaves it at 960°. The hot sodium produces steam at 600 pounds per square inch pressure and 825° F.

AEC is contributing up to $14.5 million for research and development assistance in connection with the Peach Bottom, Pa., reactor. This plant was built primarily as a prototype for a large central power-generating station.

Private and university research has contributed greatly to new knowledge on thorium uses, much of it financed by the Government under contract or as fellowships. The Babcock & Wilcox Co. expects to study the spectral-shift reactor concept at a new major fuels development center at Lynchburg, Va. This reactor appears to be well suited for thorium fuel. Allis-Chalmers Manufacturing Co. has collaborated in the construction and operation of a thorium reprocessing facility in Italy where a fast uranium-thorium reactor, called rapid thorium-uranium-sodium (RAPTUS) has been under development. This facility will reprocess and refabricate fuel from the Elk River reactor.

A review symposium on the thorium fuel cycle was held in December 1963 at Gatlinburg, Tenn., and the 33 papers presented were published in 2 volumes (*1*).

Despite the progress made, breeder reactors have not yet reached an economically useful stage of development, and from 20 to 40 years of intensive research lie ahead. Even when breeders become commercial, they will not make new fissionable material fast enough to provide fuel for new plants at the rate required if

nuclear power is to increase its proportional share of the Nation's electric-power load. Even after successful breeder reactors are developed, it will be necessary to fuel initial installations with U^{235} until sufficient U^{233} can be produced to meet the needs. Fortunately, with thorium breeder reactors, the intermediate needs can be met by substituting U^{235} for U^{233}. Considering that many decades will be necessary before nuclear reactors can displace fossil fuels in the Nation's economy, even after a successful breeder reactor is developed, research should continue at a rapid rate to assure a means of conserving all forms of energy.

The Bureau of Mines has contributed research efforts on the extraction and production of thorium as domestic problems have appeared. Other work has been done on methods for producing high-purity thorium, arc melting of thorium and other melting techniques, and the production of thorium alloys. The Geological Survey has conducted much work on the geology and geochemistry of thorium as aids to the prospector in locating thorium deposits.

OUTLOOK

Thorium production for nonenergy uses will probably increase gradually over the next two decades. This will result from increased use of thorium in magnesium-thorium alloys, the recently developed TD Nickel (nickel strengthened with a dispersion of about 2 percent ThO_2), and thoria refractories. Use in gas mantles, which still consumes large quantities of thorium nitrate, will continue at about the present rate, and some new uses may serve to raise the growth rate above the percentage increase in the gross national product.

Until demand for thorium exceeds supply from the sources now available, domestic requirements will continue to be imported. Canadian thorium, derived as a byproduct from uranium mills, will probably dominate the market, with imported monazite which has been derived as a byproduct of dredging of titanium, tin, and zirconium minerals, running a close second. Domestic thorium will continue to be produced only as a byproduct from placer mining operations such as those for titanium in Florida. Economic utilization of other thorium deposits would require a substantial increase in price. However, should demand warrant this, ample domestic resources are known and could be developed to supply the need.

Energy uses for thorium will continue on an experimental basis over the next decade at about the same rate. Such experiments require years to complete and, barring some sudden discovery, development of a full thorium-breeder reactor will take from 30 to 40 years, about the same length of time estimated for the development of the uranium-breeder reactor. Thorium has gotten a relatively late start in its development as a nuclear fuel, and the outcome in the race between the two is uncertain. In the long distant future when fossil fuels are exhausted, both thorium and uranium will probably find specific applications and complement each other.

The U.S. Atomic Energy Commission (AEC), under its civilian nuclear power program, will continue to cooperate in the research and development of thorium breeder reactors under its thorium utilization program. A thorium-uranium 233 fuel cycle development facility is scheduled for completion in 1966. The spectral shift reactor concept will also be advanced as a joint AEC-industry project, likely first as a uranium breeder and then as a thorium breeder. Several foreign countries are also committed to similar work.

PROBLEMS

Processors who recover thorium from monazite have the problem of equating supply and demand between thorium and the rare-earth metals. Furthermore, their supply of monazite comes from areas widely scattered around the world and is largely a byproduct of the recovery of titanium and zirconium minerals. The supply factor will be more acute than in the past, because the principal world producer of monazite has closed its mine in the Republic of South Africa for an indefinite time. To cope with these problems, processors are required to carry large stocks of raw concentrates, in-process materials, and finished or semifinished products.

Simpler and more economical methods of separating thorium and producing pure products are required. The prices of thorium products are high, discouraging their use in many nonenergy uses, and this fact may even tilt the balance in favor of uranium in nuclear power reactors.

Domestic producers of thorium have not been able to compete with imported materials. Foreign monazite, generally speaking, has been

richer in thorium, and the market has not been sufficiently broad to warrant development of the higher grade thorite deposits found in the western States. Thorium obtained as a by-product from Canadian uranium ores will probably dominate the near-term market at prices that are uneconomic for domestic producers. There is a need to develop low-cost mining and extraction methods for domestic thorium mineral deposits.

Development of thorium for nuclear purposes encompasses broad fields and disciplines as the development of uranium nuclear science and technology. Many of the factors being discovered in uranium reactors will be useful in thorium reactors. There is one difference, however; natural thorium has no fissionable component, and reactors using thorium for fuel will have to be of the breeder type in which excess neutrons convert Th^{232} to U^{233}. So far, thorium reactors have been operated with mixed thorium and enriched uranium, in which U^{235} provides the neutrons for the chain reaction and for breeding U^{233}. A reactor using a thorium-U^{233} cycle has not been operated, as insufficient U^{233} has not yet been produced. Until such a reactor can be operated and sufficient recycling data have been obtained, the future of thorium reactors can only be judged on theoretical aspects.

TIN

By John E. Shelton [1]

THROUGH use first in bronze and later in pewter, tin-plated iron, and solders, tin shares with a few other metals the distinction of 5,000 years of use by mankind.

Cassiterite, tin oxide, is the only commercial mineral of tin. Although cassiterite deposits are known throughout the world, those of economic importance are limited to a few areas. The principal areas are the placer deposits in Asia and Africa and the lode deposits in South America. There are no known tin deposits of economic grade or size in the United States.

World mine production was 190,300 tons in 1963. Principal contributors were Malaysia 31 percent, China 15, Bolivia 12, U.S.S.R. 10, Thailand 8, Indonesia 7, Nigeria 5, and the Congo (Leopoldville) 3; the remaining 9 percent came from 27 other countries with smaller annual outputs of 5,000 tons or less.

Consumption of tin in the United States in 1963 was 78,000 long tons—55,000 tons of primary and 23,000 tons of secondary. Annual consumption in the 5-year period 1959–63 averaged 79,000 tons—52,000 tons of primary tin and 27,000 tons of secondary tin. The domestic primary-tin supply consisted of imported metal and metal recovered from imported tin concentrates at the Texas City, Tex., tin smelter. Secondary tin was recovered as metal, compounds, and as alloys. In 1963, 14 percent was recovered as metal and 3 percent as compounds, mostly from tinplate scrap. The remainder was recovered in the form of alloys from copper-, lead-, and tin-base scrap.

The principal uses of tin are in the production of tinplate, solder, bronze, brass, and babbitt and in tinning; small quantities are used in metallic forms, miscellaneous alloys, and chemicals.

The short-term outlook is that primary world mine production will be several thousand tons lower than demand. Consumption of tin will rise as the standard of living and industrialization increases throughout the world. World mine production probably will increase at about the same rate as the increase in demand.

The disposal of surplus tin in excess to the U.S. national (strategic) stockpile totaled 12,000 tons by December 31, 1963. The disposal will continue for 5 to 7 years and will help to fill the gap between demand and supply.

In the United States the tin-consuming industry is confronted with problems relating to tin supply and price; the domestic problems are the needs (1) to develop a primary source of tin and (2) to improve secondary sources of tin supply.

BACKGROUND

Tin has been important in commerce since about 3000 B.C. Tin is a constituent of bronze which was known to ancient man. Copper was coated with tin at the beginning of the Christian era and tinplated iron was first manufactured in the 16th century.

Tin always has been an international metal. The Phoenicians were attracted to Cornwall for tin over 20 centuries ago. Production of tin before 1800, unlike that of most base metals, was relatively large compared with that since 1800. Production before 1800 was over 3½ million tons compared to over 10 million since 1800. Modern society has required an increasing quantity of tin. At the beginning of the 19th century, tin was used chiefly in bronze, pewterware, and as a lining for copper cooking utensils. Since 1800, the adoption of the steam engine and power-driven machinery, which required bronze and soft-metal bearings, the development of tin-plated containers for food and other products, electrical power machinery, automobiles, and airplanes have resulted in increased demand for tin. To meet this increase in demand, world mine production has grown to 190,000 long tons in 1963. In world output, tin ranks fifth among the nonferrous metals behind aluminum, copper, lead, and zinc.

[1] Commodity specialist.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Of the total world mine output in 1963, Malaysia produced 31 percent, China 15 percent, Bolivia 12 percent, the U.S.S.R. 10 percent, Thailand 9 percent, Indonesia 7 percent, Nigeria 5 percent, Congo (Leopoldville) 3 percent, and other countries 8 percent.

About 70 percent of the world output of primary tin is smelted in 10 countries: Malaysia 44 percent, United Kingdom 9 percent, Nigeria 5 percent, Belgium 4 percent, Netherlands 3 percent, and Australia, Bolivia, Congo (Leopoldville), United States and West Germany 1 percent each. Total smelter capacity in these countries is over 200,000 tons annually. In addition to the major tin smelters, there are a number of small units treating local output.

Over one-third of the total free world primary and secondary tin production is consumed in the United States. The United Kingdom is the second largest consumer of tin, followed by Japan, West Germany, and France in that order. In the United States, about 280 of a total of 1,800 plants consume 95 percent of the total tin and are chiefly in the Eastern States. Almost one-third of the tin consumed in the United States is derived from secondary materials.

THE INTERNATIONAL TIN AGREEMENT

The First International Tin Agreement was signed or ratified by 20 tin producing and consuming countries and became effective on July 1, 1956. The Second International Tin Agreement came into force on July 1, 1961, having been formally signed or ratified by 6 producing and 14 consuming countries. Three of the larger consuming nations, the United States, U.S.S.R., and West Germany, did not sign or ratify either agreement.

The stated objectives of the agreement are (1) to insure adequate supplies of tin at reasonable prices, and (2) to prevent excessive fluctuations in the price of tin. The governing body is the International Tin Council, composed of a representative from each producing and consuming member government. The producing countries have 1,000 votes distributed, so that each country has 5 initial votes and an additional number corresponding to their proportionate production. The consuming countries also have 1,000 votes, 5 initial votes for each country and an additional number proportionate to their consumption. The voting power may be changed to meet changing conditions.

The First Agreement established a floor price of £640 per long ton (80 cents per pound) and a ceiling price of £880 (110 cents). The floor and ceiling prices have been raised several times and on December 5, 1963, the floor price was raised to £850 per ton (106.25 cents per pound) and the ceiling price was raised to £1,000 (125 cents). The agreement provides for establishing a buffer stock of 25,000 long tons of tin or equivalent in cash. Contributions, not to exceed 75 percent in metal, of metal or cash are compulsory for producing countries. Additional voluntary contributions may be made by producing or consuming countries.

Under the agreement, when the price of tin is at or above the ceiling price, the buffer stock manager must offer tin for sale if he has tin available. When the price is at or below the floor price, the manager must buy tin if he has funds. The range between the floor and the ceiling is divided into three sections. As established on December 5, 1963: In the lower range £850–£900, (106.25–112.50 cents), the manager may buy tin; in the middle range, £900–£950(112.50–118.75cents), he neither buys or sells unless the Council directs otherwise; in the upper range, £950–£1000 (118.75–125.0 cents), he may sell.

The buffer stock manager bought tin in 1958 in an attempt to support the floor price of £730 per ton (91.25 cents per pound) until funds (both regular and special voluntary contributions) were depleted in September. In 1959, the manager liquidated tin acquired by the special fund. The remaining tin was sold in 1961 in an attempt to maintain the ceiling price of £880 per ton (110 cents per pound). The manager entered the market briefly in the fall of 1962 to support the floor price of £790 (98.75 cents) and again in 1963, in an attempt to maintain the ceiling price of £965 (120.625 cents).

Control of exports of tin by member producing countries was in effect from December 15, 1957, to September 30, 1960. The buffer stock manager was permitted to operate in the middle-price range to prevent a sharp rise in the price of tin when the export control first became effective.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Primary or virgin tin is metal produced from ore. It is cast and sold as bars, ingots, pigs, and slabs in weights of 112 pounds or less; most of the tin imported into the United States is 100-pound pigs.

Tin specifications of quality are determined principally by brand names that indicate the smelter and source of the ore. The important classes are Grade A and common tin. Grade A comprises several registered brands which

must assay 99.75 percent tin. One of the best-known brands included in the Grade A class is Straits, a product of Malayan smelters that averages about 99.9 percent tin. Common tin consists of brands assaying 99 to 99.75 percent tin. When the Texas City smelter was owned by the Government, most of the tin produced was Longhorn 3 Star Brand, containing a minimum of 99.8 percent tin.

As the United States has been dependent upon foreign tin producers, domestic industrial tin specifications have not been established. However, to provide a guide for selecting tin for various applications, the American Society for Testing Materials has proposed a tentative classification of pig tin based on market practice, grades of tin in the strategic stockpile, and use.

TABLE 1.—*Classification of pig tin*

Designation		Description		General applications
ASTM	Commercial	Class	Minimum tin content (percent)	
AA	Electrolytic	Extra-high purity.	99.98	Analytical standards, research, pharmaceuticals.
A	Grade A	High purity	99.80	Food containers, foil, collapsible tubes, block tin products.
B		Lower grade	99.7	Less exacting general purposes, electrotinning.
C-1	Common	Copper alloying.	99.0	Cast bronze, bearing metal.
C-2	do	Lead alloying	99.0	Solders, lead-base alloys.

Secondary tin metal, recovered mostly from tinplate scrap, has a purity of about 99.98 percent. M&T and Vulcan are representative brands of this class of tin.

TECHNOLOGY

Geology

The only mineral of commercial importance as a source of tin is cassiterite (SnO_2), although small quantities of tin are recovered from the complex sulfides—stannite, cylindrite, and teallite. Cassiterite has a high specific gravity (6.8 to 7.1), a hardness of 6 to 7, and usually a dark brown or black color and an adamantine luster.

The main sources of tin are placer and eluvial deposits, derived from weathering and erosion of vein and disseminated replacement tin deposits. In the placer deposits the cassiterite is relatively free of impurities because it had greater resistance to weathering than minerals originally associated with it.

Primary tin deposits are associated with granite, granodiorite, quartz monzonite, and related porphyries and pegmatites. In contrast to placer deposits, primary tin deposits usually have other minerals, mostly sulfides, containing antimony, arsenic, bismuth, columbium, copper, iron, lead, silver, tantalum, tungsten, or zinc, in the veins with the cassiterite.

Mining

The principal method of mining placer tin deposits is bucket-line dredging, although gravel-pump, hydraulicking, and various open-pit methods also are used.

Bucket-line dredges, similar to floating dredges used to mine other placer deposits, are used. The ore is excavated and transported by buckets to the interior of the dredges, washed on screens, and concentrated on jigs and shaking tables. Tailings are discharged at the rear of the dredges to fill in the mined pond, and the rougher tin concentrate is sent to the dressing sheds for final concentration. Dredges to mine the offshore tin deposits of Indonesia at depths up to 150 feet below the ocean surface are being developed.

Gravel-pump and hydraulic mining are similar in that both mining methods use water jets to break up the tin-bearing material. The methods of conveying the material to the launders differ. In gravel-pump mining a pump is used, whereas in hydraulicking the pressure developed by a natural head of water is employed. In each method the material is washed through a riffled launder, called a palong in Malaysia, where the cassiterite is collected by the riffles and the waste is washed free.

In other open-pit operations the material is excavated dry by power shovels and transported on a conveyor belt to the washing plant for treatment.

A small quantity of tin is mined in Malaysia by dulang washers—one of the oldest methods of mining tin ore and traditionally limited to women workers. A dulang is a round wooden tray somewhat like a gold pan and is worked by hand.

Vein tin deposits are mined by methods similar to those used in the hard-rock mining of other nonferrous ores. Access to the ore bodies is by adits and shafts, the ore is broken by conventional drilling and blasting, and the ore is transported from the mine to a concentrator for treatment.

Beneficiation

Impure cassiterite concentrate from dredges, launders, and other mining of placer deposits is upgraded by washing, tabling, and magnetic or electrostatic separation. Final cleaning is

done by hand washing—a method used for hundreds of years. Virtually the entire product is cassiterite containing more than 75 percent tin.

Tin ore from lode deposits is reduced to the necessary size by conventional crushing and grinding. The ore is concentrated by gravity methods, involving screening, classification, jigging, and tabling. The concentrate is usually a lower grade (60–70 percent tin) than placer concentrate owing to associated sulfide minerals. The sulfide minerals are removed by flotation or magnetic separation with or without magnetic roasting.

Recovery of tin is low, ranging from 50 to 80 percent, in the concentration of both placer and vein cassiterite ore because the finely divided cassiterite is difficult to recover. Successful flotation of tin ores has never been achieved, although considerable flotation research has been done.

Smelting

Cassiterite is reduced to tin by heating with carbon at 1,200° to 1,300° C. The tin concentrate from alluvial deposits is almost pure cassiterite and is smelted directly. Other concentrates, particularly from vein deposits in Bolivia, contain impurities that must be removed before smelting. This is usually done by roasting the tin concentrate with or without fluxes, followed by water or acid leaching. During roasting, most of the sulfur and arsenic are removed as oxides; bismuth, copper, iron, and zinc sulfides are converted to oxides, and lead sulfide is oxidized to the sulfate. Bismuth, copper, iron, and zinc oxides are removed by leaching the roasted concentrate with dilute hydrochloric acid. Tungsten may be recovered by roasting the concentrate with sodium carbonate or sulfate and leaching with water. Antimony, bismuth, lead, and silver, may be removed by a chloridizing roast followed by an acid leach.

In modern tin-smelting plants, reverberatory furnaces are used to smelt primary-tin concentrate and to resmelt the slag for additional tin recovery. Although blast and electric furnaces also are used to smelt tin concentrate, reverberatories are preferred because of better control, cleaner slags, and superior efficiency in smelting finely divided material.

Tin smelting is a batch operation. A typical charge consists of cassiterite, a carbon reducing agent, and limestone and silica fluxes. From 10 to 12 hours is required to smelt a charge. When smelting is complete, the molten batch is tapped into a settler, from which the slag overflows into cast-iron pots. The molten tin from the bottom of the settler is cast into slabs or pigs (of about 75 pounds) for refining.

After cooling and solidifying, the slag, containing 10 to 25 percent tin, is crushed to minus ¾ inch for resmelting. The reduction of tin silicate in the slag is more difficult than the reduction of tin oxide in the ore, and a higher temperature (up to 1,480° C) is necessary. Anthracite is used as a reducing agent, limestone as a flux, and either iron or lime to aid in the reduction and to replace tin in the silicate. Slag from the resmelting contains less than 1 percent tin.

Refining

Most tin produced in smelting concentrate and slag contains various metallic impurities that were reduced with the tin and must be removed before the tin is marketed. Refining may be done by heat treatment or electrolytic processes. Heat treatment is the most widely used method and may consist of one or both of two operations: (1) Liquating or sweating and (2) boiling or tossing.

In liquating, always the first operation in the sequence, the tin is heated on an inclined hearth to a temperature slightly above the melting point of pure tin but below the melting points of the impurities. Thus, the comparatively pure tin melts and flows into a kettle, leaving impurities such as iron and copper in a dross residue that is re-treated to recover the contained tin.

The molten tin is then poled with green wood, which produces a strong boiling action. During poling, the metal impurities and part of the tin are oxidized and form an oxide dross that is skimmed off. Sometimes tossing is used instead of poling. In this operation hand ladles of molten tin are dipped from and poured back into the kettle, exposing the tin to the oxidizing action of the air. Boiling or tossing is continued until the desired grade of refined tin is obtained. After refining has been completed, the tin is cast into pigs for marketing.

Electrolytic refining of tin has been used successfully to produce a purer product than heat treatment. However, owing to a low demand for extremely high-purity tin, the more costly electrolytic process seldom has been used to refine primary tin.

USES

Tin, symbol Sn, is a silvery white metal with a specific gravity of 7.29. It melts at 231.9° C, boils at 2,270° C, and changes to another form, gray tin, at 13.2° C. An unusual combination of properties—low fusibility, malleability, resistance to corrosion and fatigue, and ability to alloy with other metals—accounts for the many uses in which tin is preferred to other competing materials.

The largest use of tin is as a protective coating for copper, steel, and other stronger materials, mainly in the form of tinplate for cans. Tinplate is thin, sheet steel coated with commercially pure tin by hot-dip or electrolytic processes. Another older but minor use of tin as a coating is in the production of terneplate—sheet steel covered with a tin-lead alloy. Tin is also used as a coating on copper wire and electrical connections to prevent corrosion by the insulation and to facilitate soldering.

The second largest use of tin is in soft solders—tin-lead alloys. Because tin alloys readily with most metals, it is the essential constituent of the solders. However, the addition of lead not only reduces the melting point and cost of the solder but also increases its strength.

One of the first-known and currently larger uses of tin is in making bronze and brass. The principal tin bronzes are the phosphor bronzes (up to 12 percent tin), which have high strength, excellent resistance to corrosion, and superior bearing characteristics, and the gun metals (8 to 10 percent tin), which are used for gas-free, pressure-tight, and corrosion-resistant castings.

Substantial quantities of tin are used in producing babbitt, pewter, type metal, and die-casting and in fusible alloys. Although the use of tin in pipe, tubing, collapsible tubes, and foil has declined, tin is still preferred in applications that require purity and nontoxicity. Small quantities of tin are consumed in chemical reagents and compounds used in making glass, ceramics, and other products. Recently developed organotin compounds, containing 25 to 50 percent tin, are used as stabilizers in plastics, wood preservatives, fungicides, insecticides, and similar uses.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Columbium, tantalum, and tungsten are the principal byproducts of tin placer and vein deposits. Tin is recovered as a byproduct of molybdenum at the Climax mine in Colorado and of lead-zinc at the Sullivan mine in British Columbia, Canada, but this output is a negligible part of world production.

ALTERNATE MATERIALS

In the largest use of tin—tinplate for cans—there are numerous alternate materials, including glass, paper, enameled steel, plastics, and aluminum. Nonmetallic materials, and copper, aluminum, and zinc-coated products have largely replaced tinplate and terneplate for roofing and construction.

In solder, silver or antimony may be used in place of tin. In other alloys, low-tin bronze and roller or ball bearings may be substituted for babbitt metal containing tin.

Wrapping material, such as aluminum, plastics, or paper, may be used instead of tinfoil. Other chemical compounds may replace tin compounds for use as fungicides and insecticides, slime-control reagents, and an enamel opacifier in ceramics.

SECONDARY SOURCES AND RECOVERY

About 80 percent of the tin reclaimed each year from secondary materials is derived from copper- and lead-base alloys and 20 percent from tinplate and tin-base alloys. Of the total secondary tin recovered in 1963, over 80 percent was recovered as a component of bronze and brass, solder, type metal, babbitt, and miscellaneous tin-lead alloys in about 160 plants, principally in the Eastern United States. About 14 percent was recovered as metal and 3 percent as chemicals, mostly at 12 detinning plants scattered throughout the United States. Although small quantities of tin are also recovered at detinning plants from used tin containers, such reclamation has been attractive only under emergency conditions, owing to the high cost of collecting, transporting, and cleaning the cans.

Of the 5,361,000 short tons of tinplate produced in 1963, only 673,000 tons of waste plate was treated for reclamation of the contained tin, and the tin reclaimed from waste plate represented only about 10 percent (2,900 long tons) of the tin used in tinplate production (28,000 tons).

Several methods of recovering tin from tinplate scrap have been proposed, but three have accounted for nearly all commercial detinning—the alkali-chemical, the alkaline-electrolytic, and the chlorine processes.

In the alkali-chemical process (most widely used), the tinplate scrap is treated with a hot solution of caustic soda in the presence of an oxidizing agent. The tin is dissolved as sodium stannate and leaves the steel, which is washed and pressed into bales for shipment. The tin may be recovered from the stannate solution as metal, as sodium stannate crystals, or as tin oxide. Because of advantages in processing costs and production of a high purity metal, the common practice is electrolysis of the solution to yield metallic tin. The refined tin averages as high as 99.99 percent pure, with antimony, iron, and lead as principal impurities.

RESERVES

The free world reserves of tin are estimated to total 4.7 million long tons of contained tin. Of this total, 3 million tons is in Burma, Indonesia, Malaysia, and Thailand, 0.75 million

tons in the Republic of the Congo and Nigeria, 0.75 million tons in Bolivia and 0.20 million tons in the rest of the free world. These figures do not include the potential resources in the offshore deposits of Indonesia and Thailand. The Rondonia Province, Brazil, reportedly may have very large tin resources.

The tin reserve in the United States, mostly at Lost River, Alaska, is estimated by the Geological Survey and the Bureau of Mines at about 3,000 tons. Estimated reserves in Canada are 30,000 to 40,000 tons.

Reserves in the U.S.S.R. are estimated at about 0.5 million tons.

CONSERVATION PRACTICES IN PRODUCTION AND USES

The principal and most effective method of conserving tin is the electrolytic process of tin plating. In World War II, when the domestic tin supply was restricted, an electrolytic process was adopted. Since then, this method has progressively replaced the hot-dip method of tinplating. Coatings of any thickness, but usually ranging from 15 to 45 millionths of an inch, can be applied with electrolytic methods, whereas the minimum coating possible with hot-dip methods is 70 millionths of an inch. Moreover, in electroplating, a different thickness of tin can be applied on each side of the same sheet, thus reducing tin consumption.

After the first large-scale use of electrolytic tinplating in 1943, its share of the annual domestic tinplate output rose from 16 to 96 percent in 1963. Despite an increase of 141 percent in annual tinplate output during that period, annual consumption of tin for tinplate increased only 34 percent, as the quantity of tin used per short ton of plate dropped from 23.4 to 12.9 pounds. In 1960 double-reduced tinplate was introduced. After a second reduction, the thickness is one-half to two-thirds that of normal tinplate, resulting in more tinplate area for a given weight of steel. The weight of tin is about one-half that normally contained in tinplate.

Other conservation measures adopted during periods of limited tin supply include the use of aluminum, lead, and tin-coated lead to replace tin in collapsible tubes.

SOURCES OF STATISTICAL INFORMATION

Monthly and annual data on domestic production, distribution, stocks, receipts, shipments, and uses of primary and secondary tin are obtained by the Bureau of Mines. World production data on tin also are compiled by the Bureau from State Department dispatches, and official publications of foreign countries, and U.S. imports and exports of tin are obtained by the Bureau of the Census. The International Tin Council publishes detailed monthly data on primary production, consumption, stocks, trade, uses, and other phases of the tin industry throughout the world. As a result, nonfinancial statistical data on the world tin industry are comprehensive and relatively adequate except for data on secondary tin production.

PRODUCTION, CONSUMPTION, AND TRADE

Production, consumption, and import data are shown in tables. Exports of tin from the United States are small, averaging 1,000 tons annually from 1959 through 1963.

The significant features of these data are the concentration of tin production in the so-called underdeveloped countries, dependence of the domestic primary tin supply of imported

metal and concentrate, and concentration of more than 90 percent of the domestic tin consumption in five items—tinplate, solder, bronze and brass, babbitt, and tinning. There has been no import duty on tin since 1895. According to the Tariff Schedules of the United States as of August 31, 1963, there was no duty on cassiterite, black oxide of tin, or bars, blocks, pigs, and grain or granulated tin.

Forms of tin that are dutiable include tinplate, pewter, terneplate, foil, powder, chemicals, bottle caps, collapsible tubes, and other manufactured tin items.

STRATEGIC CONSIDERATIONS

The United States is dependent upon foreign sources for supplies of primary tin. Although some tin is mined in the United States, the total production is insignificant. The annual domestic requirements for primary tin are met by imports of metal, metal produced at Texas City smelter from imported concentrates, and release of surplus tin from the national stockpile. Although the recovery of tin from secondary sources in the United States is important, it represents only about 30 percent of the domestic tin consumption.

Because the availability of foreign tin is restricted during wartime, tin has been designated a strategic material for stockpiling. On June 30, 1964, stocks of pig tin totaled 321,600 long tons, of which 314,100 was in the national (strategic) stockpile, and 7,500 in the supplemental stockpile.

GOVERNMENT PROGRAMS

The Office of Minerals Exploration (OME) is authorized to grant loans up to 50 percent of approved costs on exploration projects for tin. No loans have been made by OME.

Tin was removed from the list of materials eligible to be acquired for the supplemental stockpile through barter or exchange transactions on May 18, 1961. During the 1958–61 period, a total of 7,505 tons of tin had been added to the supplemental stockpile.

In 1961 and early 1962, the General Services Administration sold 3,933 tons of tin that was excess to the Government's needs and not in the national stockpile. The disposal of approximately 50,000 tons of pig tin in excess of national stockpile needs was authorized by Congress, June 21, 1962 (H. Con. Res. 473), and sales began September 12, 1962. GSA sold 1,400 tons to industry in 1962, and 9,325 tons to industry, 1,298 tons to the Agency for International Development, and 3 tons to other Government agencies in 1963.

The United States has participated with the International Tin Council in a long-term study of world production, consumption, and reserves and has supplied statistical data for other studies.

During periods of emergency, tin was placed under Government control as to use and allocation. Exports of tin metal and materials containing tin required an export license to all destinations except Canada. In 1953 all controls were removed, except export controls which were extended to June 30, 1965. Exports were under general license to the free world. Entry of Chinese tin is prohibited and a permit is required for U.S.S.R. tin, as it might be of Chinese origin. Entrance of alloys that might include Chinese or Soviet tin also is prohibited.

The United States Tin Corp. Lost River tin mine, Seward Peninsula, Alaska, was granted a Defense Materials Procurement Agency (DMPA) purchase contract in 1951. By October 1954 the corporation had received $2,894,573 to purchase and operate the mine and plant. In 1957, to satisfy a judgment in favor of the Government, the property was offered for sale by bid. No acceptable offer was made and the Government took possession of the property. The property was offered for sale by GSA on August 8, 1960, and sold to Lenhart J. Grother, Red Devil, Alaska, for $21,777.

PRICES

The principal quotations for tin are those at New York, London, and Singapore. Both the Commodity Exchange, Inc., New York, and the London Metal Exchange permit trading in tin for immediate and future delivery.

The price of prompt tin in New York was relatively stable in 1959 and 1960, ranging from 98.0 cents to 104.875 cents per pound. Prices began a general upward trend early in 1961 and rose to 133 cents per pound on December 31, 1963. The average price for 1963 was 116.64 cents per pound, the highest annual average since 1951. Cash tin in London reached £1035.0 per long ton (129.375 cents per pound) in December 1963 and the yearly average was £909.7 per ton (113.72 cents per pound).

In 1961 the price of cash tin in London rose above the ceiling of £880 set by the International Tin Council, reaching £993, when the buffer stock supplies of tin metal were exhausted. When the price dropped below £850 in mid-1962, the "may buy" range at that time, the ITC buffer stock manager bought tin to prevent a further decline. The price began a steady rise and in 1963 the buffer stock was exhausted in an attempt to hold the price at £880.

TAXES

There are no special taxes imposed on the domestic tin industry. Producers are granted

a depletion allowance of 23 percent on domestic production and 15 percent on foreign production.

TRANSPORTATION

Movement of tin concentrate from the mine to the smelter and tin metal from the smelter to the market involves both water and land transportation. Tin is not mined in substantial quantities in the important industrial countries, although some have tin-smelting plants.

Most tin imported into the United States enters North Atlantic ports from the Far East through the Suez Canal and the Mediterranean. Bolivian tin concentrate for the Texas City smelter was transported from the west coast of South America to the Gulf of Mexico through the Panama Canal. Shipments of tin metal or concentrate to the United States take about 2 months from the Far East and about 2 weeks from the west coast of South America.

RESEARCH

The principal tin research organization is the Tin Research Institute, Greenford, England, which is financed by tin producers and controlled by the International Tin Research Council. The research of the Institute is aimed at developing the use of tin through scientific study of the metal, its alloys and compounds, and processes that use tin or may provide future markets. Other research on tin by the domestic consuming industry is concerned principally with improving processes using tin, chiefly tin plating.

The Bureau of Mines and Geological Survey have conducted extensive surveys of domestic tin resources. From 1939 to 1945, as part of the strategic minerals investigation instituted in World War II, special attention was given to tin. All domestic deposits that were believed to have even a remote chance of containing strategic reserves were examined. The information resulting from these investigations indicated that the tin content of domestic deposits was insignificant in terms of national requirements.

The Bureau of Mines conducts research on extracting tin from ores and secondary and waste materials. Through Bureau studies, methods have been developed for recovering tin from ores by chloridization and sulfidization, tin and tungsten from tin smelter slags, tin from hardhead, and lead-tin alloys from solder dross skimmings. In addition, the Bureau continues to examine and evaluate domestic occurrences of tin.

OUTLOOK

The short-term outlook for tin is that primary world production will be several thousand tons lower than demand. Consumption of tin will rise as the standard of living and industrialization in many countries of the world increases. The rising standard of living in these countries results in an increasing demand for tinplate and solder for canning to preserve foodstuff. As countries become more industrialized, the requirements for bronze, brass, babbitt metal, and solder for other than canning becomes greater. Usage of tin in the United States will increase, but the growth rate will be lower than the rise of gross national product in this country and at a slower rate than in many other countries.

World mine production of tin will increase in the near future, but the increase probably will be at about the same rate as the increase in demand. Bolivia, the Congo (Leopoldville), Indonesia, Malaysia, and Thailand, the major tin-producing countries, have the potential to increase production to meet demand, but political and economic upheavals in some of these areas may inhibit realization of this potential and may further enhance the shortage. The world capacity to smelt tin ore is adequate and will become greater since new smelters will be erected in several countries.

Domestic mine production of tin is insignificant and the United States must rely on foreign sources of supply. Part of the U.S. requirements and the world shortage will be met by releases of surplus tin from the U.S. national stockpile. The current disposal program will continue for the next 5 to 7 years by which time increased world mine production may fulfill the needs of the consuming industry.

The search for alternate materials seems likely to be intensified. Plastics, glass, and aluminum will replace tinplate as containers, not so much in present uses, but more in expanding and newer uses. Plastics, aluminum, and chromium coatings on steel may to some extent replace tin as the coating material.

Research is expected to be continued by the Government, industry, and various research institutions to improve extractive processes, improve efficiency and conservation in present usage, and develop new and better uses.

PROBLEMS

The major problem facing the tin industry at this time is the shortage of newly mined tin. This imbalance between supply and demand causes instability in the price which leads the consumer industry to search for alternate materials which may eventually cause the problem of loss of markets by the producers. The loss of markets may affect economic and political disturbances in the countries that depend upon tin mining as a major source of revenue, thus further impeding supply.

There is a pressing need to improve the efficiency of concentration and recovery of the tin mineral cassiterite and improve smelting practices. The depletion of higher grade deposits throughout the world intensifies these problems. Losses of fine tin minerals during concentration and tin in smelter slimes and residues results in a lower efficiency of utilization of resources and increased cost. Production of tin at an acceptable price is necessary to minimize the encroachment of substitute materials and changes in use patterns.

U.S. consumers need more stable supplies of tin. The major potential domestic source is in Alaska, but the remote nature of the deposits and short exploration seasons make evaluation difficult and expensive. Since the Uuited States is dependent upon foreign sources, reducing the loss of tin during use and for improving recovery from secondary sources are problems that need study.

TITANIUM

By John W. Stamper [1]

TITANIUM is estimated as the ninth most abundant element in the earth's crust and the fourth most abundant of the structural metals. Its oxide has been a commodity of commerce for half a century, but utilization of titanium as a structural metal was made possible only through the advances in technology that followed World War II.

Deposits of the titanium ore minerals, rutile and ilmenite, are widely scattered with major economic deposits found in Australia, Canada, Finland, India, Norway, Malaya, Sierra Leone, Republic of South Africa, and the United States. Virtually all of the rutile mined in 1963 came from sand deposits that were mined by dredging; ilmenite came from rock deposits mined by open-pit methods and from sand deposits that were dredged.

Ilmenite is more abundant than rutile and has traditionally been the principal titanium mineral produced. World output of 2.2 million tons in 1963 was 10 times the quantity of rutile produced. However, rutile contains more titanium than ilmenite and commands a higher price. Various economic and technical considerations necessitate its use instead of ilmenite for some applications.

The chief use of ilmenite is in making titanium dioxide, a white pigment. In recent years, rutile was used principally in welding-rod coatings and for making titanium metal. A commercial process developed in 1958 for making titanium pigment from rutile is likely to make pigment the chief market for rutile as well as ilmenite.

The United States is the principal consumer of titanium minerals and leads in production of ilmenite and titanium metal and pigments. It is largely self-sufficient in ilmenite but imports about 80 percent of its rutile requirements from Australia, the foremost producing country.

Most titanium pigments are made by dissolving ilmenite or titanium slag in sulfuric acid, crystallizing and separating the included iron, then hydrolyzing the solution and calcining the resulting precipitate to pure white titanium dioxide. Pigment plants in the United States built since 1958 utilize the chloride process whereby titanium tetrachloride is oxidized to titanium dioxide—the chlorine being regenerated and used for chlorinating a titaniferous material.

Titanium metal is produced commercially by a process originally conceived by Wilhelm Kroll and developed to industrial scale by the Bureau of Mines. In this process, a titanium mineral, normally rutile, is chlorinated to produce titanium tetrachloride which is then purified and reduced to titanium metal with magnesium or sodium under an inert atmosphere.

During the next decade all segments of the titanium industry should continue to expand. Consumption of titanium dioxide pigment, which on a TiO_2 basis accounts for 95 percent of all uses of titanium minerals, is likely to increase at a slightly greater rate than the Nation's average growth rate. Developments in manned space flight programs, supersonic flight, and deep-diving submarines, foreshadow an ever increasing role for titanium metal. By 1970 annual domestic requirements for titanium minerals may reach 225,000 tons of rutile and 1.3 million tons of ilmenite, including slag.

BACKGROUND

Although the element titanium was discovered by William Gregor in 1790, over 100 years passed before it was put to commercial use. The first commercial application of titanium was as an alloy additive to iron and steel, and the first ferroalloys were produced domestically in 1906. Titanium dioxide pigment was developed later and has been produced in the United

[1] Commodity specialist.

780-887 O—65——62

States since 1918. The use of titaniferous materials in welding-rod coatings first gained acceptance in the mid-1930's and the metal titanium has been of commercial importance only since 1948.

Manufactured titanium dioxide has found an expanding market in the production of paints, paper, and many other products requiring a white pigment with a high hiding power and chemical stability. Based on the TiO_2 content of minerals consumed in production, the output of titanium pigment in 1963 far exceeded the combined production of the other white pigments, white lead, leaded zinc oxide, and lithopone.

The ability of certain titanium compounds to stabilize the electric arc has been known since the 1920's, and the use of these compounds in the manufacture of fluxes and coatings for improved welding-rod has become practically universal.

Because of the importance of titanium metal for defense uses and the complex nature of the new technology involved in its manufacture, the industry received virtually all forms of government assistance during its early expansion. Selecting the Kroll process as the most likely for engineering to industrial scale, the Bureau of Mines developed a practical way to produce the metal in volume in the early 1940's, and commercial production was started by E. I. du Pont de Nemours & Co., Inc., in 1948. Expansion of the industry was phenomenal from 1948 to 1957. However, in 1957, cutbacks in requirement for titanium resulting from changes in military concepts, caused a severe decline in output, and in 1958 the industry operated at only one-fourth of its capacity. Production of the sponge metal doubled during 1959–63.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The titanium industry is characterized by a moderately high degree of integration from raw materials to semifinished products. Several companies mine and utilize the ore minerals in producing titanium pigments and metal. Significant quantities of titanium materials also are used in the welding-rod, ferroalloy, ceramic, and fiberglass industries.

Minerals

At the end of 1963, seven companies were engaged in mining and concentrating ilmenite and rutile. Operations were in Florida, New York, New Jersey, and Virginia.

The following companies mined ilmenite in 1963: American Cyanamid Co., Piney River, Va.; E. I. du Pont de Nemours & Co., Inc.; Trailridge and Highland, Fla.; The Glidden Company, Lakehurst, N.J.; and National Lead Co., Tahawus, N.Y. Production of both ilmenite and rutile was reported from the following companies: M&T Chemicals, Inc., Beaver Dam, Va.; Florida Minerals Co., Vero, Fla.; and Titanium Alloy Manufacturing Div. of National Lead Co., Skinner, Fla. The Rutile Mining Co. of Florida, produced rutile from a mine near Jacksonville.

A number of localities have produced titanium minerals in the past. The American Rutile Co., a subsidiary of Metal and Thermit Corp., mined a rutile and ilmenite deposit at Roseland, Va., from 1902 to 1949. Between 1932 and 1944 rutile, brookite, and ilmenite were shipped from a rock deposit at Magnet Cove, Ark., owned by the Magnet Cove Rutile Co. The Yadkin Mica & Ilmenite Co., a subsidiary of The Glidden Co., produced ilmenite from a rock deposit at Richland Cove, N.C., from 1942 to 1952. From 1951 to 1955 ilmenite was a by-product of monazite dredging operations in Idaho. Baumhoff-Marshall, Inc., and J. R. Simplot Co. concentrated the heavy minerals at a plant in Boise, Idaho, from nearby deposits worked by Baumhoff-Marshall's dredge and that of the Idaho Canadian Dredging Co. Marine Minerals Division of Heavy Minerals Co., operated an ilmenite and rutile mine at Bath, S.C., from 1956 to 1957.

Another operation on the North American continent is that of the Quebec Iron and Titanium Corp. (Q.I.T.) in Canada. This company is two-thirds owned by Kennecott Copper Corp. and one-third by The New Jersey Zinc Co., a titanium pigment producer. Q.I.T. mines an ilmenite-hematite ore at Allard Lake, Quebec, and smelts this material at Sorel, Quebec, to produce a high titania slag used for making titanium pigment by the sulfate process, and pig iron.

Titanium Pigments

In 1963, the titanium pigment industry was comprised of 5 companies with 10 plants and was concentrated in the eastern part of the United States. Titanium pigments were produced by the following:

Company	*Plant location*
American Cyanamid Co.	Piney River, Va.; Savannah, Ga.
E. I. du Pont de Nemours & Co., Inc.	Edge Moor, Del. (2); New Johnsonville, Tenn; Baltimore, Md.
National Lead Co.	St. Louis, Mo.; Sayreville, N.J.
The New Jersey Zinc Co.	Gloucester City, N.J.
The Glidden Co.	Baltimore, Md.

National Lead and Du Pont were the two largest producers of titanium pigments in 1963. Du pont was the first company to develop the chloride process on a commercial scale and used the method at New Johnsonville, Tenn., and at one of two plants that it operated at Edge Moor, Del. All of the other commercial plants were using the sulfate process.

Cabot Titania Corp., two-thirds owned by Cabot Corp. and one-third by Ruberoid Co., was the latest entrant into the titanium pigment industry, and in 1963 completed construction of a 20,000-ton-per-year plant at Ashtabula, Ohio. The chloride process will be used. Du Pont was building a 27,000 ton-per-year plant at Antioch, Calif., also using the chloride process. Both of these plants were expected to be producing by 1964.

American Potash & Chemical Corp., another new entrant into the titanium pigment industry, was building a 25,000-ton-per-year chloride plant at Hamilton, Miss. In addition, National Lead Company, Pittsburgh Plate Glass Co. and American Cyanamid Co. had plans to construct titanium pigment plants in the United States using the chloride process.

Titanium Metal

At the end of 1963 the following companies were producing titanium sponge metal at the specified locations:

E. I. du Pont de Nemours & Co., Inc., Newport, Del.
U.S. Industrial Chemicals Co. (Reactive Metals Products), Ashtabula, Ohio
Titanium Metals Corp. of America, Henderson, Nev.

Titanium Metals Corporation of America (TMCA) is owned jointly by the National Lead Co. and Allegheny Ludlum Steel Corp. U.S. Industrial Chemicals Co., a subsidiary of National Distillers and Chemical Corp., operated the Ashtabula, Ohio reduction plant.

Du Pont announced it would close its titanium sponge plant early in 1964, owing to available sponge production capacity by integrated producers and increased use of sponge from Japan.

Du Pont and TMCA made titanium tetrachloride for their own use, but U.S. Industrial Chemicals purchased its titanium tetrachloride from Cabot Titania Corp.

The Crane Co., through its subsidiary, Cramet, Inc., produced titanium sponge metal under a Government contract at Chattanooga, Tenn., from 1954 until the early part of 1958 when, owing to lack of a commercial market for its metal, the company closed the facilities. The Cramet plant was turned over to the Government under the contractual agreement and was later dismantled and sold. Dow Chemical Company closed a titanium sponge metal plant at Midland, Mich., in 1957. Under a government contract, Dow was required to maintain 1,300-ton-per-year capacity of the plant in standby condition until 1962.

Union Carbide Metals Co., Division of Union Carbide Corp., purchased titanium tetrachloride from Colombia Southern-Chemicals Division of Pittsburgh Plate Glass Co. and produced titanium sponge metal at Ashtabula, Ohio, from 1956 to 1960 when it closed the plant due to lack of a market.

Titanium melters in 1963 were Harvey Aluminum, Inc., Torrance, Calif.; Bridgeport Brass Co. Division of National Distillers and Chemical Co., Niles, Ohio; Oregon Metallurgical Corp., Albany, Oreg.; Crucible Steel Co. of America, Midland, Pa.; Republic Steel Corp., Massillon and Canton, Ohio; and TMCA, Henderson, Nev.

Oregon Metallurgical Corp. produced ingots and castings. The other companies produced and processed ingots into mill products such as sheet, strip, plate, forging billets, and bars. Ladish Co., Cudahy, Wis., processed ingots into forged products.

The Babcock & Wilcox Co. Beaver Falls, Pa., and the Wolverine Tube Division of Calumet & Hecla, Inc., Allen Park, Mich., produced titanium pipe, tubing, and extrusions. Titanium Products Corp. produced seamless titanium pipe at Grosse Point, Mich.

Welding-Rod Coatings and Other Products

In 1963, 22 companies reported production of welding rods with titaniferous material in their coatings. There were six plants in Ohio, three in California, two each in Pennsylvania, Maryland, and Wisconsin, and one each in Tennessee, Minnesota, New Jersey, Alabama, New York, Illinois, and Michigan.

Although the companies comprising the titanium pigment metal, and welding-rod coating industries consume most titanium raw materials, there were some 70 other companies in 1963 that used titanium minerals in manufacturing ferroalloys, ceramics, fiberglass, chemicals, soap, plastics, and other miscellaneous products.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

The preferred grades of ilmenite concentrate contain from 56 to 60 percent titanium dioxide, although lower grades find a ready market. Ilmenite shipments in 1963 ranged from 45 to 60 percent titanium dioxide. In making pigment, the principal market use for ilmenite, the chromium oxide and vanadium pentoxide con-

tent should not exceed 0.2 percent and 0.5 percent, respectively.

Domestic shipments of rutile concentrate in 1958–63 averaged 95 percent titanium dioxide.

Near Jacksonville, Fla., Du Pont produced mixed products containing ilmenite, rutile, and leucoxene, averaging 60 or 80 percent TiO_2, chiefly for its own use. Data on production and use of these products are included with data on ilmenite.

Titanium slag is produced by smelting a mixture of carbon and a titanium-bearing material (usually ilmenite) in an electric furnace. The titanium dioxide content of slag produced commercially by Q.I.T. in Quebec, Canada, averages about 70 percent.

Titanium tetrachloride is a volatile colorless liquid which is used in the manufacture of titanium metal and pigments.

Titanium dioxide pigment is sold domestically in three grades. Rutile and anatase grades are more or less pure titanium dioxide, but owing to a difference in crystal structure, they differ slightly in hiding power and chalking quality. Both contain about 95 to 99 percent titanium dioxide. Extended titanium pigment containing about 30 to 50 percent titanium dioxide also is sold. According to the techniques of manufacture, the properties of titanium pigment may vary considerably as to particle size, hiding power, dispersibility, and so forth. Potential buyers are supplied detailed information concerning these properties. These data are interpreted by each user in terms of his own needs.

Titanium metal is a low-density, silver-white metal and owes its importance to a combination of lightness, strength, and resistance to corrosion. The density of titanium is 0.16 pound per cubic inch—61 percent heavier than aluminum but only 56 percent as heavy as alloy steel. Titanium alloys usually are much stronger than aluminum alloys, having tensile strength and hardness approaching that of many alloy steels. The strength-to-weight ratio below about 1,000° F exceeds that of either aluminum or stainless steel. Titanium alloys also have good impact strength and resistance to fatigue. Titanium metal is more inert than aluminum and has shown better corrosion resistance to sea water and marine atmospheres than stainless steel. It has been specified in many applications (particularly those involving resistance to chloride ion attack) where stainless steels are rapidly attacked.

The chief disadvantages are high cost, difficulties of fabrication, and excessive reactivity at high temperature. Although the melting point of titanium—3,030° F—is very high, it absorbs oxygen, nitrogen, and hydrogen and becomes brittle with prolonged atmospheric exposure above 1,000° F.

Hardness is a relative gage of the quality of titanium metal and nearly always is quoted in specifications. The hardness of most commercial titanium metal produced during the early stages of the development of the industry was quite high, being about 200 on the Brinell scale. In 1963, commercial grades ranged from 100 to 170 Brinell. Titanium metal having a Brinell hardness as low as 50 has been produced.

Titanium sponge is the metal product from reducing titanium tetrachloride with magnesium in the Kroll process. It is called sponge because of its sponge-like appearance. Sodium reduced metal also is referred to as sponge.

Titanium alloys are of three types—according to the predominant crystal phase present—alpha, alpha-beta, or beta. Aluminum is the most prominent alpha-stabilizing addition. The alpha-beta alloys also contain some aluminum, but additional elements are added to stabilize the beta phase, thus resulting in a mixed alpha-beta structure which is predominately alpha. The beta alloys also have a mixed alpha-beta structure but are predominately beta. About 20 commercial and semicommercial titanium alloys of these three types are available to the titanium user.

No uniform system has been adopted by industry for designating titanium alloys, and producers use their own designation. Specifications for titanium alloys as well as for unalloyed titanium have been summarized (*33*).[2]

TECHNOLOGY

Geology

Although titanium is estimated to be the ninth most abundant element in the earth's crust, there are only two titanium minerals, ilmenite and rutile, that are of commercial importance. Theoretically, ilmenite ($FeTiO_3$) contains a maximum of 53 percent titanium dioxide and rutile (TiO_2), 100 percent TiO_2. Titanium-bearing minerals such as anatase, leucoxene, and brookite, are associated with ilmenite and rutile and often comprise part of the marketed titanium concentrates. Many other minerals, including sphene ($CaTiSiO_5$), perovskite ($CaTiO_3$), and pyrophanite ($MnTiO_3$), are locally abundant in some deposits but have not been utilized commercially. Titanium does not exist in a metallic state in nature because of its strong affinity for oxygen and other elements.

[2] Italicized numbers in parentheses refer to items listed in the references at the end of this chapter.

Deposits containing the two main commercial titanium ore minerals, ilmenite and rutile, are found extensively throughout the world. Ilmenite, rutile, or both of these minerals have been produced commercially in the United States, Australia, Canada, Egypt, Finland, Gambia, India, Japan, Malaya, Norway, Portugal, Senegal, Sierra Leone, Spain, and the U.S.S.R.

Two types of deposits contain titanium minerals of economic importance, namely, rock and sand. Ilmenite from rock deposits and some sand deposits commonly contain 35 to 55 percent TiO_2; however, some sand deposits yield altered ilmenite containing 60 percent or more TiO_2. In anorthosite and related rocks, ilmenite is characteristically associated with iron ores, principally magnetite, but in some places, it occurs with hematite. Ilmenite in a pure state also occurs in minable rock bodies of nelsonite and schist. The most important occurrences of rutile are in beach sands, but it is found in nearly all rocks as an accessory mineral and in some rocks is concentrated enough to make them actual or potential ores.

At Tahawus, N.Y., a rock deposit outcrops on the side of Sanford Hill overlooking Sanford Lake in the Adirondack Mountains and is composed of lenticular masses of closely associated magnetite and ilmenite separated by gabbroic and anorthositic waste zones.

Dikelike nelsonite ore bodies at Piney River, Va., contain ilmenite with apatite (calcium fluophosphate) and other gangue materials and are reported to be related to a large anorthosite intrusion approximately 19 miles long by 2 to 6 miles wide. The titanium deposits of the Roseland district, Va., consist of rutile and ilmenite disseminated in a feldspar rock.

The titanium ore body at Richland Cove, Caldwell County, N.C., near Lenoir, is a dikelike intrusion in gneiss and consists of ilmenite and rutile with a micaceous gangue formed of chlorite, talc, and mica. As the rutile occurs as fine crystals within mica, only the ilmenite was recovered in past operations.

The deposits at Magnet Cove, Ark., consist of a complex mixture of igneous, sedimentary, and metamorphic rocks, many of which contain varying quantities of rutile, brookite, and ilmenite. Rutile produced from the deposit contains about 1 percent columbium.

The largest known occurrence of ilmenite in the world has been exploited at Allard Lake, Quebec, Canada. Here the ilmenite is intergrown with hematite in ore consisting of a series of narrow dikes, irregular lenses, or sill-like bodies lying within the anorthosite mass.

In sand deposits rutile and ilmenite usually occur together and may be associated with monazite, zircon, garnet, staurolite, and other minerals of high specific gravity. Titanium and other heavy minerals in Florida sands originated in schists, gneisses, and granites in the Piedmont region of the Southeastern States. The deposits are in the form of beaches, dunes, and ancient terraces. Stream deposits in the form of valley fill and alluvial fans also represent economic sources of heavy minerals in New Jersey and Idaho.

Mining and Beneficiation

The method of mining and beneficiating ilmenite depends upon whether the ore to be mined is a sand or rock deposit.

The beach and raised terrace sand deposits in Florida are mined by dredging. The alluvial deposit near Lakehurst, N.J., is mined by dragline. Both suction and bucket dredges are worked to a depth of about 60 feet. The area ahead of the dredge is prepared for mining by removing all of the trees, stumps, and trash, and at some mines consolidated overburden and ore (hard pan) was broken up by blasting. The sands contain about 4 percent heavy minerals. The proportions of heavy mineral constituents in the concentrates varied, but at one deposit in Florida the concentrate averaged about 40 percent ilmenite, 4 percent leucoxene, and 7 percent rutile. Rough concentration of the heavy minerals is done either on a barge that followed the dredge or on a portable shore plant that moved with the operation. The rough concentrate is piped or hauled by truck to the beneficiating plant. At a typical plant, Humphrey spirals are used in rougher, cleaner, and recleaner stages to produce a heavy mineral concentrate which is dewatered, dried, and separated electrostatically into conductor (titanium minerals) and nonconductor (zircon, monazite, and staurolite) fractions. The titanium fraction is separated on induced-roll magnetic machines into an ilmenite product assaying about 60 percent TiO_2 and rutile product containing about 94 percent TiO_2 (*10*).

Mining of the ilmenite-magnetite rock deposit at Tahawus, N.Y., has been by open-pit methods utilizing electric shovels for loading and 22-ton Diesel trucks for hauling the ore. Drilling in preparation for blasting required the use of a 9-inch bit with the drill holes averaging 39 feet in depth. Optimum height of the benches was 35 feet in depth (*9*). The ore, averaging 18 percent TiO_2, was crushed and ground in a number of stages by a jaw crusher, cone crusher, and rod mill to a minus 28-mesh product. Low-intensity wet-magnetic separators were used to remove a magnetic fraction. The nonmagnetic fraction, containing the ilmenite and gangue, was sized and the ilmenite was concentrated on

reciprocating tables, dried, and upgraded to a 45 percent TiO_2 concentrate on a dry magnetic separator. The magnetite fraction was sintered to make a material suitable for blast furnace feed.

At the Piney River, Va., deposit only the unconsolidated zone of residual weathering which extends to a depth of about 40 feet has been mined in the past. It was only necessary to mine the deposit several weeks each year with a power shovel to develop sufficient feed material for the beneficiating plant. The ore was concentrated and upgraded using Humphrey spirals, then the ilmenite was separated from apatite and gangue in flotation units.

Ilmenite at the Allard Lake, Quebec deposit of Q.I.T., is intimately associated with hematite so that mechanical means of separation cannot be used (*18*). The ilmenite-hematite ore was mined by open-pit techniques, crushed in jaw crusher, and shipped 27 miles by rail to Harve St. Pierre and then 550 miles up the St. Lawrence River to Sorel, Quebec. After crushing and mixing with coke, the ore was fed to electric-arc furnaces. Titanium slag, containing about 70 percent TiO_2, and iron were tapped intermittently from the furnace.

Processing

Titanium tetrachloride is made by the chlorination of a titanium bearing material in the presence of carbon. Both static-bed and fluidized-bed chlorinators are used, but all commercial plants in the United States use the fluid bed. The static-bed chlorinator requires that the feed material be briquetted or sintered before it can be used, while in the fluidized-bed chlorinator the coke and titanium materials are fed directly to the bed. The gaseous titanium tetrachloride that forms in the chlorinating unit is condensed and must be further purified before it can be utilized in making metal or pigment. Purification is usually effected by both chemical treatment and fractional distillation (*4*).

From a technical standpoint, rutile is the preferred raw material for making titanium tetrachloride; however, ilmenite, titanium slag, or products made from these materials, also can be used for this purpose.

Pigment Manufacture

Titanium dioxide of pigment quality is manufactured principally by treating finely ground ilmenite or titanium slag with concentrated sulfuric acid (*23*). All ferric iron present is reduced with iron scrap, so the iron sulfate formed is all in the ferrous state. The titanium is dissolved in water as a basic titanium sulfate, and after selective crystallization of the ferrous sulfate it is precipitated by hydrolysis, filtered, calcined to the oxide, and ground to pigment size. The original titanium dioxide pigments were of the anatase crystal modification, but in 1941 rutile pigments having greater opacity and resistance to chalking and fading were marketed. The rutile pigments also were produced from sulfate solutions by using nucleating agents.

In the chloride process for producing titanium dioxide pigments, titanium bearing materials, mixed with carbon, are chlorinated to produce titanium tetrachloride which is purified and oxidized with air or oxygen to form titanium dioxide. The chlorine is recovered from the oxidation step and recycled. Plants built in the United States since 1958 utilize the chloride process.

Metal Reduction and Fabrication

The commercially pure titanium metal produced in 1963 was made by the sodium or magnesium reduction of titanium tetrachloride. U.S. Industrial Chemicals Co. employed sodium reduction, whereas TMCA used magnesium reduction. In the magnesium reduction process, as developed by the Bureau, purified titanium tetrachloride is reduced to the metallic state in an inert atmosphere of helium or argon. Most of the magnesium chloride formed during the reaction is drained to remove it from the titanium metal and to prevent slowing of the reaction. After the reaction is complete, the reduction vessel is opened, and the mass of sponge is removed by boring on a lathe (*5*, *19*). The sponge has to be further purified to remove magnesium chloride and any residual magnesium metal by either vacuum distillation or by acid leaching (*31*).

In the sodium reduction process, the sodium is added to the reduction vessel as a liquid. The tetrachloride may be reduced in one or more stages, with the sodium chloride being removed after the final reduction. The metal made by this process is in the form of crystals or needles and is purified by leaching with water (*14*).

Electrolytic processes are being developed whereby a soluble titanium compound is electrolyzed in a fused salt bath and titanium is deposited on the cathode. In electro-refining, the metal deposited from the bath is replenished by the electrolytic dissolution of a titanium bearing anode. In electrowinning, the deposited metal is replenished by adding titanium compounds to the bath (*13*, *19*, *22*).

Major requirements for producing 1 pound of titanium sponge metal are approximately 2.5 pounds of rutile (or some other titanium material of equivalent TiO_2 content), 5 pounds of chlorine, 1.25 pounds of magnesium (or 2.5

pounds of sodium) and about 0.9 cubic foot of inert gas. If the magnesium or sodium chloride which is formed in the reduction reaction are processed to recover the metals and the chlorine, about 0.2 pound of magnesium or 0.4 pound of sodium, and 1 pound of chlorine are required. Power requirements vary from 6 to 15 kilowatt-hour per pound of sponge. The larger power requirement includes that consumed for recovering the reductant metal and chlorine.

Plant costs for producing ductile titanium metal, under 1951–54 technology, when government contracts were let, were very high. Estimates made for rapid tax amortization purposes ranged from about $15 million for a 2,700-short-ton-per-year facility to $31.5 million for a 7,500-ton-per-year facility. The average cost per annual ton of capacity was over $4,100, compared with a cost of about $1,000 to $1,500 per ton of annual capacity for aluminum.

Having produced sponge, it is necessary to carry the process further to achieve useful metal forms. Although titanium ingots can be produced by powder metallurgy techniques, nearly all commercial metal is produced by the double consumable electrode-arc melting process in an inert atmosphere or vacuum (*6*, *7*, *15*). The power requirement to produce 1 pound of titanium ingot is about 2 to 2.5 kilowatt-hours.

Titanium in the molten state has a great affinity for all gases, except the noble gases, and reacts with all known refractory materials. In addition, due to minor inclusions of salts and reductant metal, it may froth or spatter as it melts. For these reasons, to produce a contaminant-free metal, titanium is melted in a cold-cup crucible, normally of water-cooled copper. Electrodes may be of tungsten or carbon, but the industry has now converted almost wholly to the use of "consumable" electrodes, or electrodes of titanium. Use of a vacuum in the melting vessel assists in removal of dissolved hydrogen, which embrittles the metal.

In practice, the titanium sponge is compacted, with scrap metal and alloy constituents when desired, and electrodes are formed of one or more compacts; inert-atmosphere welding is used to join the compacts. The electrodes are arc-melted into a first melt ingot, which becomes the electrode for a second ingot. This double melting process, pioneered by the Bureau for zirconium and later used for titanium, insures alloy homogeneity and ingot soundness, and actually improves the yield of metal products from sponge, since the losses in forging and rejections for other reasons are reduced. The final ingot in some plants was up to 30 inches in diameter and weighed up to 8,500 pounds. Upon final conditioning by machining or by sidewall fusion, the ingots can be hot-worked by forging, extrusion, and blooming. Billets or slabs are then processed into plate, sheet, strip, bars, rods, forgings, tubes, wire, or special shapes.

Most alloy sheets are hot-rolled between steel sheets on hand mills; however, continuous hot-strip mills, Sendzimir cold rolling equipment, and vacuum annealing furnaces for processing titanium were expected to be in operation in 1964. Brake pressing and hot sizing are the most common forming methods used with titanium. Most metal removal is done with conventional machine tools, but tools must be kept sharp to avoid overheating and other good machining practices must be observed. Virtually all joining is done with Tig (trailing inert gas) methods using argon and simple shields, such as plastic bags or aluminum foil.

Complex shapes such as gate and globe valves can be cast entirely of titanium by a process developed by the Bureau (*1*, *8*). In this process the melting furnace and mold must be enclosed in a vacuum compartment to prevent contamination by gases. Both bottom-pour and tilting furnaces have been employed. Either type may utilize the skull crucible, which is so named because metal is first melted in a cold cup crucible and after the first pour a skull of solid metal is left which does not remelt in subsequent pours. Molds for titanium casting must be nonreactive and free of contaminating gases. Carbon or graphite appear to offer the most promise for industrial use.

Preparation of Welding-Rod Coatings and Other Products

Although ilmenite, slag, or manufactured TiO_2 may be used as a source of titaniferous material in welding-rod coatings, rutile is considered to be the most desirable material for this purpose and is required for certain coatings.

At one time the rods were coated by dipping them in a slurry of the coating compound; however, the rods and coatings are now extruded from a press. The ingredients are mixed in the form of slurry, then pressed into cylindrical slugs about 18 inches long and 10 inches in diameter. These slugs are put into the extruding press and the cut welding-rods, fed into the coating die, and coated to a uniform thickness by the extruded flux. The rods are dried and then fired at 1,175°.

The three major grades of master alloys of titanium with iron made for use as iron and steel additives are high-, medium-, and low-carbon ferrotitanium.

High-carbon ferrotitanium, containing 7 to 8 percent carbon and 15 to 17 percent titanium is

made by reducing ilmenite with coal or coke in a single-arc electric furnace employing a high-current density. Medium-carbon ferrotitanium containing 3 to 5 percent carbon and 16 to 20 percent titanium is made in the same fashion as low-carbon except that some rutile is added to the feed. Low-carbon-master alloys have 0.03 to 0.1 percent carbon, 20 to 45 percent titanium and are made by the aluminothermic reduction of ilmenite and rutile.

In addition, titanium scrap or offgrade sponge may be used as an alloying ingredient for steel.

Titanium carbide may be prepared by heating a mixture of rutile or manufactured TiO_2 and carbon to above 3,270° F in a vacuum or in an atmosphere of hydrogen. In one commercial process titanium dioxide, iron, and carbon are induction-heated in a graphite crucible to over 4,800° F to effect a carburization in solution. When all of the material has reacted, it is cooled and the button formed is broken up and treated chemically to remove the iron.

USES

About 99 percent of all the ilmenite consumed in 1963 and in several preceding years went into manufacturing titanium dioxide for pigments. The remainder of the ilmenite was used in making non-titanium-base alloys, carbide, welding-rod coatings, and titanium metal.

In 1963, about half of the reported consumption of rutile was for making metal and about half was for welding-rod coatings. The remainder was used for non-titanium-base alloys and carbide, and for ceramics, fiber glass, and chemicals. A significant quantity also was used for making titanium pigments, but the actual figures cannot be reported.

Titanium slag was used mainly for titanium pigments with a minor quantity being utilized in welding-rod coatings.

Since its introduction in 1916, manufactured titanium dioxide has found an expanding market in the production of paints, lacquers, plastics, paper, floor coverings, rubber, coated fabrics, textiles, and other products. The high opacity and chemical inertness of white titanium dioxide permit it to be used in almost every variety of plastic material, resin, and molding powder, except urea and thiourea mixtures. Its resistance to erosion by lactic and acetic acid makes it particularly desirable in celluloid plastics that are often treated with acetic acid, and casein, which usually contains residual lactic acid. When used as a pigment in rubber a small quantity of titanium dioxide gives a high degree of whitening, with the result that most of the desirable natural properties of the rubber can be retained.

As an opacifier in paper, the pigment is about 10 times as effective as the ordinary fillers and improves the color, brightness, and printing surface. Its properties also favor its use as a delustrant in the production of rayon.

Chemical inactivity is an important characteristic of the compound. It may be used with virtually all types of reactive vehicles; it is not discolored by most gases that may be present in the atmosphere; it does not discolor on exposure to sunlight; and it is not affected by extremes of temperature. Titanium dioxide is resistant to alkaline, acid, and saline solutions and may be used as the pigment in chemical-resistant paints of many types. It is compatible with other white and colored pigments.

Manufactured titanium dioxide also is used in welding-rod coatings, ceramics, fiberglass, and in making titanium gems.

Titanium metal has been suggested for many applications, but its major use in 1963 was for military airplanes in the airframe and powerplant. Titanium was used by airframe producers in firewalls, skin, landing-gear components, hydraulic tubing, shrouds, oil and fuel tanks, nacelle structures, fasteners, and engine supports. The major use of titanium in aircraft powerplants, such as the Pratt and Whitney J–57 engine, was in compressor disks and blades; compressor housing, and retaining rings. Fasteners also were fabricated from titanium. Producers of civilian aircraft also used titanium for similar applications to those in military craft. Commercial jet transports built in 1963 reportedly used 700 to 2,500 pounds of titanium in each airplane.

Titanium was reported to be a basic material for America's supersonic transport (SST). The SST was expected to fly at speeds between mach 2.2 and mach 3 (1,500 to 2,000 miles per hour) and use 15 to 50 tons of titanium per plane.

Titanium used in missile and space components represented about one-third of the total consumption. The Mercury spacecraft used in America's first manned orbital flight series was made largely of titanium. A double shell of the metal, supported by titanium rings and stringers was used. Titanium also was being put to wide use in the Gemini two-man spacecraft planned for the next series of manned orbital flights. The tricycle landing gear, the pressurized compartment for the crew, various pressure vessels, and the solid-fuel cases for the retrorockets were expected to be made largely of titanium and its alloys. Tankage and other components of titanium were expected to be utilized in the Lunar Excursion Module scheduled to land on the moon. Solid rocket motors, tanks, and other components for a new upper-

stage booster for the Titan III launch vehicle were being built of titanium.

Other industrial applications for titanium in the chemical and electrochemical industries represented only about 4 percent of the total market in 1963, but the base was expanding rapidly. About 50 percent of the titanium tubing employed in the process industries was for cooling wet chlorine. Other uses included anodizing racks, chlorine dioxide mixers, and pulp and paper processing equipment. Titanium was used in solutions of sodium hypochlorite, chlorate, nitric acid, sulfuric acid, and brine. Cast titanium parts such as gate and globe valves became available in 1958.

Titanium covered with a thin film of platinum is reported to be suitable for anodes in extremely corrosive solutions and as efficient as platinum at a much lower cost.

Alloys of titanium with iron, particularly ferrocarbontitanium are used in steelmaking and as an addition in cast irons. Titanium, formerly used mainly as a deoxidizer, has assumed considerable importance in the manufacture of stainless steels as a carbon- and nitrogen-stabilizing element to inhibit intergranular corrosion.

The outstanding characteristics of titanium suggests numerous other uses. These include surgical instruments, orthopedic appliances, X-ray tube targets, and textile machinery.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Rutile and ilmenite in sand deposits may be associated with zircon, monazite, garnet, staurolite, and other heavy minerals of high specific gravity. Most deposits are mined chiefly for rutile and ilmenite, and one or more of the associated minerals are recovered as byproducts; however, in some instances the titanium values are of secondary concern. For example, mining operations in Idaho were primarily for monazite, and ilmenite was recovered as a byproduct. In Malaya, ilmenite is recovered from a tailing product from tin dredging operations.

Monazite, staurolite, and zircon are coproducts of titanium mining operations in Florida. Rutile and zircon are recovered as coproducts in Australian mining operations.

ALTERNATE MATERIALS

Possible source materials other than rutile for producing titanium metal include manufactured titanium dioxide, ilmenite, and titanium slag. Manufactured titanium dioxide, which is made from ilmenite or slag, could be chlorinated readily to produce titanium tetrachloride, but manufactured titanium dioxide costs more than rutile. There are many difficulties in the chlorination of ilmenite. A large quantity of chlorine is consumed to chlorinate the iron in the ilmenite, and the iron chlorides produced have little value. Also larger chlorinating plants must be employed to produce the same amount of titanium tetrachloride from ilmenite as could be produced by a smaller plant using rutile. Aside from these economic considerations, the use of ilmenite in chlorinators presents technical problems.

The main difficulty in chlorinating commercial titanium slag has been that the magnesium and calcium compounds in the slag form a pasty mass which clogs the reaction bed. Manganese in a slag has somewhat the same effect. Other chlorine consumers in slag increase chlorine consumption over that needed for rutile with a concurrent cutback in output of $TiCl_4$. Higher grades of titanium slag will probably minimize these chlorination problems.

Ground titanium slag can be substituted for as high as 25 to 30 percent of the rutile used in welding-rod coatings and manufactured titanium dioxide can be used in some coatings if it is reprocessed to give a satisfactory particle size. However, according to the welding-rod producers there are some coatings which rutile must be used.

Manufactured titanium dioxide could be substituted for other uses of rutile, with an increase in the titaniferous raw material cost.

Selection of titanium metal over other materials of construction normally is made on a performance versus economics basis. High-strength steels, aluminum, or other metals may be substituted for titanium in many structural applications, but such substitution usually necessitates redesign and results in lower performance. In applications where titanium's corrosion resistance is a deciding factor, other metals such as stainless steel, Hasteloy, and certain nonmetals may be used, but these are often more expensive than titanium when downtime and replacement costs are considered.

SECONDARY SOURCES AND RECOVERY

About 1.25 pounds of sponge are needed to make 1 pound of mill product and in some fabricating operations, 8 pounds of mill product may be required to produce 1 pound of finished product. The excess material is scrap for which there has been a limited demand because there is enough contaminating material in the scrap to raise the hardness and brittleness of the remelted metal. Before 1954 most

of the scrap produced was accumulated as inventory, and this loss to the fabricator increased the price of the finished product.

From 1954 to 1963 the use of scrap increased as the hardness of the primary sponge decreased. In 1963, the companies that melt titanium were using 5 to 45 percent scrap in most of their melts, and in some instances ingots were made entirely from scrap.

About 50 to 60 percent of the titanium scrap generated and received by melters is remelted with sponge metal and alloying ingredients into ingot. In recent years most of the remainder has been exported, but substantial quantities are sold for various miscellaneous uses in making steel and in the chemical and electrochemical industries.

At the end of 1963 melters had 3,400 tons of titanium scrap in inventory, compared with 2,200 tons of scrap which they consumed in 1963. Additional scrap was held by farbicators and scrap dealers. A large percentage of this material was probably alloy scrap rather than commercially pure scrap. Alloy scrap has limited use due to the difficulties in sorting into various grades.

RESERVES

Ilmenite resources in rock and sand deposits in the United States, recoverable under 1963 technological conditions, are estimated to total 100 million tons. Rock deposits in New York and Virginia, containing 7 to 20 percent titanium dioxide, comprise about half of the total. The remainder is in beach sands in Florida, New Jersey and Georgia, which contain 1 to 2 percent titanium dioxide. An additional potential resource of 100 million tons of ilmenite which is not recoverable under present technological and economic conditions is found in rock deposits in California, Colorado, Minnesota, Montana, New York, Rhode Island, and Wyoming; in the ferruginous bauxite deposits of Oregon; and in sand deposits in Oklahoma.

Most of the economically recoverable resource of rutile in the United States is in sand deposits in Florida, South Carolina, and Georgia, and in rock deposits in Virginia. Little is known of their size but they probably approach 1 million or 2 million tons of contained rutile. Rock deposits in Arkansas and Virginia may contain an additional 500,000 tons of rutile which is not recoverable under present technical and economic conditions.

Titanium resources of the world were estimated to total about 2 billion tons in 1955 with a TiO_2 content of 216 million to 265 million tons. Of this quantity, the TiO_2 content of U.S. resources was 49 million to 64 million tons, or about 25 percent of the total, and the TiO_2 content of Canadian resources was 38 million to 72 million tons, or roughly 25 percent of the total. These resources included ilmenite and rutile in both commercial and submarginal deposits (*21*).

Countries having significant resources of ilmenite, recoverable under present technical and economic conditions, included Canada, India, Norway, Australia, Finland, Malaya, and the United States. Ilmenite resources in Canada, Norway, Finland and about half of those in the United States are in rock deposits. Recoverable titanium resources in the other countries are in sand deposits. Principal rutile resources, recoverable under present technological and economic conditions were in Australia, Sierra Leone, and the United States.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines collects and publishes data on many phases of the titanium industry. Data on production, shipments, producer's stocks, and value of ilmenite and rutile concentrates are collected and published annually. Consumption and consumer stocks of ilmenite, rutile, and titanium slag also are collected and published annually.

About 35 dealers and importers of titanium ores are canvassed by the Bureau, and stocks of titanium materials held by these companies are published annually.

Production, shipments, and stocks of titanium dioxide pigment are reported annually to the Bureau by the producers of titanium dioxide. The Bureau publishes annually the percentage change in production and shipments of titanium dioxide pigments on a gross weight basis as well as the percentage distribution of shipments of pigment by end uses. The Bureau of the Census and the Business and Defense Services Administration (BDSA) collect and publish jointly the titanium dioxide content of titanium pigments produced and the stocks held by producers on a monthly basis.

Under a cooperative agreement between the Bureau of Mines, the Bureau of the Census, and Business and Defense Services Administration, monthly data are collected on the following:

consumption and stocks of titanium materials used in the production of titanium metal; titanium sponge metal production, consumption, and stocks; and titanium ingot and mill product production. The Bureau of Mines publishes quarterly data on all phases of the titanium metal industry except those concerning mill products which are published jointly by the Bureau of the Census and BDSA on a monthly basis.

The Bureau of the Census obtains monthly information on imports and exports of titanium materials including metal. The Bureau of Mines publishes import-export data on titanium materials on an annual basis.

PRODUCTION, CONSUMPTION, AND TRADE

Production

Production of ilmenite and rutile by various countries during 1954–63 are given in tables 1 and 2. The United States has been the world's largest producer of ilmenite since 1942 when disruption of seaborne imports from India made development of sources within the United States essential. Ilmenite production in Canada since 1950 includes production of titanium slag. Australia has been the world's largest producer of rutile since 1941 and accounted for 93 percent of the 1963 world total; the United States produced most of the remainder.

Statistics on the gross weight of titanium dioxide produced in the United States are not published, but the magnitude of the industry may be gaged by the data in table 3 on the titanium dioxide content of the pigments produced.

The United States has been the leading titanium metal producer in the free world since the industry was established and in 1963 produced about 80 percent of the total output. Japanese production of titanium metal has been chiefly exported to the United States, and England's output is used in its own economy. Data on world production of titanium sponge metal are shown in table 4.

Consumption

Consumption of ilmenite and titanium slag, and rutile in 1962 and 1963 is shown in tables 5 and 6. Virtually all the ilmenite consumed is used in producing titanium pigments, and most of the titanium slag also is used for this purpose. Significant quantities of ilmenite and slag are used in welding-rod coatings. The major use of rutile in the past has been in producing welding-rod coatings, and the major peaks in the consumption of rutile for welding-rod coatings have occurred during war years. Rutile used in producing titanium metal and pigment has assumed major proportions in recent years. Data on the use of rutile in making pigment are not published to avoid disclosure of individual company data.

TABLE 5.—*Consumption of ilmenite and titanium slag in the United States*

[Short tons]

Product	Ilmenite [1]		Titanium slag	
	Gross weight	Estimated TiO_2 content	Gross weight	Estimated TiO_2 content
1962:				
Pigments (mfg. TiO_2) and titanium metal	941,954	499,471	137,576	98,195

Total	874,986	459,506	152,416	108,645

[1] Includes a mixed product containing ilmenite, leucoxene, and rutile.
[2] Included with miscellaneous.

The consumption pattern for titanium pigments is shown by the distribution of shipments to various consumers. In 1963, titanium pigments, based on gross weight, were distributed by shipments from producers as follows: Paint, varnish, and lacquers, 63.3 percent; paper 12.5 percent; floor coverings (linoleum and felt base), 4.3 percent; rubber, 4.0 percent; plastics (except covering and vinyl-coated fabrics and textiles), 2.9 percent; roofing granules, 2.1 percent; coated fabrics and textiles (oilcloth, shade

[1] Does not include rutile used in making titanium pigments.

cloth, artificial leather, etc.), 2.0 percent; printing ink, 1.6 percent; and ceramics 1.2 percent. In addition, 6.1 percent of the shipments were for export and to miscellaneous industries for use in welding-rod coatings, leather products, and shoe dressings.

Domestic consumption of titanium sponge metal and ingot is given in table 7. The estimated end use distribution of titanium metal is given in table 8.

Trade

Table 9 shows imports of ilmenite and rutile by country of origin. In 1952, Canada became a major external source of titaniferous material, and the United States began importing titanium slag from that country. Most of the imports of ilmenite from Canada since 1951 were in the form of slag. Almost all of the imported rutile was from Australia.

[1] Data based on industry estimates.

The first substantial quantity of crude titanium metal imported into the United States was from Canada (500 pounds) and France (44 pounds) in 1952. The value of the metal imported that year was $2,500. In 1953, the United States imported 10 pounds of crude metal from Canada and 71,299 pounds from Japan having a total value of $269,259. Since then Japan has become the major source of titanium imported in the United States, and virtually all of the imported metal reported in

[1] Less than 1,000 short tons.

table 7 came from Japan. Prior to 1963, much of the metal imported from Japan was brought in under barter agreements between Commodity Credit Corporation and Japanese producers and was placed in the supplemental stockpile.

Before 1958 imports of titanium dioxide pigment varied substantially from year to year, depending chiefly on domestic demand. However, they steadily increased from 40 tons in 1957 to 25,000 tons in 1963. The chief sources of imported pigment in 1963 were France 4,900 tons; Japan 5,100 tons; Finland 8,900 tons; and Italy, West Germany, and Spain supplied most of the remainder.

Export data for titanium products are given in table 10. Canada has for many years received most of the titanium products exported from the United States. Exports of titanium dioxide and pigments have declined in recent years, owing to construction of pigment plants in Canada.

Tariff

The tariff duties on imports of various titanium minerals and metals, effective at the end of 1963, were as follows:

Item	Rate of duty, Aug. 31, 1964	Statutory rate of duty
Titanium ore (including ilmenite and ilmenite sand).	Free	Free.
Titanium ore (including rutile and rutile sand).	do	Do.
Titanium dioxide and pigments	15 percent, ad valorem.	30 percent, ad valorem.
Titanium salts	do	Do.
Titanium metal (unwrought, and waste and scrap).[1]	20 percent, ad valorem.	25 percent, ad valorem.
Titanium metal (wrought)	18 percent, ad valorem.	45 percent, ad valorem.

[1] The duty on waste and scrap was suspended to June 30, 1964.

STRATEGIC CONSIDERATIONS

Figures 1 and 2 show domestic production, imports, and consumption of ilmenite and rutile from 1941 to 1963 and graphically illustrate the degree of self-sufficiency of the United States in these minerals. The increasing trend toward greater self-sufficiency in ilmenite after 1957 is caused by declining imports of titanium slag from Canada and ilmenite from India, coupled with higher domestic production.

The United States has become progressively more dependent upon Australia for its supply of rutile. In the event of a war, the North American Continent could probably become almost self-sufficient in titanium minerals, inasmuch as ilmenite and possibly titanium slag could be substituted for rutile in the production of titanium metal.

About 90 percent of the titanium metal used in the United States is used in defense and space applications. Annual domestic capacity for production of titanium sponge metal in 1963 was about 14,000 tons, but with the 1964 closing of the Du Pont plant, capacity will drop to about 10,500 tons, compared with the 8,900 tons consumed in 1963. Of the total new supply of titanium sponge metal in 1963, 16 percent was imported, chiefly from Japan.

GOVERNMENT PROGRAMS

Through the Office of Minerals Exploration (OME) in the Department of the Interior, the Government loans up to 50 percent (limited to $250,000 for any one contract) of the costs of exploration for rutile.

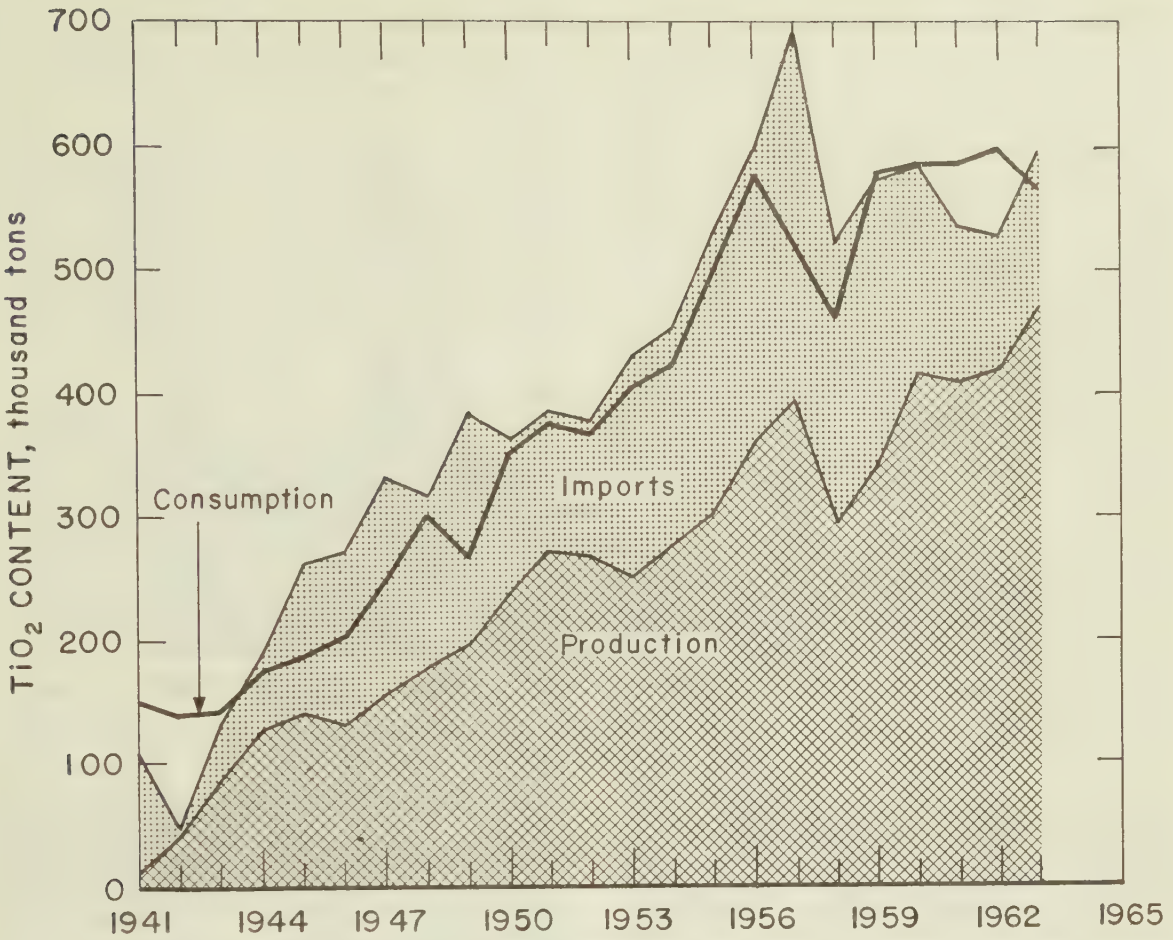

FIGURE 1.—Domestic Production, Imports, and Consumption of Ilmenite (Includes Titanium Slags and Mixed Product).

The Defense Production Act of 1950, as amended, provided authority to develop the productive capacity of the domestic economy to a level sufficient to meet existing demand and to provide a basis for full mobilization in event of a defense emergency. Titanium metal, however, was in an extremely rudimentary stage of development, and the setting of relatively high expansion goals practically required the establishment of a whole new industry. Various agencies concerned utilized nearly all the expansion aids available. Expansion incentives employed included advancement of funds and commitments to purchase output; accelerated tax amortizations; grants for research and development; and revolving inventory funds.

Overall responsibility for the titanium expansion program rested in the Office of Defense Mobilization; however, other government agencies were delegated to handle various operational functions of the program.

The first expansion goal for titanium sponge was set in March 1951 with an initial goal of 7,200 tons. By 1954, this was expanded to 35,000 tons per year. In September 1955, the sponge goal was reduced to 22,500 tons, which was the capacity already contracted for, and the goal was accordingly suspended.

Rutile was the only titanium mineral included in the National Stockpile List of Strategic and Critical Materials in 1963, and no other titanium minerals have been purchased by the Government for stockpiling purposes.

Titanium sponge metal was acquired by the Government from domestic producers through Defense Production Act contracts and from Japanese producers in exchange for surplus agricultural products through the barter program, administrated by the Commodity Credit Corporation (CCC), Department of Agriculture.

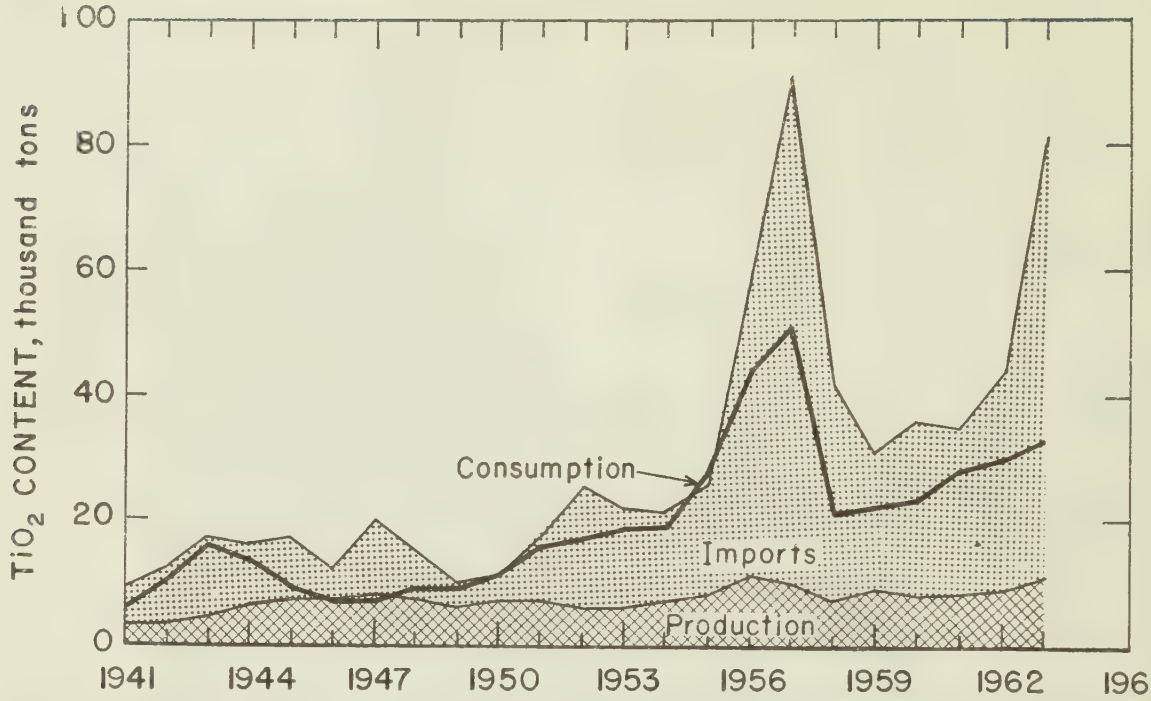

FIGURE 2.—Domestic Production, Imports, and Consumption of Rutile (Excluding That Used in 1961 Through 1963 for Making TiO_2 Pigment).

On June 30, 1964, government inventories of rutile totaled 47,600 tons, of which 18,600 tons was in the national (strategic) stockpile, 17,400 in Defense Production Act stocks, and 11,600 tons in the supplemental stockpile. In addition, stocks of titanium sponge totaled 31,400 tons, of which 22,400 tons was in DPA stocks, and 9,000 in the supplemental stockpile.

PRICES

The average year-end prices for ilmenite and rutile, which were Government-stabilized during World War II at $29 per long ton and $180 per short ton, respectively, declined to $15 per long ton and $80 per short ton by 1950. In the early 1950's increased demand for ilmenite for making pigment and new requirements for rutile for making titanium metal resulted in price increases to $20 per long ton and $250 per short ton by 1955. The decrease in rutile requirements for metal in the late 1950's caused the price to drop to the 1950 level by 1959. However, increased demand for rutile for making chloride pigment which started in 1958 caused the price to rise to $104 per short ton by 1963. Ilmenite prices rose from the 1955 level to $28 per long ton, then declined to $24.50 per long ton in 1958, the price which was in effect at the end of 1963.

The price of titanium sponge has decreased significantly since 1954. In 1948 commercial titanium sponge sold for about $5 per pound. At the end of 1963 prices quoted for various grades of titanium sponge metal ranged from $1.27 to $1.60 per pound.

Prices of titanium mill products also have shown a steadily decreasing trend, and averaged base prices for commercially pure sheet have ranged from $15 to $20 per pound in 1950 to $4.90 to $5.10 per pound at the end of 1963. Prices per pound quoted for titanium mill products f.o.b. mill, commercially pure grades in lots of 10,000 pounds were as follows:

Sheet	$4.90–$5.10
Strip	4.90– 5.10
Plate	3.80– 4.00
Wire	3.50– 3.80
Forging billets	2.40– 2.55
Hot-rolled bars	3.15– 3.35

Prices of titanium pigment have increased from the Government stabilized price of 14½ to 16½ cents per pound for anatase and rutile grades during World War II to 25½ to 28½ cents per pound at the end of 1963. Calcium-rutile base pigments containing about 30 percent TiO_2 increased from 5½ cents per pound to 9⅞ cents per pound during the same period. The half-cent-per-pound price differential on shipments of one company's titanium pigment to users west of the Rocky Mountains was eliminated in 1963. Some reductions of the

base prices was given to purchasers of large lots.

The following prices were quoted in the Oil, Paint and Drug Reporter at the end of 1963:

	Price
Anatase, Chalk-resistant, regular and ceramic, carlots, delivered, per pound	$0.25½
Less than carlots, delivered, per pound	.26½
Rutile, nonchalking, bags, carlots, delivered East, per pound	.27½
Less than carlots, delivered East, per pound	.28½
Titanium pigment, calcium-rutile base, 30 percent TiO_2, bags, carlots, delivered, per pound	.09⅜
Less than carlots, delivered, per pound	.09⅞

TAXES

The Internal Revenue Code of 1954 included for the first time a depletion allowance for ilmenite. The code states that for Federal Income Tax purposes the allowance of deduction for depletion of ilmenite, rutile, and other ores containing titanium, mined from deposits in the United States, was 23 percent of the gross income providing that this was not greater than 50 percent of the net income from the property.

RESEARCH

Studies to improve the recovery of titanium minerals from ores have emphasized development of electrostatic and flotation processes. A substantial amount of research has been directed toward development of economic methods to produce a product from ilmenite having a high titanium dioxide content that can be chlorinated as easily as rutile. These studies have centered on pyrometallurgical techniques (*3*, *12*) and acid leaching processes at high pressures and temperatures. Direct chlorination of ilmenite has been studied by the Bureau (*24*, *25*).

Development of the chloride process for making titanium pigment has led to increased industrial research to improve the purity and grain size distribution of pigment made by the sulfate process.

Titanium metal has been produced commercially only since 1948, and a large number of research and development projects by government, industry, universities, and private institutions have attempted to solve the many problems encountered in the production and use of the metal. The Bureau was instrumental in interesting private industry in the metal and in helping to solve many of the production and processing problems involved in its manufacture. The Bureau's publication Material Survey, Titanium, (*21*) contains a detailed discussion of the extensive research and development program of Government and private industry through 1954. Since that time research has focused on improvements in the commercial process using magnesium or sodium to reduce titanium tetrachloride (*19*) and development of electrorefining and electrowinning processes (*13*).

Direct reduction of titanium ores to titanium metal using carbon, calcium, magnesium, aluminum and other reducing agents has been studied by many investigators. With the exception of calcium reduction, these processes have yielded an impure metal product which has to be further refined to produce pure titanium.

Titanium semifabricators and about 60 fabricating firms, which include airframe and jet engine manufacturers, conduct the major research projects on producing end-items of titanium metal. Projects underway in 1963 included studies on methods of vapor deposition, and cladding of titanium, adhesive bonding, and high-energy rate forming.

Emphasis in the Bureau titanium research program was on fused salt electrowinning processes. Other studies by the Bureau included investigations of mineral resources, mineral dressing techniques, extractive processes, analytical methods for high-purity titanium, thermodynamic properties, and development of melting and casting techniques.

OUTLOOK

Titanium resources in rock deposits are far greater than in sand deposits. However, about half of the world's titanium mineral output comes from sand deposits. This 50–50 relation of the sources of titanium minerals probably will continue for many years because the quality of titanium minerals which can be recovered from sand is higher and mining costs are lower; however, the long-range trend is toward fuller utilization of the more plentiful rock deposits. One or more of the large rock deposits of titanium minerals in Colorado, Wyoming, Arkansas, Rhode Island, or Virginia may be developed commercially before the 1980's. Additional sand deposits may be developed in the Pacific Northwest, Oklahoma, and the Southeastern States.

Australia, Canada, and India probably will continue to supply about 25 percent of the domestic demand for ilmenite and titanium slag; however, in an emergency the entire demand could be met by domestic and Canadian sources.

780-887 O—65——63

It is likely that the United States will become increasingly dependent on Australian and African sources for rutile.

The average annual rate of increase in demand for titanium dioxide pigment in the United States during 1950–63 was almost 5 percent. This growth rate is expected to continue through 1980, resulting in requirements for about 800,000 tons of titanium dioxide in 1970 and about 1.2 million tons by 1980. The relative importance of imported material, which represented 4.5 percent of the total new supply in 1963, is expected to increase to about 8 percent of the total supply by 1970, and 15 percent by 1980. Thus the TiO_2 content of titanium materials required in the United States for pigment manufacture would be approximately 850,000 tons, and 1.1 million tons, respectively, in 1970 and 1980, assuming a 90 percent recovery of TiO_2 from all raw material sources.

It is expected that industry development of the chloride process for making titanium dioxide pigment by oxidation of titanium tetrachloride will continue to expand. From a technical standpoint rutile is the preferred raw material for making the tetrachloride, but because of its relative scarcity, ilmenite and titanium slag also may be used for this purpose.

Projected demand in thousand short tons for the various titanium raw materials for pigment production is as follows:

	1963	1970	1980
Ilmenite	873	1,100	1,100
Titanium Slag	152	185	300
Rutile	(1)	170	340

[1] Figure withheld to avoid disclosing individual company confidential data.

It is likely that ilmenite or titanium slag will be used in the chloride process by 1970 and is almost certain that they will be used by 1980. This would increase the estimates for ilmenite and titanium slag and decrease the estimates for rutile.

The pattern of consumption of titanium material in welding-rod coatings in past years indicates that this use will continue to increase at about the same rate as the national economy and will require about 23,000 tons of rutile annually by 1970 and about 35,000 tons by 1980. During periods when rutile is in short supply, which may occur as demand for making titanium tetrachloride increases, ilmenite, titanium slag and manufactured TiO_2 will be used to some extent in place of rutile in welding-rod coatings.

Miscellaneous uses of titanium compounds such as alkali titanates and titanium borides, carbides, chlorides, and organics in the chemical, electrical, and machine tool industries should expand at about the same rate as the national economy.

The large research effort to develop materials of construction for aircraft and spacecraft, underwater vehicles, and use in the chemical industries, indicates that titanium metal has a bright future. Titanium's lightweight, high strength, and corrosion resistance has made it a highly desired material in the space industry; in supersonic transports (SST) and other high performance aircraft; in deep diving submarines; and in chemical equipment used in highly corrosive media.

The relatively short history of the titanium metal industry, which was considerably influenced by government programs in the early stages of development, provides little basis for projecting its future use. However, it is significant that despite the marked decline in demand for titanium sponge metal following the curtailment of the manned military aircraft program in the mid-1950's and cessation of the Government's purchasing program for the metal in 1958, the average growth rate of the industry from its start in 1948 to 1963 was about 15 percent per year. During 1959–63, the growth rate was about 20 percent per year, chiefly because of expanding applications in high-performance airplanes, missiles, and spacecraft.

Use of titanium metal in the rapidly growing space industry is expected to continue at an increasingly higher rate; however, it may be that large numbers of spacecraft will not be necessary for many years. Consequently, the rate of increase in this application may level off or even decline in the 1970's when the range of development problems under study may not be as broad as in 1963. Conversely, the effect of many of the potentially large uses of titanium such as those anticipated in the SST program and underwater craft, which were in early development stages in 1963, is not likely to be fully realized prior to the 1970's.

Industry estimates of the future growth of titanium metal demand range from 10 to 15 percent per year. It seems probable that the lower rate will apply to 1970, resulting in demand for about 17,000 tons of sponge metal in that year. Inasmuch as chemical uses should continue to grow and some potentially large uses may not materialize until the 1970's, it is estimated that the higher rate would apply after 1970 resulting in demand for about 70,000 tons in 1980. Requirements for rutile, or some other titaniferous material of equivalent TiO_2 content, would be about 34,000 and 140,000 tons, respectively, in 1970 and 1980.

PROBLEMS

Expansion of the pigment and other segments of the titanium industry requires development of sources in sand or rock deposits and efficient methods of mining, recovering and upgrading the titanium values. The rock deposits have a higher titanium content than sand deposits and usually are larger, but the mineralization is considerably more complex. Utilization of many titanium deposits is complicated by the presence of vanadium, chromium, manganese, columbium, or tantalum in the titanium minerals. No method has been developed in the United States to use titanium minerals such as sphene, perovskite, and ulvospinel which are abundant in several large rock deposits.

Mining problems encountered in developing the rock deposits of titanium minerals are those common to open-pit bench mining in both altered and unaltered feldspathic rock. Owing to the hard and abrasive nature of the overlying rock at one mine, and overburden to ore ratio of only 1½ to 1 can be handled. The attitude of the deposit is such that the minable depth is thus limited to about 600 feet. Tests at this mine also have demonstrated a need for information on rock fragmentation, especially as related to blasting pattern. Dredging or drag-line excavating of the sand deposits, which normally are substantially lower in grade than the rock deposits, necessitate the handling of large quantities of abrasive sands. Large quantities of clay and other slime forming materials present in some sand deposits create a problem of expansive treatment and disposal or storage.

Enough rutile may not become available to meet the expanding demand for titanium tetrachloride for titanium pigments and metal. Therefore, economic processes need to be developed for chlorinating ilmenite or for making a high TiO_2 content product that is suitable for chlorination or for use directly as a pigment. If chlorination of ilmenite or other high iron materials is to become commercial, a use for the byproduct iron chloride must be found. A similar problem is encountered in the production of TiO_2 by the sulfate method—only part of the iron sulfate byproduct is utilized and the remainder constitutes an expensive waste and disposal problem.

High production costs of titanium metal stem from the fact that it must be made from very pure substances under carefully controlled conditions. The Kroll process, which is currently used, is a batch process, and although many improvements have been made it is unlikely that the method can be made continuous. Research indicated that the electrolytic process may be adaptable to continuous operation; however, numerous problems remain to be solved. For example, molten titanium cannot be obtained electrolytically, nor have suitable processes for electroplating the metal been developed. The metal is deposited as crystal, necessitating periodic cathode removal and replacement in an inert atmosphere and reclaiming of entrapped carrier salt. Moreover, the highly reactive titanium salts cause serious corrosion problems. Further complications result from the necessity to separate the anode and cathode compartments. These problems, coupled with the need for devices for continuously adding the feed and changing cathodes under a controlled atmosphere necessitate a complicated cell design.

To utilize titanium it must be melted under vacuum or an inert atmosphere. Its high chemical reactivity also complicates the selection of refractory materials for crucibles and molds, and this is a major deterrent to development of efficient melting and casting processes.

The problems in fabricating titanium can for the most part be traced to its unusual flow characteristic. More energy is required to form titanium than most steels. Excessive springback makes it difficult to cold form titanium to specifications. Some of the high-strength alloys must be formed while hot and have to be protected during the operation. Anisotropy is a problem with certain titanium alloys.

The upper limit of the serviceability of titanium alloys is about 600° C. To achieve maximum advantage of titanium in design of airplanes and spacecraft this thermal limit must be raised. In addition, sheet alloys are needed in thin gages and larger sections than have hitherto been available. Other important potential applications will require the joining and forming of large sections of titanium plate, which are difficult or impossible under present technology.

Engineering data on corrosion properties and in-plant performance of titanium are needed to enable potential users in the chemical and marine industries to determine the service life and long-range costs for titanium equipment.

TUNGSTEN

By Richard F. Stevens, Jr.[1]

TUNGSTEN metal, because it has the highest melting point, has become an important structural material in nuclear and space applications requiring resistance to extremely high temperatures. Historically, tungsten metal has been used in lighting and electrical applications; tungsten carbides have been used in metal-shaping tools, in rock bits, and in hardfacing applications where resistance to wear is required.

Although the production rate has varied widely during the past 40 years, domestic production of tungsten concentrate has been equal to approximately two-thirds of domestic consumption. As a result of increased demand during the Korean war and of Government stockpiling beginning in 1951, domestic production increased from less than 1,500 tons, tungsten metal content, in 1949 to nearly 8,000 tons in 1955. Following the termination of stockpile purchases in December 1956, production was severely curtailed. Although domestic production increased to slightly over 4,000 tons in 1961 and 1962, production in 1963 was significantly lower due to the low market price of tungsten and the oversupply of tungsten from mainland China which was sold in Europe at well below the world price. About 60 percent of the domestic output since 1900 has come from California and Nevada, but in recent years, substantial quantities of tungsten have also been produced in Colorado, North Carolina, Montana, and Idaho.

Mainland China, United States, Burma, Bolivia, Portugal, and Korea have been the leading producers, and the United States, United Kingdom, France, Germany, Sweden, and U.S.S.R. have been important consumers. Commercial-grade tungsten minerals are found primarily in quartz veins and contact-metamorphic scheelite. Other commercial occurrences have been found in replacement, placer, and pegmatite deposits. Both underground and opencut methods are used in tungsten mining operations. Tungsten concentration operations, primarily gravity and flotation methods, are usually conducted at or near the mine site. Tungsten concentrate is refined to metal powder by chemical processing followed by hydrogen or carbon reduction of the tungsten compounds. Ferrotungsten is produced primarily in the electric furnace.

Current tungsten applications are based on the extreme hardness and wear resistance of tungsten carbides; on the ability of tungsten and tungsten alloys to retain hardness at elevated temperatures; and on the high melting point, high density, low vapor pressure, and favorable electrical and thermionic properties of pure tungsten. An important objective of current research is the development of coatings and alloys to allow fuller utilization of the exceptional high-temperature properties of tungsten in reactor and aeronautical structural applications. Its melting point of 3,410° C (6,170° F) is higher than that of any other metal, and it has superior mechanical properties at high temperatures.

The measured, indicated, and inferred domestic resources range in grade from 0.3 to 1.0 percent tungsten trioxide (WO_3) and contain over 70,000 tons of tungsten metal. The domestic supply of tungsten is more than adequate for short-term requirements. For the long term, however, adequacy of supply at reasonable cost is uncertain.

Although world tungsten resources are widespread, by far the largest reserve occurs in mainland China. The free world reserve (excluding mainland China, North Korea, and the U.S.S.R.) is estimated at about 295,000 tons, tungsten metal content. Reserves in mainland China, North Korea, and the U.S.S.R. may be about four times as great as those in the free world.

Free world production of tungsten in 1963 was estimated at slightly over 11,000 tons, metal content. Of this quantity, about 4,000 tons (domestic mine shipments plus imports) was supplied to the United States and about 7,000 tons was available to other free world countries. U.S. consumption (11.1 million pounds contained tungsten in 1963) is estimated at 30 to 50 percent of free world consumption.

[1] Commodity specialist.

Problems of the tungsten industry include: Establishing an adequate resource base to meet future requirements; the balancing of a stable peacetime production with consumption; improving quality of products and reducing costs by the use of improved mining and processing procedures; and developing of coatings and alloys to allow more effective use of the special properties of tungsten. The latter relates to the need for materials in the nuclear and space industries capable of withstanding extremely high temperatures.

BACKGROUND

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Records show that from 1905 to 1954 mainland China produced about 28 percent of the world's tungsten. The United States produced 13 percent, Burma 10 percent, Bolivia 8 percent, Portugal 8 percent, and Korea 7 percent. Recent data on tungsten production in China are not available, but the productive capacity of free world sources was greatly increased in the 1950–56 period, largely because of the U.S. Government stockpiling program. Free world production was estimated at 9,000 tons, metal content, in 1949, 25,000 tons in 1956, and nearly 14,000 tons in 1958. U.S. sources of supply in recent years are shown in table 9.

Domestic mines and mills in the past 40 years have produced concentrate containing more than 80,000 tons of tungsten, equal to about two-thirds of consumption during the same years. Production ranged from none in 1921 and 1922 to a peak of nearly 8,000 tons in 1955 when output was reported from 700 mines. Consumption and prices also have varied widely.

Most of the output has come from a relatively few large mines. In 1955, 48 percent of the Nation's production came from the 5 largest mines, 73 percent came from the 10 largest, 82 percent from the 15 largest, and 92 percent from the 40 largest. Thus, about 650 other producers supplied only about 8 percent. In 1963 the two major producers accounted for over 90 percent of the domestic shipments.

Crude tungsten ores are nearly always treated at or near the mine site by gravity and/or flotation methods which produce a market-grade concentrate, a low-grade concentrate (requiring chemical treatment), or both. In 1955 and 1956, three principal chemical plants in the United States treated low-grade concentrate on a custom basis. These plants were located near Bishop, Calif., at Salt Lake City, Utah, and at Glen Cove, Long Island, N.Y. The latter plant was established chiefly to treat imported concentrate.

In 1963 ferrotungsten was manufactured by three firms in the United States, but substantial quantities were imported. Hydrogen reduced tungsten powder was produced by eight firms and carbon reduced powder by two firms. Chemicals were produced as coproducts at some of the above plants and as chief products at some others. The geographic locations of domestic producers of tungsten concentrate and principal producers of tungsten products are given in table 1.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

A short ton unit of WO_3 (tungsten trioxide) is equivalent to 1 percent of a short ton, or 20 pounds of WO_3, and contains 15,862 pounds of tungsten metal (W). A short ton of concentrate with 60 percent WO_3 contains 60 short ton units equivalent to 1,200 pounds of WO_3 (951.72 pounds of tungsten metal). In foreign countries, tungsten is measured in long ton units (22.40 pounds of WO_3), metric ton units (22.046 pounds of WO_3), or in other units. The WO_3 may be contained in scheelite, $CaWO_4$; ferberite $FeWO_4$; huebnerite, $MnWO_4$; or wolframite (Fe, Mn) WO_4 concentrate.

Synthetic scheelite ($CaWO_4$) is used for the same purposes as other tungsten concentrates. This compound results from a chemical process used for upgrading concentrates low in tungsten, for chemical cleaning of impure concentrates, or from processing scrap.

Scheelite concentrate for direct addition to steel melts is usually high grade and low in certain undesirable impurities. The following specification is typical for this use:

		Percent by weight
Tungsten trioxide (WO_3)	minimum	70.00
Tin (Sn)	maximum	.10
Copper (Cu)	do	.05
Arsenic (As)	do	.10
Antimony (Sb)	do	.10
Bismuth (Bi)	do	.25
Molybdenum (Mo):		
Class A steels	not specified	-----
Class B steels	maximum	.80
Phosphorus (P)	do	.05
Sulfur (S)	do	.50
Manganese (Mn)	do	.50
Lead (Pb)	do	.10
Zinc (Zn)	do	.10

TABLE 1.—*U.S. producers of tungsten concentrate and principal producers of tungsten products in 1963*

Company	Location of mine, mill or processing plant	Major products produced
Climax Molybdenum Co., Division of American Metal Climax, Inc.	Lake County, Colo. Coldwater, Mich., Langeloth, Pa.	Tungsten concentrate.
Union Carbide Nuclear Co., Division of Union Carbide Corp.	Pine Creek, Inyo County, Calif.	Chemicals, Ammonium paratungstate (APT).
Tungsten Mining Corp	Vance County, N.C	Tungsten concentrate.
A & B Metal Manufacturing Co. Inc	Houston, Tex	Crushed cast carbide powder.
Adamas Carbide Corp	Kenilworth, N.J	Carbide powder, made from hydrogen reduced tungsten powder.
Oregon Metallurgical Corp	Albany, Oreg	Ingots and other mill products.
Allegheny Steel Co	Ferndale, Mich	Carbide powder, made from hydrogen reduced tungsten powder.
Chem-Met	Clinton, Md	Scheelite produced from scrap.
Cleveland Tungsten, Inc	Cleveland, Ohio	Metal powder—hydrogen reduced.
Diamond Metal Division, Reed Roller Bit Co.	Houston, Tex	Carbide powder, crushed cast.
Fansteel Metallurgical Corp	North Chicago, Ill	Metal powder—hydrogen reduced, chemicals.
Firth Loach	McKeesport, Pa	Carbide powder made from hydrogen reduced tungsten.
General Electric Co	Euclid, Ohio	Chemicals, metal powder—hydrogen reduced.
General Electric Co., Metallurgical Products Department.	Detroit, Mich	Carbide powder made from hydrogen reduced tungsten.
General Electric Co., Lamp Metals & Components Department.	Cleveland, Ohio	Ingots, rod, wire, and other mill products.
Hughes Tool Co	Houston, Tex	Crushed cast carbide powder.
Kennametal, Inc	Latrobe, Pa	Carbide powder made from hydrogen reduced tungsten, carbide powder—crystalline.
M & R Refractory Metals, Inc	Springfield, N.J	Metal powder—hydrogen reduced, tungsten metal pellets.
McCaine Metal Co	Houston, Tex	Crushed cast carbide powder.
Metal Carbides Corp	Youngstown, Ohio	Carbide powder—made from hydrogen reduced tungsten.
Molybdenum Corporation of America	Washington and York, Pa.	Ferrotungsten, chemicals.
Nevada Scheelite, Division of Kennametal, Inc.	Fallon, Nev	Crystalline carbide powder.
Newcomer Products, Inc	Latrobe, Pa	Carbide powder made from hydrogen reduced tungsten.
Stoody Co	Whittier, Calif	Crushed cast carbide powder.
Sylvania Electric Products, Inc	Towanda, Pa	Chemicals, metal powder-hydrogen reduced, billet, rod, wire, and other mill products.
Union Carbide Metals Co., Division of Union Carbide Corp.	Niagara Falls, N.Y	Ferrotungsten, hydrogen and carbon reduced metal powder.
Vascoloy-Ramet Corp	Waukegan, Ill	Carbide powder made from hydrogen reduced tungsten.
Victor Equipment Co	Norwalk, Calif	Crushed cast carbide powder.
Wah Chang Corp	Glen Cove, N.Y	Ferrotungsten, metal powder-hydrogen reduced, chemicals (APT).
Wah Chang Corp., Albany Division	Albany, Oreg	Ingots and mill products.
Westinghouse Electric Corp	Bloomfield, N.J	Metal powder—hydrogen reduced, ingots and mill products.
Willey's Carbide Tool Co	Detroit, Mich	Carbide powder made from hydrogen reduced tungsten.

Copper, arsenic, antimony, phosphorus, sulfur, and manganese are the impurities that are most often a problem in meeting the specification. Some scheelite contains chemically combined copper and/or molybdenum which can be removed only by chemical decomposition and precipitation. Synthetic scheelite, if nodulized, is an ideal product for direct addition to steel, but unnodulized material of fine particle size is not desirable because of high dust losses. Natural scheelite concentrate of the all-slime type is not wanted in this use for the same reason. Concentrate of the black-ore (wolframite type) minerals is not satisfactory in steel manufacture because of its manganese content.

Hydrogen-reduced tungsten metal powder is the intermediate product from which tungsten metal (wire, rod, sheet, etc.), and cemented tungsten carbides are produced. It is also used for making tungsten alloys. Carbon reduced tungsten metal powder is the intermediate product used principally in the manufacture of cast carbides and in alloys. Both types of metal powder result from the reduction of chemically produced oxides of tungsten.

Tungstic acid, sodium tungstate, ammonium paratungstate, and tungstic oxide are chemical forms produced at intermediate stages in manufacturing metal powder.

The national stockpile specification shown in table 2 is for concentrate to be consumed in chemical-type plants. This specification is not as rigid as those of some industrial users because of the difficulty in obtaining high-grade concentrate in the quantity required for the stockpile. Nearly all plant managers prefer concentrate containing 70 percent or more WO_3. Some report that scheelite concentrate containing more molybdenum and phosphorus than the maximum listed in table 2 is satisfactory, but producers of filament wire call for a maximum molybdenum content of 0.025 to 0.002 percent.

TABLE 2.—*National stockpile specification for tungsten concentrate*

Constituents	Chemical requirements, percent by weight (dry basis)			
	Type A, B, or C—ferberite, huebnerite, or wolframite ores and concentrates		Type D—natural scheelite ores and concentrates	Type E—synthetic scheelite precipitates
	For carbide powder	Pure metal		
Tungsten trioxide [1] (WO_3)—minimum	65. 00	65. 00	65. 00	65. 00
Tin (Sn)—maximum	1. 50	1. 50	. 10	. 05
Copper (Cu)—do	. 50	. 50	. 10	. 05
Arsenic (As)—do	[2]. 20	[2]. 20	. 10	. 05
Bismuth (Bi)—do	. 50	. 50	. 25	. 25
Antimony (Sb)—do	. 05	. 05	. 10	. 05
Molybdenum (Mo)—do	. 10	. 025	. 10	. 10

[1] Corrected for columbium and tantalum, if present.
[2] Maximum, 0.1 percent arsenic for processed Government-owned material returned under beneficiation contracts.

Molybdenum, antimony, and to a less extent bismuth are objectionable because they pass through the process unaffected and appear in the end product. Arsenic, phosphorus, and sulfur interfere with the process but do not contaminate the end product. Tin, copper, and manganese, which are detrimental in high-speed steel, are not detrimental at chemical-type plants.

Antimony attacks the "boats" used for reducing tungsten compounds in the hydrogen-reduction furnaces, and is undesirable in filament wire for electronic purposes. Some firms specify maximum antimony in concentrates at 0.005 percent; others as much as 0.05 percent.

Many consumers will not accept concentrate higher than 0.02 percent in arsenic or more than 0.05 percent in phosphorus; nearly all plants will reject concentrate containing more than 0.25 percent of combined arsenic and phosphorus. These elements, frequently present in the original ore and in imported concentrate, are objectionable in the manufacture of both steel and chemicals.

Ferrotungsten is a crude alloy of tungsten and iron consumed in manufacturing alloy steel. The standard specification by industry (American Society for Testing and Materials (ASTM) Specification A 144–50) and the Government (National Stockpile Specification P–57a–R2) are the same; they are summarized as follows:

a. Chemical requirements: Ferrotungsten shall meet the following chemical requirements:

	Percent
Tungsten	70 to 80
Carbon—maximum	. 60
Manganese—do	. 75
Phosphorus—do	. 06
Sulfur—do	. 06
Silicon—do	1. 00
Copper—do	. 10
Arsenic—do	. 10
Antimony—do	. 08
Tin—do	. 10
Sum of arsenic, antimony and tin—do	. 20

b. Physical requirements: Ferrotungsten shall be furnished crushed to a size 1 inch and less.

The consuming firm also specifies the maximum molybdenum content allowable; this is often set at 0.6 percent if tungsten tool steels are being produced.

TECHNOLOGY

Geology

Tungsten-bearing ore and concentrate are of two principal types; calcium tungstate, comprising the first three minerals listed in table 3, of which scheelite is by far the most important; and iron-manganese tungstates comprising the last three.

TABLE 3.—*Commercially important tungsten minerals*

Mineral	Composition	Formula	Tungsten, percent
Scheelite	Calcium tungstate	$CaWO_4$	63.9.
Powellite	Calcium tungsto-molybdate.	$Ca(Mo,W)O_4$	Not fixed.
Cuprotungstite	Copper tungstate	$Cu_2(WO_4)(OH)_2$	45.
Ferberite	Iron tungstate	$FeWO_4$	60.6
Wolframite	Iron-manganese tungstate.	$(Fe,Mn)WO_4$	60.6 to 60.7.
Huebnerite	Manganese tungstate.	$MnWO_4$	60.7.

The iron-manganese tungstates form a continuous series from the iron to the manganese end. The name wolframite is often applied to the entire series, but arbitrary splits are made at 20–80 and 80–20 mole-percent to ferberite, the iron-rich end member, and huebnerite, the manganese-rich end member. Together, the wolframites are known as "black ore."

Tungsten-bearing minerals listed below have not been significant sources of tungsten.

Minerals	*Formulas*
Ferritungstite	$Fe_2O_3 \cdot WO_3 6H_2O$.
Tungstite	$WO_3 \cdot H_2O$.
Russellite	$Bi_2O_3 \cdot WO_3$.
Stolzite	$PbWO_4$.
Raspite	$PbWO_4$.
Chillagite	$Pb(W,Mo)O_4$.
Tungstenite	WS_2.
Sanmartinite	$(Zn,Fe,Ca)WO_4$.
Anthoinite	$Al(WO_4)(OH) \cdot H_2O$.

Most commercial tungsten occurrences have been found in quartz veins and in contact-metamorphic deposits, but replacement, pegmatite, and placer deposits have also been productive. Tungsten mineralization is nearly always associated with siliceous granitic rocks; the distribution of tungsten minerals is typically irregular.

In the United States, vein deposits in Vance County, N.C., and Lemhi County, Idaho, have been important as sources of huebnerite and in Boulder County, Colo., as sources of ferberite. Lesser quantities of scheelite also occur in these deposits.

Contact-metamorphic deposits supply about 75 percent of the U.S. total production, but worldwide they are less important than vein deposits. Scheelite occurs sporadically in the metamorphic rock (tactite) at or near contacts between limestone and the intruding granitic rocks. Important deposits of this type occur at the Pine Creek and Black Rock mines in California. Other scheelite deposits occur in Nevada and in Montana.

A hydrothermal replacement deposit at the Yellow Pine mine in Idaho was a major producer of tungsten in World War II. Stibnite and gold were associated with scheelite in a brecciated quartz monzonite.

Weathered outcrops and placer deposits have been important in some areas. However, they usually are not large or far from the source. Tungsten minerals are friable and rather soluble and may be leached from an ore body without being redeposited. More than 8 million units, at a very low concentration, are contained in the brine of Searles Lake, Calif.

Huebnerite is disseminated in the molybdenum ore of the Climax mine in Colorado. Even though the huebnerite content of the ore is very low, substantial tungsten production is achieved as a coproduct because of the large-scale mining operation.

In many deposits tungsten is the only valuable mineral; other deposits contain tungsten-tin, tungsten-molybdenum, tungsten-antimony, tungsten-silver-gold, tungsten-copper, and tungsten-silver-copper-lead-zinc. Tin and tungsten minerals occur together in mainland China, Burma, Malaysia, Thailand, Bolivia, Brazil, Portugal, Spain, and other countries. Important occurrences of tungsten associated with molybdenum are found in the United States at the Pine Creek mine of Union Carbide Nuclear Co., in California and the Climax mine of American Metal Climax, Inc., in Colorado.

Mining

Mining methods have ranged from primitive to highly mechanized. Only a few tungsten mines (probably no more than one or two in the United States) have produced as much as 1,000 tons of ore per day on a continuing schedule.

By far the largest production has come from underground mines using conventional methods such as shrinkage, square set, open stope, room and pillar, and various adaptations. In 1955, about 20 percent of domestic output came from open pit and placer operations, but in 1963 all output came from two underground operations.

Beneficiation

Crude ore mined and milled in the United States in 1955 and 1956 averaged about 0.5 percent WO_3, and the lowest grade was not much below 0.3 percent. Virtually all of the tungsten produced in 1963 was a coproduct of molybdenum mining.

Gravity methods of concentrating the relatively heavy tungsten minerals have been used most frequently. The specific gravities of scheelite, huebnerite, and ferberite are 6.10, 7.12, and 7.51, respectively. Small mills may employ only crushing and grinding equipment, jigs, and tables. Recovery at such plants averages 60 to 70 percent, but the product is often a good grade concentrate. The high losses caused by the tendency of tungsten minerals to slime during grinding have led to many modifications in flowsheets and equipment.

Flotation processes have gained importance since about 1930, and most modern, large-scale mills use these in combination with gravity methods. Well-equipped mills recover more than 90 percent of the tungsten mineral content, but though part of the product may be high grade, a substantial part is low-grade concentrate requiring chemical treatment.

If calcite and apatite are the principal contaminants, the low-grade concentrate may be brought up to market specifications by acid leaching; a number of tungsten mills in operation during 1955–57 used this procedure. But much low-grade concentrate is shipped from mills to chemical plants to produce market-grade synthetic scheelite. Tungsten concentrate (as low as 5 percent WO_3) is dissolved in sodium carbonate solution under pressure at some plants and by lixiviation after sintering or fusing with sodium salts at others. Calcium chloride is added to the solution to precipitate calcium tungstate; in some instances, molybdenum is first removed from the solution by precipitation as molybdenum sulfide. The pressure method is said to be less costly than sintering if concentrate containing less than 20 percent WO_3 is treated, and more costly if a higher grade feed is used. In either circumstance, the cost is appreciably more than production of a tungsten concentrate by gravity-flotation methods.

Roasting, magnetic separation, or electrostatic separation may also be used to improve the product grade. Separation of scheelite from wolframite, required by some consumers, is accomplished by magnetic separation.

A Bureau of Mines Report (*18*)[2] summarized the milling practice and chemical treatment methods at most of the major and many of the smaller domestic tungsten operations in 1956.

Refining and Preparation of Products

The flow sheet shown in figure 1 indicates the methods of treatment of tungsten ores and concentrate used to obtain industrial products. Most tungsten concentrate is converted to ferrotungsten, metal powder, or other intermediate products before being consumed in end uses. Some scheelite however is used as such in steelmaking. For this use, synthetic or natural scheelite of suitable grade requires no processing except that it is usually nodulized to minimize dust losses.

In producing ferrotungsten, concentrate is reduced in electric furnaces, with carbon or silicon as the reducing agent, or it may be made by aluminothermic or metallothermic methods. A batch-type operation is necessary because the high melting point of ferrotungsten precludes tapping. Any tungsten mineral, or combination of minerals, can be used provided the iron-tungsten ratio will permit formation of an alloy containing 70 percent or more of tungsten. Through the control of slag types and the high temperatures involved, producers of ferrotungsten can lower the impurity content and can therefore use concentrate that would not meet specifications for direct charging to steel.

Ferrotungsten (about 78 percent W), melting base (about 35 percent W), scrap high in tungsten content, and high-purity scheelite (both natural and synthetic) are all used for charging tungsten to steel. Metal powder, pellets, and certain proprietary compositions are also used. Ferrotungsten is used commonly when tungsten tool steels (6.75 to 22 percent W) are manufactured; however, some firms use only the other tungsten products listed above when molybdenum, chromium, and miscellaneous tool steels (less than 6.75 percent W) are produced. Tungsten tool steels require a low-molybdenum content in the charge; most molybdenum tool steels require several percent molybdenum. This is important to producers of tungsten concentrate that contains molybdenum; nearly every use of tungsten, except charging to molybdenum, chromium, and miscellaneous tool steels, requires a product low in molybdenum.

In general, the higher the percentage of tungsten desired in the steel, the greater the need for ferrotungsten. However, the recent trend has been toward the low-tungsten-content steels, and less ferrotungsten has been used, relative to total tungsten consumption.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

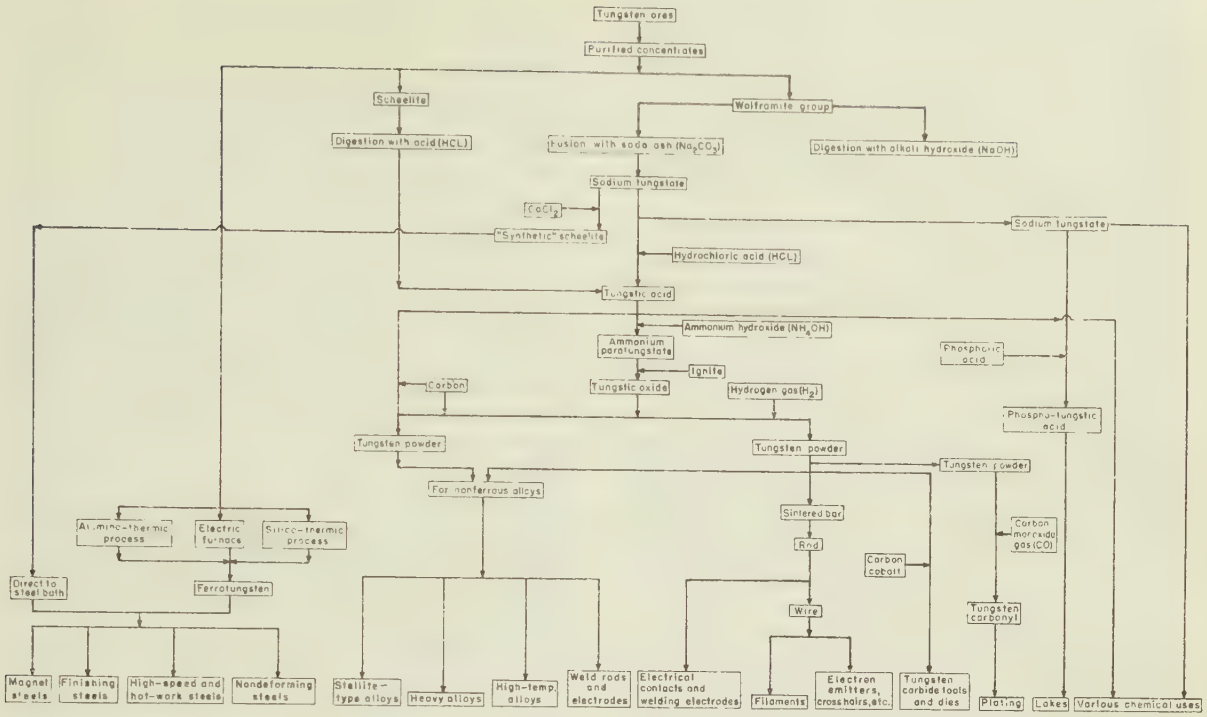

FIGURE 1.—General Treatment of Tungsten Ores and Concentrates to Industrial Products.

In manufacturing tungsten metal powder, the concentrate is treated by chemical methods to produce compounds which are then reduced to metal by hydrogen or carbon. The processes vary according to raw materials, product specifications, and plant design. Methods designed for treating wolframite-type minerals are not satisfactory for treating scheelite and vice versa.

In treatment of wolframite-type concentrate, a typical procedure may include:

(1) Decomposition of the concentrate with sodium hydroxide (NaOH) solution, under pressure or in open tanks; or fusion with sodium carbonate (Na_2CO_3) followed by leaching with water.

(2) Filtering and reaction of the filtrate, containing sodium tungstate, with hydrochloric acid to form a tungstic acid (H_2WO_4) precipitate; or evaporation of the filtrate to form sodium tungstate crystals; or treating the filtrate with calcium chloride ($CaCl_2$) to precipitate calcium tungstate ($CaWO_4$). Additional steps in each of the two latter cases would convert the tungsten to tungstic acid precipitate.

(3) Conversion of the tungstic acid to the oxide by ignition or by treatment with ammonia (NH_4OH), to produce ammonium paratungstate which is converted to the oxide by thermal decomposition.

(4) Reduction of the tungstic oxide to tungsten metal powder, using either carbon or hydrogen as a reductant.

In treating scheelite, concentrate decomposition is accomplished with hydrochloric acid. The resulting tungstic acid precipitate may then be dissolved either in ammonium hydroxide or sodium hydroxide to produce the corresponding tungstate solution, and subsequent steps are similar to those outlined above.

Hydrogen-reduced tungsten powder is produced from ammonium paratungstate or tungstic oxide placed in iron or nickel boats and pushed through tubes counter to a flow of hydrogen. Heat is applied to the outside of the tubes. Grain size of the metal powder product is a primary consideration in its use for manufacturing pure tungsten or tungsten carbide products. Particle size of the metal powder is directly related to particle size of the oxide from which it is reduced and is also partially dependent on temperature and time of reduction. For example, if other variables are suitably fixed, a maximum of 800° C produces a particle size (mean diameter) of 0.5 micron whereas a maximum of 1,200° C produces a particle size of 10 microns. The reduction rate also increases with higher temperatures, resulting in greater furnace capacity for production of coarse powder than for production of fine powder.

Carbon-reduced powder is produced from tungstic acid in crucibles or in tubular furnaces similar to those used for hydrogen reduction. Lampblack is the usual reductant in crucibles; natural gas or manufactured city gas is the reducing agent in tubular furnaces. Skill is required to produce a powder low in carbon and of a satisfactory grain size.

Tungsten chemicals used for manufacturing pigments are produced as coproducts at some plants or they may be the chief product. Quantitatively this is not an important phase of the tungsten industry.

Because of the difficulty encountered in fabricating tungsten mill products, the production of tungsten wire, rod, and sheet is based primarily on hydrogen-reduced powder metallurgy procedures although recently tungsten has also been successfully prepared by arc-melting techniques. The powder is compressed, sintered, heated to incipient fusion by passage of an electric current, swaged, and drawn or rolled.

Cemented (or sintered) carbides are usually made from hydrogen-reduced tungsten powder. The powder is carburized, compacted with a cobalt binder into the desired shape, and sintered. Grain size and cobalt content are important factors in determining hardness and other properties. Mixed carbide powders containing titanium carbide or tantalum carbide or intermetallic compounds such as $WTiC_2$ are also used. Crystalline tungsten carbides, made directly from concentrate, are gaining in use.

Cast (or fused) tungsten carbide is made mostly from carbon-reduced tungsten powder and scrap. These are melted, together with a carbonaceous material, and cast into shapes for use as such, or for crushing and use as a hardfacing material.

USES

The major uses of tungsten can be divided into four end-use categories: In alloys, chiefly alloy steels; in carbides (cemented or cast); as a pure or substantially pure metal; and in various chemical compounds. The consumption of tungsten products by end use, as reported to the Bureau of Mines in 1963, is shown in table 4.

Hardness at elevated temperatures is the important property possessed by tungsten alloys such as high-speed tool steels, die and hot-work steels and other special alloys. The greatest use is in the shaping of metal by high-speed drilling, cutting, milling, etc., or by hot-forming methods. Wear and abrasion resistance, shock resistance, corrosion resistance, and increased strength, at elevated temperatures are other properties of tungsten-bearing steel alloys. The standard types of high-speed and hot-work tool steels are listed in table 5.

Alloys of cobalt, chromium, and tungsten have been used to a large extent as hardfacing materials and for cutting and shaping of metals. They retain a higher hardness at temperatures above 1,100° F than the best high-speed steels. Tungsten alloys are increasingly being used for structural applications in temperature environments of 1,700° F or higher. Valve steel, turbine blades, and vessels for containing high temperature materials are examples of this use. Six alloys that have been developed for high temperature applications are listed in table 6.

Other alloys include tungsten-silver and tungsten-copper compositions for electrical contacts and welding applications and "heavy metal" alloys for high-density applications such as counterweights or shielding. The density of tungsten is 19.3. Heavy metal, about 90 percent tungsten and 10 percent copper or copper-nickel is also used as a high-strength material for applications such as boring bars.

Cemented (or sintered) tungsten carbide is used for cutting edges, in dies, for machine parts subject to wear, and in similar applications where extreme hardness is desirable. The largest use is in machine tools, but large quantities are also consumed by the mining industry as carbide-tipped rock bits. Most often the carbide component is a small insert, razed or clamped to the cutting edge, but there is a trend toward the use of solid carbide tools. During World War II and the Korean war, large quantities of tungsten carbide were used in armor-piercing shells.

Cast (or fused) carbide is used principally as a hardfacing material. In one such application, crushed and sized particles are encased in a hollow steel tube which, when applied as a welding rod, melts to form a matrix for the carbide particles. Cast carbide is also used in dies and in some wear resistant parts.

Pure or substantially pure tungsten is important in electric lighting, electronics, and electrical contact applications. Its melting point, 3,410° C (6,170° F) is higher than that of any other metal and its vapor pressure is lower. Some tungsten is used for welding electrodes, some for shielding, and some for X-ray tube components. Tungsten heating elements are used extensively to vaporize certain metals ("metalizing" plastic name plates, etc.). The filament of electric lamps and the distributor points of automobiles are well-known uses of tungsten. Metallic tungsten coatings applied by various methods, such as flame spraying and vapor deposition, are increasing in importance. Tungsten carbonyl, $W(Co)_6$, has been used to produce acid-resistant linings for cast iron and steel pipes.

Tungsten chemicals are used in textile dyes, ink, paints, enamels, and glass manufacture. Because of the luminescence of certain tungsten compounds and their derivative phosphors, they are used in luminescent pigments. They are also used in X-ray screens and television picture tubes. Tungsten phosphors are used in fluorescent lighting.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Tin and molybdenum minerals are the most important byproducts of tungsten mining and conversely tin and molybdenum mines are the most important sources of byproduct tungsten.

Other byproducts or potential byproducts of tungsten mining include pyrite, antimony, copper, bismuth, lead, zinc, fluorspar, gold, silver, and beryllium. However, tungsten mining has not been an important source of byproduct metals. A potential byproduct source of tungsten is the brine of Searles Lake, Calif.

ALTERNATE MATERIALS

Molybdenum, to a large extent, is substituted for tungsten in tool steels. Titanium or other carbides and sintered aluminum oxide are used in some applications to replace tungsten carbides. The use of transistors in place of vacuum tubes may reduce the need for tungsten in electronics; fluorescent lighting has reduced the importance of electric-lamp filament.

SECONDARY SOURCES AND RECOVERY

Industry returns to producing plants its tungsten-bearing steel scrap. Scrap is also saved at producing wireworks, and sold or returned to the chemical processing units. Tungsten carbide and tungsten metal sludge from grinding are usually reclaimed by chemical treatment to produce synthetic scheelite or they may be used in production of cast carbides. Imports of scrap increased from 200,000 pounds in 1953 to more than 400,000 pounds in the first half of 1956. Subsequent scrap data are not available. A relatively high price for concentrate and suspension of duty 1953–56 contributed to the increase of imports.

High-temperature alloy scrap is potentially an important source of tungsten and other elements, but most alloy scrap consumption in the United States has been confined to remelting without separation of the constituent elements.

RESERVES

The domestic reserve of tungsten ore was estimated in 1957 at about 9 million short ton units of WO_3 equivalent to about 142.5 million pounds of contained tungsten (*15*). Recent data have indicated that this figure may be conservative. Domestic tungsten reserves are shown in table 7.

It is estimated that an additional 8.5 million short ton units of WO_3 are present in the brine solutions of Searles Lake, Calif. If an economic method of recovering this tungsten is developed, the domestic reserves might be doubled. However, this source is not considered to represent a tungsten reserve under present technology.

At the 1963–64 price level, virtually all the domestic tungsten deposits are submarginal except where production is as a byproduct or coproduct of another marketable mineral.

Although the largest world tungsten resource is in mainland China, few data, other than what can be implied by observing China's tungsten trading practices, are available on recent developments there, in the Soviet Union, or in North Korea. Although an estimate of world reserves is given in table 8, commercial reserves in 1963 were substantially less because of the decline in prices caused by the disposal of large quantities of tungsten, believed to be from mainland China, at prices well below the world quotations.

CONSERVATION

Mining and benefication research have contributed to the improved recovery of tungsten minerals. Better mining equipment and mining practice and use of flotation and leaching processes have made possible the exploitation of lower grade deposits.

Past scarcities and high cost of tungsten have tended to restrict its use and promote the use of substitutes. Tungsten requirements for tool steel have been reduced by the use of small carbide inserts at cutting edges. Collection and use of scrap are well established and are becoming increasingly important.

SOURCES OF STATISTICAL INFORMATION

Data on production, shipments, consumption, and stocks of tungsten concentrate are published by the Bureau of Mines in monthly and annual reports. Export and import data are collected by the Bureau of the Census. Data on consumption of tungsten in tool steel are published by the American Iron and Steel Institute.

The Statistical Summary of the Mineral Industry, a British publication, contains data on foreign shipments. The Statistical Yearbook

of the United Nations and publications of foreign countries contain additional statistical information.

TABLE 7.—*Tungsten reserves of the United States, by grade of ore, 1955*

[Thousand short-ton units of WO_3]

Grade	Measured and indicated	Inferred
1.0 percent WO_3 plus	130	120
0.5 to 1.0 percent WO_3	3,200	3,800

Cambodia	300	Thailand	500
Japan	100	United Kingdom	400
Korea	7,000	U.S.S.R.	1,700
Malaysia	1,400	United States	9,000

PRODUCTION, CONSUMPTION, AND TRADE

Consumption of tungsten in the United States has exceeded domestic production except 1953–56; imports have exceeded domestic production in all but 13 years between 1919 and 1963. Sources of domestic production and import sources for 1959–63 are shown in table 9.

Complete data on world consumption of tungsten are not available, but in 1952 it was estimated that the United States with 49 percent, United Kingdom 20 percent, West Germany 9 percent, France 8 percent, and Sweden 3 percent, accounted for 89 percent of free world consumption. In more recent years, the United States consumption has been between 30 and 50 percent of the total. No estimate is included for the U.S.S.R. although consumption there is believed high in view of the availability of tungsten from China and the relative scarcity of molybdenum in that country. U.S. consumption 1959–63 is given in table 9.

Although the domestic mining industry has operated continuously (except for 1921 and 1922) for more than 50 years, rate of production has varied widely due, in part, to changing military requirements, and the Government stockpiling program. Only a few domestic producers have been able to compete consistently on the open market with foreign pro-

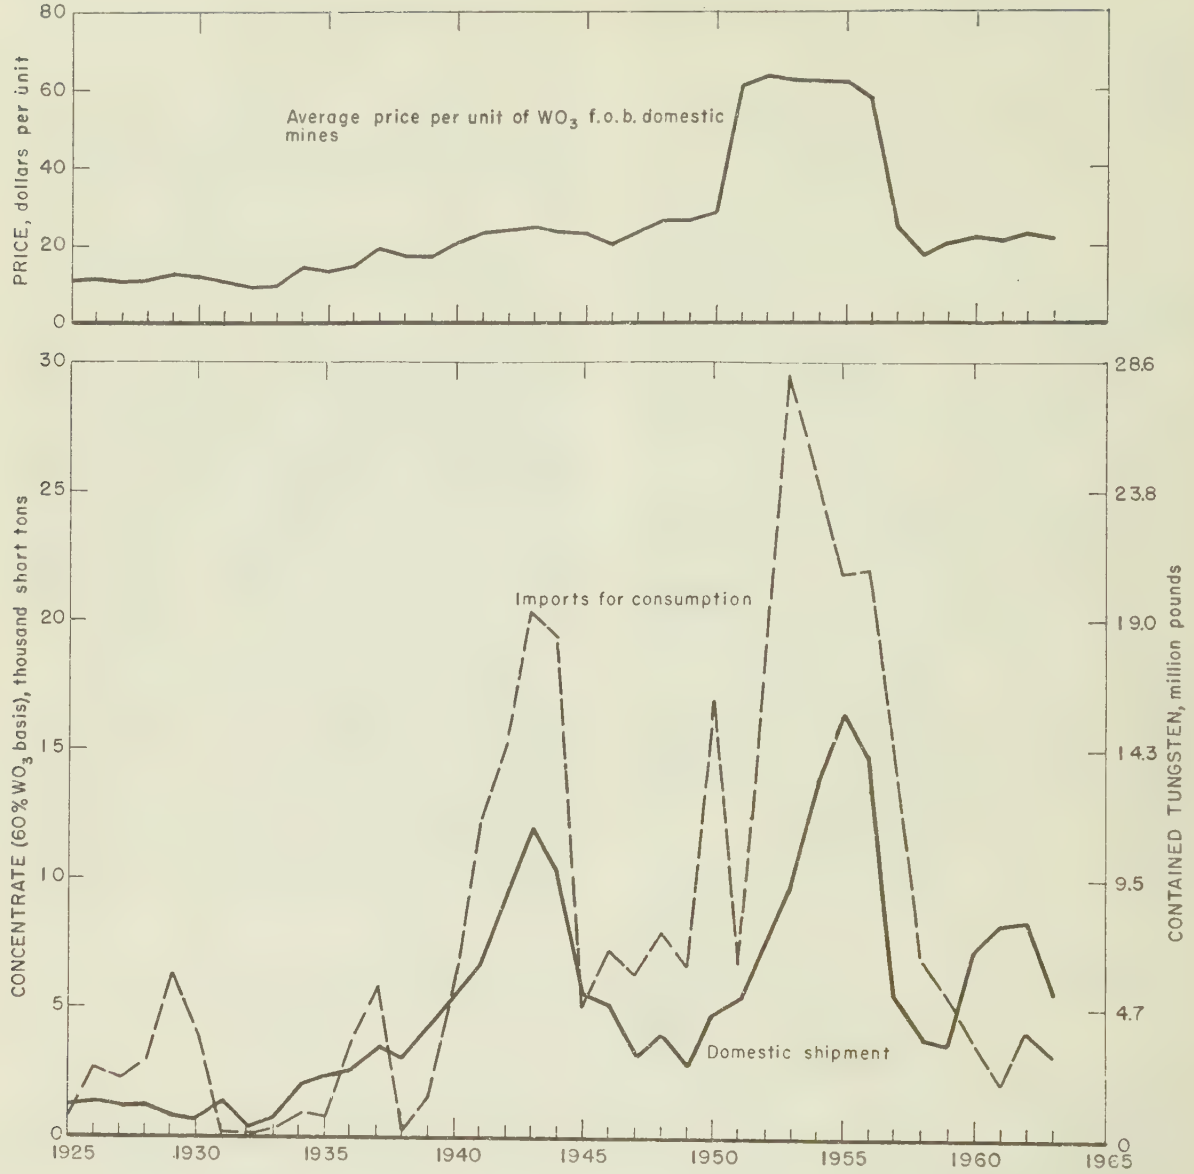

FIGURE 2.—Domestic Mine Shipments, Imports, and Average Price of Tungsten Concentrate.

ducers. Exports of concentrate have been negligible. Domestic mine shipments are shown in figure 2.

The duty on tungsten ore and concentrate under the "Tariff Schedules of the United States, Annotated (1963)" is 50 cents per pound of tungsten content (equivalent to $7.93 per short ton unit of WO_3) as indicated in table 10. Under TSUS the statutory Rates of Duty for tungsten are:

Ore and concentrate	50 cents per pound.
Ferrotungsten	60 cents per pound + 25 percent ad valorem.
Metal, carbide and combinations	60 cents per pound + 50 percent ad valorem.
Ingots and shot	50 percent ad valorem.
Sheet, wire, or other forms	60 percent ad valorem.

STRATEGIC CONSIDERATIONS

A large domestic productive capacity, under a sufficient price incentive to assure supply for the national stockpile, was demonstrated in the 1950–56 period. Current stockpiles have been deemed adequate for emergency requirements. However, it is probable that imports will con-

NOTE.—Public Law 869, 81st Congress, suspended the duty on scrap metal (including tungsten) until July 1, 1951. This suspension was continued to July 16, 1956, when it was reimposed by Public Law 723, 84th Congress.

tinue to comprise a substantial portion of U.S. supply because of economic factors favoring foreign producers.

Termination of U.S. Government stockpile purchases was followed by closure of nearly all tungsten mines in the United States, and many in the free world, but, many of these mines continue to represent potential sources of supply. Although the largest proportion of world reserves is in mainland China, the widespread tungsten occurrences are an important strategic factor, and production also comes from many different countries.

Tungsten is a strategic material because of its use in the tools of production. The machine-tool and mining industries, especially, rely on tungsten, and demand rises sharply during periods of expanding industrial production. Possibly of equal importance, but requiring a smaller tonnage, is the use of tungsten in lamp filaments and electronics. Tungsten and tungsten-base alloys for use at elevated temperatures have become important in the nuclear and space industries. Although the current volume of tungsten in these applications is relatively small, it is expected to increase significantly.

GOVERNMENT PROGRAMS

Stockpile purchase of tungsten concentrate was authorized under the Strategic and Critical Materials Stock Piling Act (Public Law 520 approved July 23, 1946) and the Defense Production Act of 1950 (Public Law 774, approved September 8, 1950). Purchase of concentrate from domestic producers was terminated in December 1956, and the last contract for acquisition of foreign concentrate was fulfilled in 1959. On June 30, 1964, Government inventories totaled 80,400 tons, of which 51,900 tons was in the national (strategic) stockpile, 26,300 in DPA stocks, and 2,200 in the supplemental stockpile.

Under the Defense Minerals Exploration Administration, a program beginning in April 1951, provided exploration loans up to 75 percent of the cost. This program, for tungsten, ended on September 11, 1958.

Government policies have played an important role in the history of the domestic tungsten industry. Imposition of a tariff in 1922 was a factor in increasing the domestic component of U.S. supply. Rapid increase in scrap imports occurred during suspension of the duty on scrap. Price controls, as with other commodities, were in effect during World War II. The stockpile program, beginning in 1951, greatly stimulated domestic and free world production. Defense Minerals Exploration Administration assistance served as an incentive for exploring new deposits and in finding additional ore in known deposits.

During wartime shortages, tungsten was allocated to the most critical and essential uses.

PRICES

Figure 2 shows prices and corresponding domestic mine shipments for the years 1925–63. Although domestic prices under the Government purchase program exceeded $60 per short ton unit of WO_3 throughout the 1951–56 period, peak production was not reached until 1955.

TAXES

A 23-percent domestic and a 15-percent foreign depletion allowance is applicable to tungsten mines.

RESEARCH

Government agencies, private research organizations, and industry intensified the research effort on tungsten in the 1950–63 period. The effort was stimulated primarily by the increasing need for materials capable of withstanding extremely high-temperature environments.

Much of the research was basic in nature and included studies of structure, mechanical properties, oxidation mechanisms, thermodynamic properties, and phase equilibria. Preparation of extremely pure tungsten, research on analytical methods for determining impurities in minute quantities, and studies of the effects of impurity elements were also studied by numerous organizations.

Difficulty in fabrication arising from high, hot strength and room temperature brittleness has comprised one of the major obstacles to the wider use of tungsten. Melting and casting, metalworking, and alloy development comprised an important area of research aimed at improved fabricability, better oxidation resistance (above 2,000° F), or other special properties. Development of protective coatings for high-temperature applications was also an important objective.

Notable improvements were made in the techniques of powder metallurgy, especially in the production of larger size ingots and in the production of intricate shapes.

Other developments in tungsten fabrication include spinning, vapor deposition, flame plating, and explosive and high-energy rate forming (H.E.R.F.).

The Bureau of Mines tungsten program before 1957 was devoted largely to resources and extraction studies. In 1957, emphasis was shifted to research on analytical methods and preparation of ultrapure tungsten, and the Bureau investigated methods of obtaining tungsten metal by electrolytic and bomb-reduction techniques (*3–8*, *14*). Various radiotracer, fluorescent, and spectrographic methods were developed to analyze high-purity tungsten metal (*1–2*, *9*, *16*). Thermodynamic studies were conducted by Bureau scientists to obtain basic properties of tungsten compounds. Tungsten research was continued on vapor deposition and preparation of thick coatings (*10*, *13*). In a continuing search for new tungsten resources, Western deposits and reserves were investigated and evaluated in Montana, Arizona, Utah, and Colorado by Bureau geologists and mining engineers.

Continued tungsten research is being conducted at Bureau research centers. Metallurgists of the Albany Metallurgy Research Center, Albany, Oreg., are conducting investigations on the physical and extractive metallurgy of tungsten. At the Reno Metallurgy Research Center, studies of fused-salt extractive techniques are being conducted. Studies on the vapor deposition of tungsten are being continued at the Rolla Metallurgy Research Center, Rolla, Mo. Tungsten electroplating studies are being conducted at the College Park Metallurgy Research Center, College Park, Md. Additional tungsten research is being conducted or sponsored by the National Aeronautics and Space Administration (NASA), the Atomic Energy Commission (AEC), and by the Department of Defense (Navy and Air Force).

OUTLOOK

Because of tungsten's applications in the tools of production and its excellent high-temperature strength properties which are important in the growing nuclear and space industries, demand for it should increase. The tungsten mines of California and Colorado will continue to produce about 5.5 to 7 million pounds of tungsten annually if prices continue at the 1963 level. It is unlikely that any additional large mines will open at these prices unless lower cost mining and/or beneficiation processes are developed or cheaper and more efficient ways are developed to extract and process tungsten from low-grade ores.

Comparatively significant increases in tungsten consumption could result from the development of new applications for coated tungsten and its alloys having excellent high-temperature properties. Tungsten carbides are expected to continue to account for about 40 to 45 percent of the tungsten market since they are important constituents of modern tools and weapons. A short-term demand for tungsten is expected to arise from the research being conducted for the aircraft and space effort. Long-term demands are expected to depend on developing industrial applications which will utilize the high-temperature properties of tungsten in sheet and fabricated forms. Applications such as the direct use of nuclear heat to raise the temperature of process reactants probably will utilize the exceptional high-temperature strength of tungsten and its alloys. Because of its combination of high-temperature strength and resistance to penetration by subatomic particles, tungsten metal may be used in shielding applications. Other potential uses of tungsten are in structural components of fast nuclear reactors, aircraft engines, missiles, and space vehicles. Tungsten will find increasing application in the rocket-motor and rocket-nozzle fields. Because no other metal surpasses its high melting point and high-temperature strength, tungsten, when made oxidation resistant by the application of a suitable coating, is assured of an important place in future high-temperature metallurgy.

Although the U.S. tungsten ore resource of 140 million pounds represents about a 13-year supply, based on the 1963 consumption of 11 million pounds, domestic tungsten requirements are expected to increase to about 25 million pounds annually by 1980. This projected annual consumption, based on the projected growth of tungsten consumed in the steel, carbide, automobile, and aerospace industries, is almost one-fifth of the total measured, indicated, and inferred tungsten resources of the United States. Consequently, the presently known tungsten resource base will be inadequate to support any significant expansion in the years after 1980. The development of methods to recover tungsten from the brines of Searles Lake, Calif., could provide the required resource base to support the anticipated expansion after 1980.

During the past few years the world tungsten market has been disrupted by the abundant supply of tungsten which has been sold well below the market price. This material is believed to have originated primarily from mainland China and to have been shipped through the U.S.S.R. In the latter part of 1963 when a political rift developed between these two countries the supply of tungsten from China decreased significantly and world price steadily increased. The outlook for world supply of tungsten is one of surplus with possible continued disruption of world marketing channels by mainland China and U.S.S.R.

PROBLEMS

Although tungsten has excellent high-temperature properties, it, like the other refractory metals, oxidizes excessively at temperatures above 1,000° C. Currently the most urgent tungsten problem is the need to develop an oxidation-resistant coating or surfacing to protect tungsten and its alloys so that their high-temperature properties can be utilized. Tungsten alloys that are presently available have sufficient high-temperature properties to warrant their immediate application in missiles and rocketry, but these applications will be limited until the problem of oxidation resistance is overcome. Until adequate protective coatings are developed, the use of tungsten at high temperatures will be limited to short-term exposures, as in rocket nozzles, and to nonoxidizing environments.

Tungsten metal lacks ductility at room temperatures and consequently must be fabricated in nonoxidizing or inert atmospheres at elevated temperatures. Overcoming the problem of tungsten fabrication requires expensive and often complex equipment. Tungsten is ductile at room temperature if it is alloyed with rhenium. The resulting alloy has both good ele-

vated temperature properties and room temperature ductility. Rhenium, however, is expensive, $600 per pound, and in relatively short supply. To overcome the inherent disadvantages of rhenium, other metals are being considered for use as an alloying material with tungsten in an attempt to lower the ductile-brittle transformation temperature and obtain room-temperature ductility. One of the metals under consideration for this purpose is technetium, a sister element to rhenium, which can be obtained from the waste-fission products of nuclear reactors. This potentially large source of supply is in turn dependent upon the existence of waste-isotope separation facilities.

Resource problems revolve about knowing and defining the tungsten resource base. Some fundamental problems are associated with methods of exploring, appraising, and sampling. More complete and detailed information is needed on tungsten resources which are not currently considered commercial. Sufficient tungsten resources required for the long-term needs of the country have not been outlined. Measured, indicated, and inferred domestic tungsten ore resources constitute about 13-year supply at the present rate of consumption and only about 5-year supply at the demand rate expected in 1980. Much of this material is currently considered economic only at prices two to three times greater than present quotations. Incomplete knowledge of both domestic and free world tungsten resources and requirements indicates that more extensive exploration work should be conducted to adequately determine the reserves and resources.

URANIUM

By Charles T. Baroch [1]

URANIUM is the primary nuclear fuel which, with thorium, forms the only fresh energy source developed this century. Reserves and resources are sufficient to supply the world's long-range energy demand for many generations as gas, oil, and coal resources become depleted.

Uranium is a fairly rare element comprising about 0.0002 percent of the earth's crust. It never occurs uncombined in nature. More than 150 minerals have been identified, but the chief ones are pitchblende and coffinite (primary) and carnotite (secondary). The major world sources are the Western United States, the Elliot Lake and Beaverlodge areas in Canada, Republic of South Africa, France, Australia, and several areas in Communist countries. Natural uranium consists principally of two isotopes. It is about 99.3 percent U^{238} and 0.7 percent of the fissionable isotope U^{235}.

When sufficient quantities of U^{235} or Pu^{239} are brought together in a properly shaped mass, a chain reaction occurs, releasing a vast store of energy which is actually derived from the conversion of matter to heat energy. Such a reaction, if uncontrolled, produces a violent explosion—the atom bomb. However, the flow of neutrons can be controlled at the proper rate to release this energy for the production of heat and power. It is unquestionable that the greatest contribution uranium will make in the future will be in creating useful power.

As soon as the military potential of uranium became known, practically every country in the world established controls over the production, transfer, or delivery of uranium and thorium materials. The first domestic controls were assumed by the War Department which established the Manhattan Engineer District in 1942. In 1946, control passed to a civilian agency, the U.S. Atomic Energy Commission (AEC) (*10*).[2] The Nation's first problem was a source of uranium supply. To supplement the meager supply available from the then known Colorado Plateau deposits, material was obtained from the Belgian Congo and Northern Canada. Additional early dependence for a substantial supply was placed on the uranium-bearing gold ores of South Africa, discoveries in Ontario, and smaller sources from Portugal and Australia. The Belgian Congo, Portuguese, and Australian contracts have been completed, all the South African contracts terminate on or before December 31, 1966, and the Canadian contracts have been modified to extend deliveries to the end of 1966. In the meantime deposits in the Western United States have been developed so that domestic production is adequate to supply present and near-future domestic requirements.

Initially, AEC contracted to purchase concentrates from several small mills which were reopened near Uravan, Colo. Later AEC opened its own mill at Monticello, Utah. As more ore discoveries were made, AEC made additional contracts with mills to produce specification-grade concentrates. Over 1,000 mines were producing ore by 1961, and developed reserves exceeded all expectations; more than enough uranium became available for any foreseeable military emergency. Consequently, production was cut back beginning in 1963 when uranium producers were invited to submit proposals for deferral to 1967 and 1968 of a portion of the concentrates originally contracted for delivery through 1966. An additional quantity of concentrates, equal to the amount deferred, will be purchased by AEC during 1969 and 1970.

As civilian uses of nuclear energy increased and as experience was gained in regulating those uses, AEC began to review the legal requirement for Government ownership of special nuclear material. The Atomic Energy Act was amended in 1964 to state that by June 30, 1973, all nuclear materials for civilian use, must be owned outright by private organizations. The amended act will lead to a competitive industry with prices for nuclear material based on fuel value rather than on weapon value. A transition period was provided for.

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

As military requirements for uranium became assured, more attention was directed to peaceful uses of nuclear energy. The first extensive civilian and industrial application of nuclear forces was that of radioisotopes, which could be manufactured quite readily by irradiation of certain elements with neutrons or which were recoverable from fission products. Nuclear power reactors were more complicated and required more time and money to develop. By 1957, the first domestic commercial-sized nuclear power station started operation at Shippingport, Pa., with a capacity of 60,000 kilowatts. By the end of 1964, 13 central-station type plants having a capacity of more than 1 million kilowatts were operable, 5 others were under construction, and several more were under consideration. Also the nuclear-powered ship *Savannah* was sailing the high seas, as were 3 naval surface ships and 51 submarines.

The recovery of uranium from ore involves complicated and costly processing. Privately owned mills near the mines leach the ore with either acid or alkali carbonate, recovering the uranium from leach solution by direct precipitation, ion exchange, or solvent extraction methods and producing a concentrate known as yellow cake containing about 75 percent U_3O_8. Concentrates are refined by a nitric acid and solvent extraction process producing UO_3 which is then converted to uranium fluorides. Uranium tetrafluoride is reacted with magnesium to produce uranium metal, and the hexafluoride is sent to gaseous diffusion plants for enrichment in the U^{235} isotope. Metal is used in production reactors to produce plutonium, also a fissionable element used in weapons and fuel for other reactors.

Uranium concentrates from the mills are refined in plants owned by AEC but operated under contract by private firms. Three gaseous diffusion plants and two plutonium plants, also owned by AEC and largely a part of the weapons-production stream, are also operated by private firms under contract. Under the Atomic Energy Act of 1954 all source nuclear material had to be owned by the Government but could be made available to licensed users on a lease basis, but the law passed in 1964 will permit private ownership of nuclear materials.

As of July 1964, the known domestic ore reserve was about 160,000 tons of U_3O_8, and known free-world reserves totaled about 600,000 tons of U_3O_8.

The outlook for uranium is one of transition from a forced-draft subsidized military economy to a competitive market. The diminishing needs of the weapons program have left the future of the industry largely dependent on peaceful uses for uranium. Nuclear energy, a revolutionary source of new energy, is now developing into a competitive source of electricity. For the near term it will supplement rather than supplant the use of fossil fuel, and will provide a source of energy when fossil reserves are in short supply or become depleted. Some nuclear power plants now under construction are expected to be competitive in high cost fossil-fuel areas, and the AEC target growth curve indicates that nuclear power might supply as much as one-half of all electricity generated in the year 2000.

The next 20 years are expected to be transition years for the nuclear-power programs. New and improved reactor designs, accelerated rate of reactor construction, and improved reactor economics are expected. In 30 or 40 years breeder reactors are expected to become the principal source of nuclear power and, with their increase fuel economies, almost unlimited supplies of high-cost uranium and thorium should become economic.

AEC research will probably continue for some time in chemistry, metallurgy, and physics. Part of this research is conducted in its own laboratories operated by industrial concerns, and part is conducted by research grants to educational institutions.

Many problems confront all phases of the nuclear-power industry. A broad field for research lies in the operation and design of nuclear reactors and the search for a highly efficient type to reduce the cost of nuclear power. Both government and industry have made progress in solving many uncertainties, and many experimental power reactors are forming the base for the accumulation of knowledge and experience.

BACKGROUND

Uranium was discovered by H. M. Klaproth in 1789 in pitchblende and was named after the planet Uranus. In 1896, Henri Becquerel discovered radioactivity while studying the phenomena of phosphorescence and fluorescence. He noticed that uranium salts emitted an invisible radiation that was capable of traversing thin layers of opaque materials and affecting a photographic plate. He also discovered that the air near uranium salts was ionized; that is, it was electrically conducting so that a charged electroscope would be discharged.

In 1898, G. C. Schmidt and Madame Curie independently observed that similar radiations were emitted by thorium, and Madame Curie and her husband, Pierre Curie, discovered the

highly radioactive elements polonium and radium. Other radioactive elements were isolated, and in 1902, Ernest Rutherford and Frederick Soddy proposed the theory of radioactive disintegration. Scarcely noticed by the rest of the world, these tortuous years of physical research by a few geniuses opened up revolutionary concepts of matter and laid the foundation of the nuclear age.

Radium, one of the natural products from the radioactive decay of uranium 238, is strongly radioactive, and it soon found applications, principally in medicine for cancer therapy. In spite of its scarcity and its high price, a demand began to grow. The first radium was recovered from pitchblende from the Joachimsthal mine in Bohemia. In the search for additional uranium-radium sources attention finally centered on southwestern Colorado and southeastern Utah where carnotite was known. Colorado became a major producer of uranium ore for its radium content about 1911, and in 1912 about 1,200 tons of carnotite was shipped to France from which about 8 grams of radium was extracted. The Bureau of Mines and the National Radium Institute cooperated in mining and concentrating carnotite ore from 1914 to 1916. A radium recovery plant was built in Denver, and about 69,000 pounds of U_3O_8 and 8.8 grams of radium were recovered under this agreement. Then the plant passed into private hands. However, rich deposits were discovered in Katanga, Belgian Congo, and soon dominated the market; the domestic uranium industry collapsed around 1923.

The rich pitchblende deposits at Great Bear Lake, Canada, were discovered in 1930, and a refinery at Port Hope, Ontario, began extracting radium in 1933. From then until the early 1940's the uranium industry was divided between Canada and Belgium under a cartel agreement, and radium was the chief product sought. The uranium content had few uses, although a small amount was recovered for use as a coloring agent in ceramics and glass products and in photography. The market in these fields prior to World War II was about 200 tons per year.

In January 1939, when war clouds were first gathering in Europe, word was received that two German scientists, Otto Hahn and Fritz Strassman, had split the uranium atom. The experiment was repeated within a matter of days in a number of U.S. laboratories, and the scientific community became aware of the enormous amounts of energy that could theoretically be released in a chain reaction. After World War II started, the military possibilities of nuclear energy loomed importantly, and the interest in military uses was given a sense of urgency by the fear that Germany was experimenting in this direction.

On August 2, 1939, Albert Einstein signed a letter advising President Roosevelt of the possibilities of an atomic bomb, and the President soon after appointed an Advisory Committee on Uranium to examine the possibilities. In March 1940, it was conclusively demonstrated that uranium 235 could be fissioned. Three months later, the United States began a small integrated research program, and in August 1942, the Manhattan District, U.S. Army Corps of Engineers, was established to launch a full-scale research program on the atomic bomb, including the difficult problem of separating U^{235} from U^{238} (*10*).

On December 2, 1942, Enrico Fermi, with his small staff present, slowly withdrew the cadmium control rods that initiated the world's first self-sustaining chain reaction. This first reactor, designated as CP–1, was a makeshift pile without even a container jacket surrounding it, containing almost 400 tons of graphite, 6 tons of uranium metal, and 58 tons of uranium oxide, had been built in a converted game court at Stagg Field, University of Chicago. The reactor had operated only a few minutes with a release of less than a watt of energy, when the rising radioactivity required Fermi to shut down the reaction. However, the reaction was sufficient to initiate the so-called "atomic age," and the race for the bomb took tangible direction.

Procurement of uranium ore in sufficient quantities for large-scale production of fissionable materials began late in 1942. The Radium Chemical Co., Inc. of New York, had had sufficient foresight to import about 1,200 tons of high-grade pitchblende ore from the Belgian Congo in 1939 and 1940. It was intended as a wartime source of radium, but it assisted greatly with the work of the Manhattan District. In 1943, ore began to come by airlift from the rehabilitated Eldorado mine, by boat from the Congo, and as a byproduct of vanadium production at Naturita, Colo. Initially the Port Hope refinery was the only processor, but other plants were built in 1943 and 1944. The Combined Development Agency was created in 1944 by agreement between the United States and Great Britain to gain control of and to secure uranium and thorium supplies in certain areas of the world. Contracts were let to purchase uranium concentrates produced in the Belgian Congo, the Republic of South Africa, Australia, and Portugal. Deliveries on all these have been completed except those from South Africa which are to continue to the end of 1966.

Meanwhile an intensive effort to develop the atomic bomb continued in other fields. In 2½

years, the Manhattan District assisted by many giant American industrial concerns, built secret cities and plants, which included among others the billion-dollar Oak Ridge, Tenn., isotope-separation plant and laboratories; the $350 million Hanford, Wash., plutonium production plant; and the Los Alamos, N. Mex., Scientific Laboratory. The project ranks high as an engineering feat; yet, the most remarkable part was the fact that tens of thousands of people worked on the project, but probably not over 100 of them knew the full purpose of the work.

The purpose of nuclear developments up to 1945 was exclusively military, even though the peacetime possibilities of nuclear energy became apparent when the first chain reaction was confirmed. The Atomic Energy Commission was created by the Atomic Energy Act of 1946, and it was given the full burden of nuclear responsibilities formely held by the Army's Manhattan District. As an independent civilian agency of the Federal Government, it assumed direction of the development, use, and control of atomic energy for the defense and security of the United States and for peaceful applications. The Atomic Energy Act of 1954 permitted private persons to possess and use special nuclear materials under license, but required the mandatory government ownership of all nuclear materials. In effect, this invited the public to participate in the coming nuclear developments.

As late as 1946, domestic resources of uranium appeared to be negligible; only about 15 mines on the Colorado Plateau produced in that year. In 1948, AEC initiated a procurement program that provided guaranteed minimum prices for domestic ore, a bonus for the discovery and production of high-grade domestic ore, a mine-development allowance, premiums for higher-than-average grade ore, and allowances for haulage. Gold tailings from some of the mining operations in the Union of South Africa contained uranium, and arrangements were made to recover it. Production began in 1952. The 1948 program also was extended to Canada, leading to the discovery of significant deposits, and contracts for the purchase of Canadian uranium resulted.

The program's incentives produced results beyond expectation beginning with the finding of large deposits in the Colorado Plateau and Wyoming. One discovery led to another, and by 1954 over 900 mines produced uranium ore in the Western United States. In 1956 a new program provided for the purchase of concentrates at $8 per pound of U_3O_8 to begin after the ore-buying program expired on March 31, 1962. An announcement on November 24, 1958, limited the previous offer to uranium concentrates derived from reserves developed before November 24, 1958.

The peaceful uses of nuclear energy were designated by the act of 1946 as an important part of the AEC responsibility, and the development of reactors and radioisotopes proceeded on a large scale. The program spread worldwide through the International Atomic Energy Agency (IAEA), and later the European Atomic Energy Community (Euratom) was established by Belgium, France, West Germany, Italy, Luxembourg, and the Netherlands—all working under the slogan "Atoms for Peace." These programs led to the building of research, test, and training reactors all over the world, and the planning of various types of power reactors. In the United States the first large-scale power reactor, the Shippingport, Pa., Atomic Power Station, achieved full power in December 1957, and by the end of 1964, 13 power reactors with a rated capacity of more than 1 million kilowatt-hours were operable.

Uranium production caught up with the requirements, and a substantial military stockpile, so urgently needed at the start, showed signs of reaching fulfillment. Consequently, steps had to be taken to reduce the threat of overproduction. In November 1962, AEC announced that uranium mills could elect to defer to 1967 and 1968 a portion of the concentrates contracted for delivery by the end of 1966. In return for the stretchout, AEC would contract to receive during 1969 and 1970 an additional amount of concentrates, equal to the amount deferred beyond 1966, but at a price based on cost of production and not to exceed $6.70 per pound of U_3O_8.

AEC, although entitled by law to consider all things nuclear to be its monopoly, has pursued a consistent policy of liberalizing its regulations. Certain phases of regulatory authority have been delegated to those States that showed capability to control nuclear materials and which would enter into agreements with AEC regarding the same. In 1964, Congress passed Public Law 88–489 which amended the Atomic Energy Act of 1954 to permit private ownership of special nuclear materials and repealed the requirement of their mandatory Government ownership. Licensing will still be necessary, but after December 31, 1970, AEC will not be able to distribute special nuclear material except by sale.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

The uranium industry throughout the world has been developed under the direction of

the various governments. Demand has been founded almost entirely on military requirements. Prices were largely determined by military necessity and, in many cases, involved above-cost incentives or permitted accelerated amortization of development work to be calculated into costs. In free-world countries most of the production has been done by privately owned mines and mills licensed by a Government agency which has also been the purchaser. Roughly about 85 percent of free-world uranium produced through 1963 was purchased by the United States, and most of the balance went to the United Kingdom.

In the United States, the Atomic Energy Act of 1954 required Government ownership of all fissionable materials but provided for the encouragement of private development within vaguely defined boundaries of peaceful uses of nuclear energy. Procurement of domestic uranium concentrates was arranged through contracts with privately owned mills. The 20 mills operating at the end of 1964 are shown in table 1. The mills receive ore from company-owned mines or purchase it from independent operators. AEC has always required each mill to accept a certain portion of their capacity from custom shippers. Contracts with the mills control the rate of concentrate delivery and prescribe by allocation the amount of ore deliverable. Acceptable concentrates have to be produced from ore reserves developed prior to November 24, 1958.

TABLE 1.—*Uranium processing plants in the United States, Dec. 31, 1964*

State and company	Plant location	Date of first delivery to AEC	Capacity, tons per day
Arizona: El Paso Natural Gas Co	Tuba City	July 1956	300
Colorado:			
American Metal Climax, Inc	Grand Junction	June 1951	330
Cotter Corp	Canon City	Aug. 1958	200
Union Carbide Corp., Nuclear Division	Rifle	Dec. 1947	1,000
Do	Uravan	Mar. 1950	1,000
New Mexico:			
The Anaconda Co	Grants	Sept. 1953	3,000
Homestake-Sapin Partners	do	Sept. 1958	3,000
Kermac Nuclear Fuels Corp	do	Dec. 1958	3,300
Vanadium Corp. of America	Shiprock	[1] Jan. 1955	300
South Dakota: Mines Development, Inc	Edgemont	Aug. 1956	400
Texas: Susquehanna-Western Corp	Falls City	June 1961	200
Utah:			
Atlas Corp	Moab	Nov. 1956	1,500
Do	Mexican Hat	[1] Nov. 1957	1,000
Vitro Chemical Co	Salt Lake City	Oct. 1951	600
Washington: Dawn Mining Co	Ford	Sept. 1957	400
Wyoming:			
Federal-Radorock-Gas Hills Partners	Fremont County	Dec. 1959	520
Globe Mining Co	Natrona County	Feb. 1960	490
Petrotomics Co	Carbon County	Apr. 1962	200
Utah Constructions & Mining Co	Fremont County	Mar. 1958	980
Western Nuclear, Inc	Jeffrey City	Aug. 1957	850

[1] First delivery from plant by previous owner.

As many as 1,000 mines have been in production in any one year, and in 1963, 730 mines in 14 States provided about 5.9 million tons of ore. Individual mines vary in size from small "gopher holes" that produce only a few tons to those that have produced in excess of 200,000 tons annually. In 1963, about 400 mines individually produced over 1,200 tons of which about 90 produced over 12,000 tons.

Uranium concentrates are shipped to the AEC refinery at Weldon Spring, Mo., which is operated by Mallinckrodt Chemical Works and produces UO_3, UF_4, and high-purity natural uranium metal. Production reactor fuel cores are fabricated in an AEC plant at Fernald, Ohio, operated by National Lead Co. of Ohio. About 600 people are employed at Weldon Spring and 1,750 at Fernald. UO_3 is processed to UF_6 at the AEC plant at Puducah, Ky., which is used there as feed to a gaseous diffusion plant. The product is then sent to AEC gaseous diffusion plants at Oak Ridge, Tenn., and Portsmouth, Ohio, for further enrichment. The Paducah and Oak Ridge plants are operated for AEC by Union Carbide Corp., and the Portsmouth plant is operated by Goodyear Atomic Corp. These plants represent investments of about $785 million, $850 million, and $770 million, respectively, and during peak op-

erations employed about 1,800; 6,000; and 2,700 people.

Private industry has gradually developed a capability for producing uranium materials and fabricating nuclear fuels, and about the only remaining major area in the fuel cycle still performed solely by the Government is gaseous-diffusion uranium enrichment. Principal producers of uranium materials and fabricators of uranium fuels are listed in table 2.

Plutonium is produced in nine graphite-moderated production reactors at Hanford, Wash., which have been operated by General Electric Co., and which is withdrawing from the operation in 1965. Battelle Memorial Institute was selected to operate the laboratories. Five heavy-water production reactors at Savannah River, S.C., operated for AEC by E. I. du Pont de Nemours & Co., Inc., also produce plutonium.

Early in 1964, President Johnson announced a cutback in nuclear weapons production beginning July 1, 1965, and spread over approximately 3 years. The feed plant at Paducah was closed June 30, 1964, and three production reactors at Hanford were to be shut down, one January 1, 1965, and the other two at 3-month intervals after that. One reactor at Savannah River was shut down in July 1964.

TABLE 2.—*Principal producers of uranium materials and fabricators of uranium fuels*

Company and principal location	Metal, oxides, and compounds	Coated particles	Fabricators of uranium fuels
Aeroject General Nucleonics, San Ramon, Calif			×

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS (11)

Uranium, chemical symbol U and atomic number 92, is the last member of the series of naturally occurring elements in the Periodic Table. Natural uranium contains the three isotopes U^{238} (99.285 percent), U^{235} (0.71 percent), and U^{234} (0.0051 percent).

U^{235} is the only naturally occurring, fissionable nuclide, and its content in natural uranium varies only slightly, from about 0.7103 to about 0.7113 percent by weight, depending on its geographical source. Effective July 1, 1963, the accepted value of 0.711 was established by AEC unless an actual measured U^{235} value was determined. U^{235} is not a member of either the uranium-radium or thorium disintegration series, and its origin in natural uranium is a matter of deep speculation.

U^{238} is the most common natural isotope and is of great importance because it is one of the two fertile materials available for producing fissionable material. U^{238} yields plutonium 239, Pu^{239}, under neutron bombardment.

U^{234} is a nonfissionable, long-lived isotope of no practical importance as a nuclear material as it is not fertile.

All uranium isotopes are naturally radioactive, and the half-lives of U^{235} and U^{238} are

7.1×10^8 and 4.51×10^9 years, respectively. Because of the slow rate of radioactive decomposition, recently prepared pure uranium is only mildly radioactive. Freshly mined ores that are in equilibrium with their daughter products, are radioactive largely because of the presence of short-lived and intensely radioactive elements, such as thorium 234, radon 222, polonium 218, and others. U^{238} decays in accordance with the uranium-radium series and leads to a stable lead isotope, Pb^{206}. U^{235} decays through the actinium series, producing also a stable lead isotope, Pb^{207}.

A number of uranium isotopes can be produced artificially. U^{233} is an important fissionable material that is formed by the neutron bombardment of thorium 232. It has the highest neutron yield in thermal fission and offers great promise as a power source in breeder reactors. U^{236} is formed to a slight extent in reactors by irradiation of U^{235}. Like U^{234} it has no use as a fuel and serves only to complicate the reprocessing of nuclear fuel. U^{237} is a short-lived isotope (6.8 days) and decays to Np^{237} which is a source material for Pu^{238}, a good heat source for special applications.

Uranium has a density of 18.7, nearly that of gold and 65 percent heavier than lead. It is reasonably ductile and can be fabricated by usual metal-working methods. It has poor structural strength and is generally regarded as being semiplastic. It is highly reactive chemically, and a freshly cut surface of silvery gray rapidly oxidizes to black oxide in air at room temperature. Chips and powder are highly pyrophoric, and the metal is a strong reducing agent reacting with all nonmetallic elements. The normal valences of uranium are +3, +4, and +6, and four oxides, UO, UO_2, U_3O_8, and UO_3 are known, but pure UO has been definitely established only as a thin surface layer on the metal.

U_3O_8, a uranium-uranyl oxide, is olive-green in color and contains 84.8 percent uranium. Most chemical analyses for uranium are expressed in terms of U_3O_8 and ore purchases are made on that basis.

UO_2, or *brown oxide*, is commonly used for fabricating fuel elements for power reactors and is also an intermediate product in producing uranium tetrafluoride from UO_3.

UO_3, or *orange oxide*, is produced at one stage of the refining process.

Yellow cake is the term applied to certain uranium concentrates produced by mills. It is the final precipitate formed in the milling process, and it is usually considered to be ammonium diuranate, $(NH_4)_2U_2O_7$ or sodium diuranate, $Na_2U_2O_7$, but the exact composition is variable and depends upon the precipitating conditions.

AEC has established specifications for uranium concentrate delivered under its contracts. All concentrate shall pass through a 0.25-inch screen and shall be amenable to refining by solvent extraction as determined by standard tests. Price penalties are provided for concentrates containing less than 75.00 percent U_3O_8 and for specific impurities exceeding the following maximum allowable quantities expressed as a percentage of the contained U_3O_8, except in the case of the last two items:

Constituent:	*Percent*
Vanadium oxide, V_2O_5	2.00
Phosphate, PO_4	4.00
Molybdenum, Mo	.60
Boron, B	.20
Halogens, Cl, Br, and I, expressed as Cl	.30
Fluorine, F	.10
Arsenic, As	2.00
Carbonate, CO_3	4.00
Sulfur as SO_4	10.00
Calcium, Ca	1.50
Thorium, Th	2.00
Zirconium, Zr	2.00
Samarium, Sm	.015
Europium, Eu	.015
Gadolinium, Gd	.015
Dysprosium, Dy	.015
U_3O_8 insoluble in nitric acid [1]	.10
Organic content [1 2]	.10
Moisture, H_2O [3]	10.00

[1] As determined by the standard method used by AEC for making such determinations.
[2] Concentrate shall be free of surface-active organic materials, which are found by AEC to interfere with subsequent refining of the concentrate by solvent extraction.
[3] Determined on an "as received" basis and drying at 110° C.

Fission and Nuclear Energy

Fission, when applied to nuclear phenomena, is the transmutation process whereby a fissionable element is divided into two other elements. Fission occurs when an atomic nucleus is hit by a free neutron which has the proper amount of energy (speed) to be captured (or incorporated) into the nucleus. The nucleus responds by flying apart violently, forming two new elements, known as *fission fragments*, which range in mass from 72 to about 160. The combined mass of the fission products is less than the mass of the original atom. The difference represents matter that has been converted into heat energy in accordance with Einstein's law.

Nuclear energy, often called *atomic energy*, is energy derived from fission. Albert Einstein stated the relationship between mass and energy which is fundamental to the whole subject of nuclear energy. This equation shows that the relationship between energy (E) and mass (m) is $E=mc^2$, where c is the velocity of light. Since the velocity of light is large (nearly 3×10^{10} centimeters per second), a small mass is equivalent to a very large quantity of energy.

One gram of matter is equivalent to 25 million kilowatt-hours of energy. In the fission of uranium only about 0.1 percent of its mass is converted into energy, and the fission of all the atoms in a gram of U^{235} will yield about 23,000 kilowatt-hours or about 1,000 kilowatt-days of energy. Conversely, 1,000 kilowatt-days of energy equals the fission of 2.70×10^{21} atoms. Thus, 1 gram of U^{235} burned in a nuclear way will release as much heat as 3 tons of good quality coal. One pound of fissionable matter will yield 0.999 pound of fission products, and the 0.001 pound of mass is converted into the heat equivalent of over 10 million kilowatt-hours of energy.

In addition to the fission products and energy produced by fission, an average of about 2.5 high-energy neutrons are also released. This is one of the most notable features of nuclear fission, and the one that makes nuclear energy possible. These released neutrons have the capability of causing additional fission to continue in a process known as a *chain reaction*. Under certain conditions, a chain reaction can proceed rapidly and result in an enormous explosion, such as that produced by nuclear or atomic bombs. On the other hand, the reaction can be controlled by neutron-absorbing materials and neutron moderators, so that fissioning takes place at a selected rate.

A nuclear reactor is an assembly of nuclear fuel, control devices, coolant, and containment vessels capable of sustaining a chain reaction at a desired rate. *Power reactors* are used as an energy source for electric-power production, space heating, or for propulsion. *Production reactors* are used to produce plutonium 239 for defense stockpiles. *Research*, *test*, and *training reactors* are used to provide intense beams of fluxes of neutrons for experimental purposes or for producing radioisotopes.

Fertile materials are uranium 238 and thorium 232 which can be transmuted by the capture of neutrons into fissionable plutonium 239 and uranium 233, respectively. Fertile materials are frequently incorporated into the fuels of nuclear reactors, and reactors can be designed to operate on *natural uranium*, which contains essentially 0.71 percent U^{235} and 99.285 percent U^{238}. *Depleted uranium* is uranium from which the fissionable isotope, U^{235}, has been partially or completely separated. It can refer to any U^{239} containing less than 0.7 percent U^{235}.

An *isotope* or *nuclide* is a variant form of a given chemical element due to differences in the number of neutrons contained in their nuclei. Isotopes of the same element have the same number of protons in their nuclei and the same electron arrangement, hence they are practically identical in chemical behavior but differ in atomic mass.

A radioactive isotope is called a *radioisotope* or *radionuclide*. A few radioisotopes are found in nature, but many more can be made in nuclear reactors by bombarding elements with neutrons. Typically, natural and stable cobalt 59 can be converted into cobalt 60 which emits gamma rays, similar to X-rays, and is used for medical teletherapy and industrial radiography. *Fission fragments* or *fission products* resulting from the fission of heavy nuclei are a mixture of about 35 elements and may contain nearly 200 different stable and radioactive isotopes. Fission products are possible sources of high-intensity radiation for various industrial applications.

Neutrons are uncharged or *neutral* particles which, with *positively charged protons*, make up the *nucleus*, the dense, positively charged core of all atoms heavier than the hydrogen atom. An atom is similar to a tiny solar system with a nucleus surrounded by orbiting *electrons*. Electrons are elementary particles carrying a *negative* charge and having a mass when at rest equal to $\frac{1}{1838}$ that of the hydrogen atom, which consists of one proton and one electron. Neutrons have approximately the same mass as protons, therefore, the bulk portion of an atom is the nucleus. Nuclei of different elements are made up of different numbers of neutrons and protons and, when electrically neutral, the atom has the same number of electrons as it has protons. For instance, U^{235}, which is one of the largest and most complex of the naturally occurring elements, has a nucleus of 143 neutrons and 92 protons, totaling 235 mass units, around which 92 electrons are orbiting.

Fusion, or *thermonuclear fusion*, occurs when nuclei of lightweight elements combine to form heavier nuclei. In many respects the fusion process is just the opposite of fission. However, a large amount of energy is released in the fusion process, which is also the result of transformation of mass into energy. Fusion is the basis of the hydrogen bomb and depends on the fusion of either two deuterium nuclei or of a deuterium nucleus with a tritium nucleus to form helium 4. Deuterium and tritium are isotopes of hydrogen. Deuterium occurs naturally in the ratio of 1 part in 6,000 of hydrogen, and the ocean contains enough deuterium to provide power requirements at the present rate of use for many hundreds of millions of years. A great number of formidable problems must be solved before fusion power can become a reality.

Radiation Hazards

Atomic energy is unique compared with other energy sources because of its radioactivity, which is associated with the entire nuclear program from the uranium minerals in the earth to the end product of its use. Radioactive materials emit energy that can damage living tissue. The major forms of radiation are alpha particles, beta particles, gamma rays, and neutrons (radiation is described in the Radium chapter). Some elements such as uranium, thorium, and radium, are naturally radioactive, while others become radioactive after bombardment with neutrons. Many radioactive isotopes are produced by placing material in a nuclear reactor and bombarding it with neutrons.

Potential danger of exposure to radiation has become a major concern to the public. Military and civilian atomic energy use, along with the great increase in production and processing uranium ores, introduced new sources of radioactive materials into man's environment. New problems requiring thorough study and careful long-range planning have been created.

Uranium miners are exposed to alpha, beta, and gamma radiation. The hazards exist as external sources and as radioactive gas (radon) and particulates which can be inhaled and retained in the body. Radiation studies in uranium mines show that the greatest hazard to the miners is produced by radon decay products (daughters). Radon is a highly radioactive gas derived from the disintegration of radium. It has a half life of 3.825 days and disintegrates successively into various radium isotopes, finally ending as stable Pb 206. Practically all mines require mechanical ventilation to reduce the atmospheric concentrations of radon and its daughters to the working levels recommended by the Public Health Service and other agencies.

Radium A and Radium C′, the two alpha-emitting isotopes of the daughter products, are the principal direct sources of excessive radiation dosage. Studies by the Public Health Service have shown that a serious health hazard exists from ingestion of radon daughter products that might cause lung cancer if continued over a number of years. A tolerance level for radon daughter product concentrations of 300 micromicrocuries per liter of air was recommended in 1955 at a joint conference of government agencies and mine operators. Studies and research by government and State agencies are continuing toward control and attenuation of the hazard.

Uranium mills employing modern wet processes usually have no serious difficulty in maintaining safe working levels of radioactivity for employees. The major problem of the mills is the disposal of effluent liquors and tailings that may contaminate surface and underground water resources. The principal source of contamination is the radium content remaining in the tailings. The radium is slowly water-soluble and may become a contaminant.

External radiation presents only minor problems in mines and mills because both uranium ore and concentrate emit only low-level radiation which is not considered dangerous under normal working conditions.

Development of atomic energy has brought about radiation intensities far greater than anything that had been previously experienced. Radiation from the fission of uranium, spent uranium fuel elements, and radioisotopes, among others, must be attenuated to protect personnel. Attenuation by shielding and other means increases the costs of atomic energy. In addition, the hazards of reactor operation present civil as well as technical problems. Localities, States, and governments are concerned about potential hazards of atomic energy, including those associated with disposal of radioactive wastes and radioactive fallout produced by the detonation of nuclear weapons. Regulations on standards for protection against radiation were issued by the AEC in January 1957. The rules establish standards for protection of atomic energy workers and the public against radiation hazards arising from activities licensed by the Commission (*1*).

TECHNOLOGY

Geology (*9*)

Geochemists estimate that uranium makes up about 1 to 2 parts per million of the earth's crust, greater than that of antimony, bismuth, mercury, silver, and gold and about the same as that of cobalt, lead, and molybdenum. Many primary igneous rocks, particularly the granites, contain uranium in concentrations rarely as high as 50 parts per million. Such rocks existing in past geologic ages are considered to be the sources of many of the higher grade concentrations now being exploited, particularly those found in sedimentary rocks.

Uraninite, the most common uranium mineral, ideally is UO_2, but usually contains UO_3. The massive form is called pitchblende. As a primary mineral it is found in small amounts throughout the world, often concentrated in pegmatites and primary vein deposits. It is also found in secondary deposits.

Coffinite, a uranium silicate, is a major uranium mineral in the unoxidized ores of the Western States.

Carnotite, $K_2O \cdot 2UO_3 \cdot V_2O_5 \cdot nH_2O$, is the

most important secondary uranium ore mineral. Probably another 150 secondary uranium minerals have been identified and are found in small concentrations, many of them being complex hydrated compounds of uranium, copper, lead, vanadium, molybdenum, iron, magnesium, calcium, potassium, and sodium oxides or phosphates. The more common secondary minerals in addition to carnotite are—Tyuyamunite, $CaO \cdot 2UO_3 \cdot V_2O_5 \cdot nH_2O$; autunite, $CaO \cdot 2UO_3 \cdot P_2O_5 \cdot nH_2O$; uranophane, $CaO \cdot 2UO_3 \cdot 2SiO_2 \cdot 6H_2O$; torbernite, $CuO \cdot 2UO_3 \cdot P_2O_5 \cdot nH_2O$; and gummite, $UO_3 \cdot nH_2O$ containing also various quantities of other elements. Combinations of these minerals often form spectacular displays of color. In many carnotite deposits, the uranium is intimately associated with carbonized wood or other carbonaceous matter, which are good indicator substances to the prospector.

Uranium is also found as a minor constituent of many minerals which are multiple complex oxides, such as thorianite (uranothorianite), $(ThU)O_2$; and the fergusonite-formanite, samarskite-yttrotantalite, and euxenite-polycrase series of minerals, which are made up of rare-earth oxides and either or both columbium or tantalum. Quadrivalent uranium is isomorphous with thorium, zirconium, and the rare-earth elements, and may be found associated with minerals of these elements.

Probably no other metal has ever received such concentrated mineralogical and geological study as uranium received from 1946 to 1960. Practically all occurrences were included in the studies, and the literature is very extensive.

The chief sources of ore in the United States are found in sedimentary strata, consisting of sandstone, mudstone, and limestone in which the uranium minerals occur as pore fillings, replacements of woody tissue or other carbonaceous matter, or as cement between quartz grains or along fractures. Several theories have been advanced to account for the origin of these deposits. They were formed later than the enclosed rocks, and evidently the primary ores, uraninite and coffinite, were deposited in carbonaeous sandstones under reducing conditions. Lowered ground water level permitted oxidation, changing uranium from the quadrivalent to the hexavalent form.

The largest and most numerous sedimentary uranium deposits are found on the Colorado Plateau, an area embracing about 150,000 square miles of western Colorado, eastern Utah, northeastern Arizona, and northwestern New Mexico. The uranium deposits occur as bedded bodies chiefly in the Morrison formation of Jurassic age and the Chinle conglomerate and Shinarump formation of Triassic age. In Wyoming, extensive uranium deposits occur mainly in sediments of Tertiary age. Other smaller deposits are found in Mesozoic, Paleozoic, and Tertiary sediments on the fringes of the Plateau and in California, Montana, Neveda, North Dakota, South Dakota, and Texas.

Uranium ore bodies in sedimentary rocks are spotty in distribution and vary from a few inches to several feet in thickness and up to several thousand feet in length. They are usually irregular in shape and most are tabular, paralleling the bedding, but some form lens-shaped bodies. Uranium content of most ore bodies ranges from 0.10 to 0.50 percent U_3O_8, with much higher grade local enrichments, and many contain vanadium.

Very few deposits similar to the sedimentary deposits of the Western United States are known elsewhere, and these are notably in Argentina and the U.S.S.R.

Some of the world's richest and most productive uranium deposits have been found in vein deposits. Pitchblende, associated with gold, silver, and base-metal sulfides or with fluorite, is the principal uranium mineral at depth. Uranium is mined in the United States from veins principally in Washington, Arizona, Utah, and Colorado, and to a lesser extent from veins in Oregon, Nevada, California, New Mexico, Montana, and Idaho.

Uranium vein deposits in Canada include the famous Eldorado mine in the Great Bear Lake area, Northwest Territories and the Goldfields Region in Saskatchewan. In Europe, vein deposits are found in Joachimsthal, Bohemia, and the Erzgebirge district which extends into East Germany; in Saxony; the Black Forest, Germany; and the Brittany Massif, Massif Central, and Vosges, France. The principal uranium deposits in Portugal are veins in coarse-grained granite, of which the Urgeirica mine is the most famous and dates from 1911, when it started as a producer of radium. The Shinkolobwe mine in Katanga, Congo (Leopoldville), began producing radium in 1921 and was unrivaled until the Eldorado mine began production in 1933. The Shinkolobwe mine closed down in 1960, its ore exhausted. Australian vein deposits are found at Rum Jungle in the Darwin-Katherine area.

In the Republic of South Africa, the Witwatersrand deposits are the important sources of uranium. Gold ores occur in about a dozen thin conglomerate beds called "reefs," some of which contain an average of nearly 0.5 pound of U_3O_8 per ton. A few bodies that could not be mined profitably for gold alone, contain about 1.25 pounds of U_3O_8 per ton.

Few replacement uranium deposits are known, but exceptions are the uranothoranite deposits in the Bancroft region, Ontario, and the Man-

dare River basin in the Malagasy Republic, as well as the Mary Kathleen pitchblende deposit in Queensland, Australia.

In the Blind River district north of Lake Huron, in Ontario, uranium occurs in Precambrian pyritic conglomerate beds containing disseminated grains of uraninite and brannerite. Some thorium is associated with the uraninite, together with cobalt and tungsten.

Many radioactive mineral occurrences in the United States have been found in pegmatites; however, few have produced significant quantities of ore. Typical deposits that have been economic sources of uranium lie in the Malagasy Republic, the Evje district in Norway, the Bancroft district in Ontario, and several occurrences in South Dakota and Colorado.

Nearly all igneous rocks contain trace amounts of uranium and thorium, and no nation need be deprived of either of these elements—at a price. The silicic and alkali silicic rocks contain the most uranium, and one of the highest grade large deposits is the Conway granite, outcropping over 300 square miles of area in New Hampshire, which averages about 12 parts per million uranium and 50 parts per million thorium.

Uraniferous black shales containing 0.001 to 0.006 percent U occur in many States, often covering large areas. The Chattanooga shale covers about 40,000 square miles across central Tennessee and into Kentucky and Alabama. It is generally less than 35 feet thick and the favorable uraniferous member averages about 0.006 percent U, and will yield up to 15 gallons of shale oil per ton. Other shales are found in Illinois, Kansas-Missouri-Oklahoma, Wyoming-Nebraska, North Dakota, and Montana, and deposits are known in Norway and the U.S.S.R. These deposits are low in grade and will serve only as resources for the distant future. Some higher grade shale in Sweden is being processed for uranium.

Many western lignites contain small amounts of uranium. Some of the largest deposits are in western North Dakota and South Dakota, extending into Montana, ranging from 0.01 to 0.20 percent U_3O_8. After burning, the ash from some of the higher grade lignites contains up to 0.50 percent U_3O_8, and 0.20 to 0.40 percent molybdenum, both of which have been recovered profitably. Other deposits are found in Wyoming, Utah, Nevada, New Mexico, and Idaho.

Uranium occurs in small quantities in most phosphate deposits. The Florida land-pebble deposits contain about 0.015 percent U_3O_8, and uranium has been recovered as a byproduct from the production of phosphoric acid. Phosphate beds of the Phosphoria formation underlie parts of Utah, Idaho, Wyoming, and Montana, and contain around 0.012 percent U_3O_8.

The broad and indefinitely bounded area in which uranium and uranium-rich rocks are relatively abundant has been defined as a uranium province. Such areas are believed to be the most favorable areas for large-scale prospecting for new uranium deposits. The chief provinces are considered to be as follows:

1. The Colorado Plateau and the surrounding areas of uranium deposits extended from the Black Hills southward through the Front Range to New Mexico and Arizona, and northward through Utah and Idaho into eastern Washington. Sandstone deposits dominate, but veins, pegmatites, uraniferous lignites, black shales, and uraniferous phosphates are present.
2. The Rim of the Canadian Shield, ranging in a narrow belt from the Bancroft area through Blind River, Manitoba, and Goldfields to Great Bear Lake. This province contains veins, pegmatites, and contact deposits mostly in Precambrian rocks.
3. Eastern Brazil in Espirito Santo, Sao Paulo, Minas Gerais, Rio Grande do Norte, and Paraiba where granitic pegmatites and pitchblende-gold in conglomerates predominate.
4. Western and Central Europe from Urgeirica (Portugal) through the French Le Massif Central, to Erzgebirge (East Germany), and Joachimsthal (Czechoslovakia) and including Cornwall, England. This province contains mostly vein deposits.
5. U.S.S.R., probably in the Ferghana-Kara region where disseminated sandstone deposits are known.
6. Southern Africa in a discontinuous belt from the Congo (Leopoldville) (Katanga) south through Rhodesia to Republic of South Africa (Witwatersrand) and southeastward to Mozambique and Malagasy. Uraniferous conglomerates, pegmatites, replacement, and vein deposits are found here.
7. Eastern Australia, including Darwin-Katherine area (Rum Jungle) Northern Territory; Mt. Isa in Queensland; Broken Hill, New South Wales; and Radium Hill, South Australia. Replacement and vein deposits predominate.

Prospecting and Exploration

The discovery of uranium ore is made difficult by the size and shape of the ore bodies, their erratic distribution, and the frequent lack of outcrops. Because of the intensive prospecting efforts from 1948 to 1960, it is likely that most of the outcropping deposits have been found, and prospecting hereafter will require subsurface methods.

Systematic exploration for uranium mineralization requires the study of geologic features,

application of radiometric or geochemical techniques, and ultimately the use of subsurface methods. Knowledge of uranium geology has advanced rapidly, and all the known characteristics of uranium occurrences are helpful to the prospector. In most areas, the occurrences are confined to certain formations, and in others the genesis of ore depended on the relationship of permeable and impervious formations. The ratio of mudstone to sandstone, for instance, proved useful in one extensive prospecting program, and the bleaching of Moenkopi beds from dark red to light yellow indicated the presence of former water channels and the possibility of mineralization. Structure of the rocks, such as faulting and folding, often plays an important part in the deposition of ore (*14*).

Radiometric methods have been of great importance in prospecting. Uranium and thorium minerals are radioactive, and this provides a major advantage over prospecting for other minerals. The *Geiger-Muller counter* was the first portable instrument. When the tube of a Geiger counter is placed near a source of radioactivity, the radiations produce pulses of electric current which can be amplified and can be used to actuate a meter, flash a neon light, or produce an audible click in a headphone. The *Scintillation counter* is more sensitive than the Geiger counter. Radioactivity occurs everywhere, as all rocks contain minute amounts of uranium and thorium, and cosmic rays are continually striking the earth from outer space, hence, a counter will always show a *background* count and only the radioactivity above that is important. Prospecting with a counter varies from tests of individual specimens and outcropping rocks to systematic radiometric surveys of extensive areas, which may include airborne surveys as well as ground surveys. From 1950 to 1960 AEC and the U.S. Geological Survey, acting for AEC, made many airborne anomaly maps which showed the location on the public domain of surface areas of high radioactivity.

Geochemical methods have been used to a slight extent in recent years and have good possibilities for the future. A study of the relative abundance of the elements is involved, and the methods depend on the analysis of trace amounts of uranium or other indicator elements in soil or rock. Considerable technical knowledge of chemistry and analytical techniques is necessary, but the method is relatively cheap and rapid. A phase of the subject is geobotanical prospecting, in which the uranium content of plant ash is analyzed. Uranium deposits as deep as 60 feet have been detected chemically in surface vegetation (*13*).

The final appraisal of an ore body requires delineation of its extent and thickness. If the ore body outcrops on the surface, some of the work can be done by surface sampling, but in most cases it must be done by exploration mining or drilling. Drilling is the most economical method of exploration. About 9 million feet of drilling was done annually during the peak of the domestic uranium exploration program in 1956–58. The Ambrosia Lake, N. Mex., ore bodies were discovered at depths of about 300 feet by drilling. Other ores in the district are as deep as 1,500 feet.

The diamond core drill was used extensively on the Colorado Plateau in early exploration drilling. The wire-line method of extracting core is satisfactory in well-consolidated rocks, but in drilling through loose overburden or unconsolidated rock formation, the core can be frozen by circulating a chilled low-temperature fluid, such as dewaxed diesel oil cooled with dry ice, to form solid cohesive cores. Cheaper methods of drilling have become popular, particularly for development drilling. Noncore drilling methods utilize rotary-table, swivel-head, cable-tool (churn), or pneumatic-percussive drills. Much exploration is done under contract with firms that specialize in drilling (*15*).

Mining

The mining of uranium ore can be classified broadly into open-pit and underground methods. In 1963, almost 3.5 million tons of ore valued at $19.67 per ton (including $0.11 for byproducts), together with 36.5 million tons of waste was mined in the United States by open-pit methods; while an almost identical amount of ore valued at $20.55 per ton (including $0.16 for byproducts), together with 1 million tons of waste was mined by underground methods.

Open-pit mining is particularly well adapted to flat beds of ore that lie relatively near the surface. A few shallow deposits covered with loosely consolidated soil or detritus could not be mined by any other method. In other cases, the choice of method depends fundamentally on the relative mining costs for the required output and often presents a complex engineering problem. Size, shape, grade, depth, and thickness of the ore body must be considered. Stripping overburden may be a large part of the cost of mining, and the depth that may be removed depends on its character and accessibility. Some may be mined to depths of more than 500 feet, but as overburden above the ore zone increases over 300 feet, underground methods may become more feasible (*6*).

Front-end loaders, small gasoline or diesel shovels, and trucks have been used to mine small deposits within 30 feet of the surface. Bulldozers are often used to shove loose overburden to one side, with wagon drills and jackhammers being used where drilling is necessary. Sinuous

and irregular masses of ore are easily followed with this equipment. In larger operations, stripping to depths of 60 feet can be accomplished economically by power shovel and dragline. Since 1959, virtually all stripping in the larger operations has been done by rubber-tired motor scrapers, pushed when loading by crawler tractors. Crawler tractors are often equipped with rippers, and drilling and blasting are seldom necessary.

Ore and waste removal from the ore zone is done with small shovels, front-end loaders, draglines, and backhoes. Backhoes are particularly effective in removing small pockets or erratic seams. Ore grade control is important in uranium mining, and each mine must develop methods that are suitable for its particular ore body. Most mines resort to stockpiling and blending, and blended material is controlled principally by chemical analyses.

Stripping is often done under contract by earth-moving firms, and costs in 1962 for motor-scraper operations ranged from 10 to 12 cents per yard at 50 feet of depth to 32 to 45 cents at 225 feet of depth. Excavation costs with trucks and 1½- to 2-cubic-yard power shovels ranged from 25 to 50 cents per cubic yard. Ore and waste removal ranged from 40 cents to $1 per ton. Ore control costs ranged from 25 to 80 cents per ton. Haulage costs from stockpiles to mills, usually done by contract, were from 4.5 to 6 cents per ton-mile. Diesel tractor trucks, hauling 20 to 90 tons, are used.

Underground uranium mines use many mining methods and variants because the ore bodies are erratic in shape, size, attitude, and grade. In the early days on the Colorado Plateau, most of the deposits were developed by adit or inclines that followed mineralized outcrops from the rims of canyons or mesas. The discovery of larger and deeper ore bodies made development and mining more complex. The trend towards mechanization has been significant. Few outcropping deposits are unexplored, and new discoveries are being made away from canyon rims or are in relatively flat country, and entry by shaft or incline is more common.

Mining of the smaller ore bodies is usually done by open stoping methods, which may be unsupported or supported by roof bolting and, in the wider places, pillar supports may be used often approaching a room-and-pillar method. Timbering is used scantily around working openings and in emergencies. Very small, irregular ore bodies may be mined by gophering where the ore is followed and mined as found. Development and mining are carried on simultaneously, and many small mines operate with practically no measured ore reserves. Long-hole drilling of walls, roof, and floor is used as an effective means of exploration. Drillings are tested with a Geiger counter or chemical analysis and sometimes the holes are probed. The operator follows the ore by checking the working face with a counter after each round. Separate blasting of ore and waste is often necessary to maintain ore grade (*4*, *5*).

Mining equipment in the small mines varies. Jackleg drills are popular, and jumbo mountings are used in development work in many mines. Transportation may vary from rubber-tired wheelbarrows in gophering operations to hand tramming, animal haulage, and mechanical haulage; any of these can be either the track or trackless type. Motive power for mechanical haulage may be compressed air, storage batteries, or diesel engines. Shuttle cars are often used, and, ore loading varies from hand-mucking to loading by scrapers or mucking machines. The track-mounted overhead mechanical loader is popular (*3*).

The larger mines differ mainly in that planned methods of ore extraction can be applied. Deposits, typically, may range from 300 to 500 feet wide and from 1,200 to 2,200 feet long, with a thickness of 5 to 20 feet. Depth of burial may be 300 feet or much more. The larger shafts are steel or concrete lined and are usually sunk using mechanical shaft muckers.

Mining methods used in the larger ore bodies include the room-and-pillar, longwall retreat, and panel methods. Modifications of each are common, and some features of each may sometimes be found in all three methods (*3*, *4*, *5*). Sublevel haulage is usually used in these operations, the haulage level being driven about 50 feet below the ore horizon and a series of vertical raises to workings in the ore body provide ore transfer and some storage (*2*). Haulageways are sometimes large enough—up to 12 by 15 feet—to accommodate large, trackless haulage equipment. In other cases electric trolley locomotives are used.

In a typical room-and-pillar operation, rooms are about 20 feet wide with the heights depending on the thickness of the ore, usually a maximum of 20 feet. Pillars 50 to 80 feet square are left and can be recovered when retreating from a mined-out area. Drill jumbos, comprising two or more hydraulic booms carrying air drills, are mounted on diesel driven tractors. One miner can drill up to 100 rounds per shift, and about 200 tons of ore is broken per round. Roof bolting, sometimes with chain-link fencing, is required.

In developing an ore body for the longwall retreat method, cuts are made at right angles both ways from a central haulageway on the ore level. Ore broken in the cut is dragged to this haulageway by slusher hoists and loaded by mucking machine into cars to be hauled to a

780-887 O—65——65

transfer raise which leads to the main haulage level below. Two rows of retractable steel props on about 4-foot centers are erected in the completed cut, and they support the ground while the next cut is being made. As each cut is completed, the outer row of steel props is removed and re-erected as an inner row. The mined-out area tends to cave as the cuts retreat, but if it does not do so, previously drilled holes are loaded and blasted. This keeps the roof in the mining area from becoming dangerously stressed.

The panel method has some similarities to both the room-and-pillar and the longwall retreat methods. As in the other two methods, a working or slusher drift is driven along the bottom of the ore body, a sublevel haulage drift is driven below it and the two are interconnected at intervals by ore passes. Ore is systematically blocked out along the slusher drift and, beginning at the far end, mining is started. Rooms about 12 to 15 feet wide are driven perpendicular to the slusher drift, and pillars about 6 feet wide are left between the rooms. Ore is removed from the rooms by slusher hoists which drag lightweight scrapers carrying the ore to transfer raises. When the room is mined out, the pillar is mined, and the ore is recovered with slushers or scrapers. If the roof fails to cave soon after ore removal, it is blasted. Ore recovery with this system approaches 100 percent.

Water is not a big problem in the Colorado Plateau mines. Some mines in Arizona and Utah scarcely produce enough water to supply requirements. At Ambrosia Lake, N. Mex., the ore is in water-saturated sandstone, and the water-saturated ground above the ore was unstable. However, after the ore bodies were drained by the sublevel drifts, the ore and roof rock became more stable.

Ventilation is a problem in uranium mines because of the presence of radon and its radiation hazard. (See Radiation Hazards.) The Division of Occupational Health, U.S. Public Health Service, suggests that at least 500 cubic feet per minute of fresh air be directed to dead-end workings, or 1,000 cubic feet per minute where high concentrations of radon are found. For large stopes or areas, these figures should be increased to 1,000 and 2,000 cubic feet per minute, respectively. Fresh air should be delivered to within 30 feet of the working area. Forced ventilation may be induced by blowers or exhaust fans, directing the air to working areas by doors or ventilation tubing. Secondary ventilation openings can be supplied by large drill holes, 10 to 36 inches in diameter. These are drilled to intersect workings near mining faces, with exhaust fans at their collars. Radon gas and mine dust are thereby removed from these areas without contaminating the rest of the mine. The large 36-inch holes also can serve as escapeways (*1*).

Operating costs in underground mines, including direct and indirect mining costs, exploration, development, and amortization, have ranged from about $11 to nearly $20 per ton of ore mined in the larger developments. In the smaller mines direct and indirect mining costs and exploration drilling ranged from about $12 per ton of ore to as high as $45 in a small high-grade carnotite mine in Colorado, where no breakdown was made between mining and development costs.

Uranium Ore Processing (*2*)

The processing of uranium ores to produce required end products can be divided into the following stages: (1) mill concentrating, (2) refining, and (3) production of the purified end product. Mill concentrating is done by hydrometallurgical leaching methods using either dilute sulfuric acid or alkaline carbonate solutions. Leaching is accomplished with conventional equipment and techniques, but the recovery of uranium from leach solutions involves new techniques. The secondary minerals of the carnotite type, in which the uranium is in the hexavalent form, are rapidly soluble in dilute acid or carbonate solutions. Primary minerals, principally uraninite, coffinite, and uranothorite in which the uranium is quadrivalent, require an oxidizing agent for solution in either acid or alkaline solutions. Fine grinding may be required to insure that uraninite is accessible to the leaching solution. Oxidants added to the leach solution include soluble ferric salts and manganese dioxide or sodium chlorate in the presence of dissolved iron.

Beneficiation of ores prior to leaching has been successful in some cases. Attrition grinding has been used on low-grade ores where the standstone gangue is coarse-grained and loosely cemented with carnotite and a minimum of clay or other friable gangue minerals. Both wet and dry methods have been used. One wet mill ground the crushed ore with rod mills, and desanded the pulp in classifiers and cyclones. The sands were discarded, and the slimes containing 65 to 70 percent of the U_3O_8 and V_2O_5 were sent to leaching. Feed containing 0.04 percent U_3O_8 and 0.4 percent V_2O_5 was upgraded to 0.25 percent U_3O_8 and 2.0 percent V_2O_5, the concentrate comprising about 10 percent of the original ore weight.

A dry upgrader used an Aerofall mill, and the ore was dried concurrently with hot air that swept out the fines for collection as a concentrate in dry cyclones. The coarse material was given a quick leach with acid solution to extract additional uranium. Feed containing 0.25 percent

U_3O_8 was upgraded to about 0.9 percent U_3O_8 in 25 percent of the original ore weight.

Flotation has been tried in a number of circuits but has worked best where a sulfide concentrate, such as pyrite or chalcopyrite, or calcareous impurities could be removed from the ore. Some South African ores are floated to remove pyrite which is required for acid making.

Leaching with sulfuric acid is favored for ores that have small amounts of lime or lime-consuming minerals. Uranium is recovered from leach solutions by either ion exchange or solvent extraction, and variations of the process are based on different methods of accomplishing this. One of the big problems in leaching is to separate the pregnant solution from the solids. Preroasting the ores or adding certain flocculating agents to the leach pulp aided the thickening and filtering of some ores, but had little effect on others. A number of reagents, such as cactus extract, guar and other vegetable gums, glue, and a number of synthetic compounds, were developed and are used as aids in filtering and thickening.

Ion exchange is based on an exchange of ions between a solution and an insoluble resin. This method is particularly applicable to the removal of small amounts of solutes from large volumes of solutions. Anion exchange resins used for uranium recovery are high molecular-weight organic polymers. They contain immobile amine groups and associated mobile ions such as chloride or hydroxyl ions. The resins are virtually insoluble but are porous and contain about 50 percent water so that the mobile ions can diffuse through the resins. In practice, the resins are contacted with the leach solution and the uranium is adsorbed by the resin. While the theory of ion exchange is quite complex, for all practical purposes the uranium passes into the resin molecule in exchange for another anion. The reaction, which is reversible, may be expressed by the following generalized chemical equation, where R^+ represents the fixed portion of the ion-exchange resin, and X^- represents either NO_3^-, Cl^-, HSO_4^-, or $\frac{1}{2}$ $SO_4^=$ ions:

$$4R^+X^- + UO_2(SO_4)_3^{-4} = (R^+)_4UO_2(SO_4)_3^{-4} + 4X^-.$$

Typically, the complex uranium ion in the pregnant leach solution is exchanged for a nitrate (NO_3^-) ion. After the resin is almost saturated or loaded, it is washed free of all leach solution and then it is eluted. In this particular example, the eluting solution or elutriant could be one containing ammonium nitrate. The ion-exchange reaction under these conditions would be reversed from the loading cycle, taking the uranium ion back into solution and replacing the NO_3^- ion in the resin for reuse in the loading cycle. The concentration of uranium in the elutriant is usually much greater than it was in the original leach solution and is recovered from the elutriant by precipitation with ammonia, magnesia or other base, yielding yellow cake, the final mill product.

Ion exchange is essentially a batch operation, but continuous operation is achieved by using multiple units of equipment with staggered operating cycles. In conventional systems the resin beds are in a fixed position in packed columns and the clarified pregnant uranium solution passes through a series of columns. When the first column of the series becomes saturated (loaded), it is removed from the circuit and a newly regenerated column is added to the end of the series. The loaded column is washed and backwashed to remove any sediment and to rearrange the resin particles to prevent channeling. Then, the column is eluted, washed, and is again ready to reenter the loading circuit. Elution is usually done in multistages, which aid in removing all the uranium and producing a richer eluate.

A special adaptation of ion-exchange recovery is the resin-in-pulp (RIP) method. It has the advantage of being able to extract uranium directly from slime pulp, eliminating the clarification steps. After leaching, the pulp is desanded in classifiers and cyclones, and the sands are washed before being discarded. The pulp, now contains only slimes and dissolved uranium. If this slurry was to be passed through a fixed-bed resin unit, solid slimes would accumulate between the resin particles. To prevent this from happening, the resin is contained in rectangular baskets made of stainless steel screen. The baskets are connected to a crankshaft which raises and lowers each one 5 to 10 times per minute in a tank containing the slime pulp. Up to 15 such baskets in series may constitute a bank and the desanded pulp flows into one end continuously. The up-and-down movement of the baskets is sufficiently violent to keep the slimes in suspension and prevent silting, while at the same time giving good contact between solution and resin. Resin for the RIP process is usually made in the form of spherical beads which also help prevent silting. The beads are between 10- and 20-mesh in size. Resin life is usually 2 years or more.

Solvent extraction (SX) is another method of recovering uranium from acid pregnant leach solutions and is also used in uranium refining and fuel reprocessing. The solvent-extraction process consists of intimately contacting the uranium solution with an immiscible solvent, usually kerosine containing a dissolved organic compound. Organic compounds used include some long-chain alkyl phosphates and amines,

di-2-ethylhexyl phosphoric acid (EHPA) being among the most important with tributyl phosphate (TBP) as an additive. Such compounds are functionally similar to the anion-exchange resins and the reactions are similar. A typical amine reaction may be expressed as follows:

$$(R_3NH)_2SO_4 + UO_2(SO_4)_2^{=} = (R_3NH)_2UO_2(SO_4)_2 + SO_4^{=},$$

where R is the organic radical. As with ion-exchange resins, the reaction is reversible.

Uranium ore is leached with dilute sulfuric acid by standard procedures, and a clear pregnant solution is delivered to the solvent extraction plant. Here the solvent extractant and aqueous leach solution are mixed together violently by turbine mixers or high-speed agitators then allowed to settle into two layers, with the kerosine-solvent mixture coming off the top and aqueous solution passing out the bottom. Usually the two solutions pass countercurrently through at least four mixer settlers that sometimes are designed as a single piece of equipment. After extraction, the aqueous solution, called the raffinate, usually contains less than 0.01 gram U_3O_8 per liter and is discarded. The uranium-rich solvent may be stripped of its uranium with soda ash solution. Solvent and stripping solution are intimately mixed and settled in a series of mixer settlers in which the two liquids move countercurrently, very similar to that used in the extractant circuit. Stripped organic liquid is regenerated in this operation and is recycled to the extractant circuit, while the aqueous soda ash solution, now carrying the uranium, goes to precipitation.

Uranium is recovered from the soda ash solution either by neutralizing with acid with subsequent alkaline precipitation or by adding caustic soda to precipitate the uranium as yellow cake. The uranium precipitate is recovered by filtration, then dried and packed in drums for shipment. Causticized soda ash solution may be regenerated by carbonation, but the sulfate solution produced by acid precipitation goes to waste.

Radium, which is always present in uranium ores, is slightly soluble in the leaching process but is not recovered and remains in the waste liquors. Such waste must be handled properly to prevent contamination of streams or underground waters. The Bureau of Mines has conducted investigations of the problem in several mills. The best methods, to-date, consist of (1) recycling of the raffinate, (2) providing for soil seepage and treating the solution with a barium salt which tends to precipitate and immobilize the radium. The problem has not yet been solved satisfactorily.

Refining (*7, 8*)

Uranium metal and compounds used in the production of plutonium and for nuclear reactors require a high degree of purity. Modern feed-materials processing is conducted on a large scale using conventional chemical-engineering equipment, but the purity requirements of the product are those of the fine-chemical or pharmaceutical industries.

Three final products form the principal products: Uranium hexafluoride for isotope enrichment, uranium metal for plutonium production and other reactors, and uranium dioxide for reactor fuel elements. The normal processing stages are the preparation of orange oxide (UO_3); conversion of orange oxide to brown oxide (UO_2); and the fluorination of UO_2 to produce green salt (UF_4), part of which is reduced to uranium metal and the rest is fluorinated to UF_6.

Yellow cake from the mills is dissolved in nitric acid, and the resulting uranyl nitrate, $UO_2(NO_3)_2$, solution is extracted by solvent extraction with a countercurrent flow of a solution of TBP in hexane or kerosine. TBP is highly selective in extracting uranyl nitrate from the digest liquor. This is heightened by giving the loaded organic a light scrubbing with water. The aqueous scrub-solution is recycled and the purified uranyl nitrate is recovered from the organic solvent stream by mixing with pure water. After settling, the stripped solvent stream is recycled to the primary extraction mixer, and the pure aqueous solution is boiled down to molten uranyl nitrate hexahydrate which is then denitrated to produce UO_3. Until recently, the denitration was done batchwise by heating the solid uranyl nitrate in gas or electrically heated, stainless steel pots at atmospheric pressure, but is now being done in a continuous fluid-bed denitrator.

UO_3 is reduced to UO_2 in a two-stage fluidized-bed reactor at 650° to 800° C, using hydrogen as a reductant. Interest in UO_2 as a reactor fuel is growing, and this may be the end product for power reactors. For isotopic enrichment in the gaseous diffusion plants and for the production of uranium metal, uranium tetrafluoride (UF_4) is required as an intermediate. UF_4 is produced by reacting UO_2 with anhydrous hydrofluoric acid (HF). Anhydrous HF at 120° C is introduced countercurrently to UO_2 which is being moved by motor-driven spiral screws along a long cylindrical reactor. The reaction is highly exothermic and rises to about 600° C near the end, where the HF enters and the UF_4 discharges.

Uranium metal is prepared by metallothermic reduction of UF_4 with magnesium in a bomb

reactor. UF_4 and magnesium chips are blended and charged into a steel reactor lined with magnesium fluoride. After charging and capping, the bomb is placed in an electric or gas-fired furnace and heated to about 600° C. Complete reaction requires up to 10 hours, and a regulus of uranium metal about 17 inches tall and 17.5 inches in diameter, weighing almost 3,000 pounds, is produced. Other methods of producing uranium metal include reduction of UF_4 with calcium and sodium, reduction of oxide with calcium and aluminum, electrolysis of fused salts, and decomposition of uranium hydride (UH_3), above about 310° C in a vacuum.

UF_6 is made by reacting UF_4 with elemental fluorine. A monel reactor heated to about 500° C is used and the UF_6, which sublimes at 56.4° C, volatilizes and is deposited as a solid on a cold surface. The UF_6 is shipped to gaseous diffusion plants, where it is enriched in the U^{235} isotope. The separating media in a gaseous diffusion plant are porous barriers, through which the lighter $U^{235}F_6$ vapor diffuses slightly more rapidly than does the $U^{238}F_6$, and a partial enrichment in U^{235} is achieved. In each passage, the proportion of U^{235} is raised a factor of about 1.0014; therefore, to obtain 99 percent pure U^{235} requires about 4,000 diffusion stages. The diffusion plant at Oak Ridge, Tenn., was designed with hundreds of acres of diffusion barriers and thousands of miles of piping.

The fabrication of fuel elements for reactors is extremely complex and involves so many metallurgical and fabrication techniques that it can only be mentioned here. The reader can find many comprehensive texts on the subject (*12*).

Plutonium 239 (Pu^{239}) is produced by irradiation of U^{238} metal in a production reactor. Neutrons captured by the U^{238} produce highly radioactive U^{239}, which decays with a half-life of 23.5 minutes to neptunium 239 (Np^{239}). This in turn decays with a half-life of 2.3 days to Pu^{239}. Pu^{239} is an alpha-emitter with a fairly long half-life of 2.44×10^4 years. The metal is highly reactive and is very difficult to handle because it is one of the most toxic radioactive materials known. It may enter the body through inhalation, ingestion, and absorption through the skin. Once ingested it enters the blood stream and is rapidly assimilated in bones, where most of it will remain indefinitely.

Pu^{239} is also produced in any power or production reactor using fuel elements that contain the U^{238} isotope. Some power reactors, particularly those operating on natural uranium fuel or that have natural or depleted uranium blankets, produce Pu^{239} as a byproduct, which is potentially usable as fissionable fuel. Production reactors are designed especially to produce Pu^{239}.

Natural-uranium metal used in production reactors is encased in aluminum cans prior to being charged into the reactors. After several months' irradiation, the cans are pushed out of the reactor into a canal filled with 30 feet of water. After a month or so of "cooling" to permit some of the intense short-lived radioactivity to die, the cooled elements are sent to the fuel reprocessing plant where the fission products, the Pu^{239}, and residual uranium are separated. Beyond this point, the processing of Pu^{239} for military use is under strict security. Some Pu^{239} is being tested in the Plutonium Recycle Test Reactor (PRTR) at Hanford to demonstrate the feasibility of using plutonium as fuel for civilian power reactors.

USES

Uranium has been used principally for atomic weapons, but the development of nuclear reactors is proceeding methodically and this will be the principal use in the future.

A nuclear explosion occurs when two or more subcritical masses of fissionable material are brought together and held together long enough for a supercritical state to develop. The first bomb dropped over Hiroshima, Japan, was made with U^{235} and the second one, dropped on Nagasaki, was composed of plutonium; each had a detonation yield of approximately 20,000 tons of high explosive, yet weighed only about 10,000 pounds completely encased. The most sophisticated and destructive weapon known to man is the thermonuclear device, known as the hydrogen bomb or H-bomb, the energy of which is created by fusion. Heat and pressure from a fission explosion is used to initiate the fusion reaction.

Nuclear explosives are also being developed for peaceful purposes under the AEC Plowshare program discussed under Research.

Nuclear reactors can be divided broadly into four categories based on their uses—(1) electric-power reactors, (2) propulsion reactors, (3) research and development, testing, and medical therapy reactors, and (4) space and process heat reactors, particularly water desalting.

The great promise of nuclear energy lies in the application of nuclear reactors to electric-power production and propulsion. With a wide variety of fuel, fertile material, coolants, geometry, and types of moderators available, some 900 combinations of reactor design are possible and as many as 100 of these may be feasible. The principal civilian nuclear power reactors in operation, under construction, and under consideration as of December 31, 1963, are shown in table 3. Only reactors with an electrical capacity of over 10,000 kilowatts are listed. In

addition to the 22 listed, 9 smaller electric-power experimental reactors were operable, 5 were being built, 2 were planned, and 8 were operated in the past and dismantled, making a total of 47 power reactors that have developed data on nuclear power.

In addition, 69 military reactors, including those on 3 surface ships and 34 submarines were in operation; and 58 more were being built and 3 planned. Also a total of 125 test, research, and teaching reactors were operable, being built, or planned.

In the United States, the boiling-water and pressurized water reactors are currently the best contenders for full-scale power generation, and a number of companies have selected these for major development. General Electric Co. and Allis-Chalmers Manufacturing Co. are promoting boiling-water reactors, and Westinghouse Electric Corp. and Babcock & Wilcox Co. favor pressurized-water reactors. Atomic Energy of Canada, Ltd., has been developing a pressurized-water reactor that uses natural uranium with heavy water for moderator and coolant. India is constructing a heavy-water reactor and a boiling-water reactor. The British have favored a high-temperature, gas-cooled graphite-moderated reactor using natural uranium. The Peach Bottom, Pa., reactor is a similar type and was built by General Atomic Division, General Dynamics Corp. as a prototype facility.

TABLE 3.—*Principal civilian nuclear power reactors* [1]

Reactor	Location	Electrical capacity, kilowatts	Initial criticality
Operable:			
Shippingport Atomic Power Station	Shippingport, Pa	[2] 60, 000	1957
Dresden Nuclear Power Station	Morris, Ill	200, 000	1959
Yankee Nuclear Power Station	Rowe, Mass	175, 000	1960
Big Rock Nuclear Power Plant	Big Rock Point, Mich	73, 800	1962
Elk River Reactor	Elk River, Minn	[3] 23, 000	1962
Indian Point Unit No. 1	Indian Point, N.Y	[3] 255, 000	1962
Hallam Nuclear Power Facility	Hallam, Nebr	75, 000	1962
Humboldt Bay Power Plant	Humboldt Bay, Calif	48, 500	1963
Piqua Nuclear Power Facility	Piqua, Ohio	11, 400	1963
Carolinas-Virginia Tube Reactor	Parr, S.C	[3] 17, 000	1963
Enrico Fermi Atomic Power Plant	Lagoona Beach, Mich	60, 900	1963
Experimental Breeder Reactor No. 2	Idaho Falls, Idaho	16, 500	1963
Total operable capacity		1, 016, 100	
Under construction:			
Boiling Nuclear Superheat Reactor	Puente Higuera, P.R	16, 300	1964
Pathfinder Atomic Power Plant	Sioux Falls, S. Dak	58, 500	1964
Peach Bottom Atomic Power Station	Peach Bottom, Pa	40, 000	1965
La Crosse Boiling Water Reactor	Genoa, Wis	50, 000	1965
Experimental Gas-Cooled Reactor	Oak Ridge, Tenn	21, 900	1965
San Onofre Nuclear Generating Station	San Clemente, Calif	375, 000	1966
Connecticut Yankee Atomic Power Station	Haddam Neck, Conn	463, 000	1967
Jersey Central Power & Light Co	Oyster Creek, N.J	515, 000	1968
Under consideration:			
Malibu Nuclear Plant	Corral Canyon, Calif	463, 000	1968
Niagara Mowhawk Power Co. (Nine Mile Point)	Oswego, N.Y	500, 000	1968

[1] Including experimental reactors of over 10,000-kilowatt generating capacity.
[2] An increase to 150,000 kilowatts was scheduled for mid-1964.
[3] Including organic-fueled superheat.

NOTE: Power conversion equipment will utilize heat from the New Production Reactor at Hanford, Wash., for generating 800,000 kilowatts in 1966.

Source: Updated from AEC Annual Report for 1963, pp. 75–90.

The development of nuclear energy for water desalting is gaining in importance in the United States and in other countries where potable water is a problem. The International Atomic Energy Agency has undertaken to exchange technical information between interested countries, particularly Israel, Tunisia, Mexico, the Soviet Union, and the United States. In this country, the Department of the Interior and AEC, in consultation with the Office of Science and Technology are collaborating on an aggressive and imaginative program for a large-scale plant to desalt sea water.

Radioisotopes are useful products obtained from special reactors and from the reprocessing of partly burned nuclear fuels. More than 1,000 different radioisotopes have been identified, but most are either too difficult to produce or have too short a half-life to be of practical value. About 100 different ones are useful and com-

prise over 12,000 shipments per year made by AEC at the Oak Ridge National Laboratory, Oak Ridge, Tenn. They are used as a substitute for X-rays for inspecting castings and welds; for sterilizing drugs, medical supplies and foodstuffs; as a power source for small quantities of electricity; gaging control of industrial operations; and many tracer or activating uses.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Much of the vanadium produced on the Colorado Plateau is a byproduct of the roscoelite-carnotite ores. These were mined for their vanadium content long before uranium came into prominence.

Thorium is found in the thorianite-uraninite deposits of the Bancroft Region and in the uranium ores of the Blind River area both in Ontario, Canada. Thorium is recovered as a byproduct from the processing of uranium at the Elliot Lake plant of Rio Tinto Dow, Ltd.

Some of the gold ores of the Republic of South Africa carry recoverable quantities of U_3O_8, in recent years yielding around 0.4 to 0.5 pound U_3O_8 per ton and 0.3 ounce of gold per ton. Other ores in the Transvaal have been primarily uranium producers with about 1.3 pounds U_3O_8 and only about 0.1 ounce of gold recovered per ton of ore.

Uranium also occurs in the land-pebble phosphate deposits of Florida, but the quantity is only about 0.015 percent. A process, nevertheless, was worked out and operated for several years at one of the phosphate plants. The cost of recovery was too high to compete economically with uranium from the Colorado Plateau and large areas of phosphate rock are being mined out without recovering the uranium.

Molybdenum and vanadium occur in the uraniferous lignites of North and South Dakota. These lignites are burned and the ash sent to various mills where molybdenum is leached along with the uranium and, to some extent is recovered separately. The slime tailings from the uranium circuit carry vanadium and a separate recovery system has been installed to recover it.

Copper occurs in recoverable amounts in uranium ore deposits near the Arizon-Utah boundry. A sulfide concentrate is recovered by flotation but requires acid-leaching to remove a small amount of uranium before being sent to a copper smelter. Not all of the copper is recovered by flotation, and most of that remaining is leached with the uranium, where it is recovered by cementation on scrap iron.

Major byproducts of uranium fission are the "atomic ashes" or fission products formed in splitting uranium nuclei into lighter elements. The fission products are a mixture of more than 30 elements, from zinc (atomic number 30) to gadolinium (atomic number 64). About 200 different isotopes have been identified, but only about 80 are produced in fission. The major fission products and the approximate weight percentage present in spent reactor fuel after a 100-day cooling-off period are—

	Percent		*Percent*
Strontium 90	3.8	Ruthenium 103	5.0
Barium 131	4.0	Neodymium 147	10.0
Yttrium 91	2.3	Xenon 133	10.0
Lanthanum 140	4.0	Cesium 137	10.0
Cerium 141	10.1	Molybdenum 99	8.0
Zirconium 95	9.9	Praseodymium 144	4.5
Columbium 95	4.7	Samarium 153	3.0
Tellurium 125	1.2	Technetium 99	2.7
Iodine 129	.6		

Nearly all fission fragments are radioactive, emitting negative beta particles. Many of the products emit gamma rays in addition to beta particles, representing the so-called delayed fission gamma radiation which presents many shielding problems.

The nuclear age has placed emphasis on the development of new special and high-purity materials. These include beryllium, zirconium, hafnium, boron, and cadmium, which are discussed in separate chapters. Other materials, which have a large capacity for capturing neutrons, require development.

ALTERNATE MATERIALS

No immediate substitutes exist for uranium as a nuclear fuel; thorium may complement uranium in nuclear reactors within the next decade. A great international interest in thorium exists, and it is felt that the long-range possibilities of nuclear power include the use of uranium 233 derived from thorium 232.

Controlled release of energy from fusion in thermonuclear devices offers the potentiality of an essentially unlimited source of energy. However, practicality of electrical power from fusion will be dependent upon successful solution of a great multitude of formidable problems.

SECONDARY RECOVERY

Under current technology, about three-fifths of the uranium that enters a fuel element fabrication plant will leave in usable fuel elements. Of the remaining two-fifths, one-half can be recovered in the fabrication plant by remelting and the other half will be so contaminated with foreign matter that it must be recycled through various processing steps and returned to the original stream at appropriate points.

The quantity of atomic fuel used per cycle or fuel burnup ranges from a fraction of 1 percent to about 10 percent of the total amount of fissionable and fertile material. To utilize the equivalent of a single fuel charge in a nuclear reactor, many cycles of burnup and reprocessing recovery, or separation, operations are necessary. The separation process must remove the highly radioactive fission products as well as any accompanying structural or cladding materials from both the fissionable or fertile material; in addition, there must be a degree of separation between the fertile and fissionable material.

RESERVES

Domestic inplace uranium reserves at the end of 1963, shown in table 4, were estimated by AEC to total 66 million tons averaging 0.24 percent, or 160,000 tons of U_3O_8; these inplace reserves are distributed principally in New Mexico, Wyoming, Colorado, and Utah, with small quantities in 11 other States. These data are conservative and probably as well founded as those on any mineral commodity; they are based on uniform statistical analyses of certified and checked sample data. Basic sampling data were reviewed by AEC for accuracy, problems of the mining methods in use were considered, and estimates include only those reserves for which specific data are available. The figures, therefore, represent ore minable under present conditions at $8 per pound.

TABLE 4.—*Domestic uranium ore reserves by States as of Dec. 31, 1963*

State	Million tons of ore	Percent U_3O_8	Thousand tons U_3O_8
New Mexico	32.0	0.24	76.8
Wyoming	24.7	.24	57.0
Colorado	3.1	.27	9.3
Utah	2.3	.30	6.7
Other States (Alaska, Arizona, California, Idaho, Montana, Nevada, North Dakota, Oregon, South Dakota, Texas, and Washington)	3.9	.22	10.2
Total	66.0	.24	160.0

Free-world reserves, shown in table 5, were estimated at 612,000 tons of U_3O_8, over 87 percent being in Canada, United States, and the Republic of South Africa. Data for table 5 were derived from estimates made by AEC, U.S. Geological Survey, Canadian Department of Mines and Technical Surveys, European Atomic Energy Community (Euratom), and industrial staffs. These in turn credit various atomic-energy agencies for their original data. They have been updated to agree with papers presented at the Third Geneva Conference in September 1964. The data are based roughly on the same degree of probability in each case, and on the same criteria as the domestic reserve estimate, following the practice of AEC. Different estimates showed slight variations in a few cases, few of which would be significant.

Data on reserves in Communist-controlled countries are difficult to obtain. Probably among the best are those cited in the Robert McKinney report to the Joint Committee on Atomic Energy, October 1960, volume 4, pages 1613–18. These data list a total of 100,000 to 370,000 metric tons of uranium metal, of which 80,000 to 270,000 metric tons was estimated for U.S.S.R., 20,000 to 100,000 metric tons for China, 100,000 metric tons for East Germany, and the balance for Czechoslovakia, Bulgaria, Rumania, Poland, and Hungary. Materials of a wide range in uranium content were included, and no clear-cut distinction was made between reserves and resources in the sense used for the free-world data.

TABLE 5.—*Free-world uranium reserves by countries as of July 1964*

Country	Tons U_3O_8	Approximate grade, percent U_3O_8
Canada	210,000	0.124
United States	160,000	.24
South Africa, Republic of	150,000	.02
France [1]	40,000	.14
India	12,000	.05–0.30
Australia	10,000	.26
Portugal	7,000	.2
Spain	6,000	.12–0.70
Others, including Argentina, Brazil, West Germany, Italy, Japan, Mexico and Sweden	17,000	.02–0.15
Total	612,000	

[1] Including Malagasy Republic and Gabon.

The estimated resource of domestic uranium is very large. In the frenzied quest for sources of uranium, which began in 1944 shortly after the first self-sustaining nuclear chain reaction had taken place at Stagg Field (December 2, 1942), all known potential resources of uranium were examined and evaluated, and several were tested for possible mining methods and metallurgical recovery. Only the discovery of the high-grade western deposits relegated many of the categories to the status of resources. The magnitude and potential reasonably assured and total resources are listed in table 6. In the distant future, with increasing demand and exhaustion of deposits of the type presently exploited, the price of uranium will rise gradually into the higher categories. The successful development of breeder reactors would utilize uranium so efficiently that higher prices for U_3O_8 would have a relatively small effect on the cost of power.

TABLE 6.—*Magnitude and sources of uranium in the United States*

Group [1]	Price range per pound of U_3O_8	Reasonably assured resources of U_3O_8 (thousand short tons)	Estimated total resources of U_3O_8 (thousand short tons)
1	Under $10	[2] 380	800
2	$10 to $30	400	700

Fuel Value of Uranium Resources

The total energy content of the domestic uranium resources listed in table 6 is shown in table 7. The energy values listed are the theoretical heat units that would be derived by complete fission of all the uranium including the conversion of U^{238} to Pu^{239} and its fission.

TABLE 7.—*Energy content of domestic uranium resources*

Source: AEC, Civilian Nuclear Power, A Report to the President, 1962, Appendix II, p. 34.

In 1963, Department of the Interior Energy Policy Staff prepared a report—Supplies, Costs, and Uses of the Fossil Fuels. In this report, the known recoverable and marginal and undiscovered marginal resources of coal were estimated at 4,220 billion tons with an energy value of 88.6 Q (Q=10^{18} Btu) and the energy value of petroleum, natural gas, natural gas liquids, oil in bituminous rock, and shale oil were estimated at an additional 41.5 Q or a total energy value for all fossil fuel at 130.1 Q.

As with the fossil-fuel resources, all energy in the uranium resources will not be recoverable. Current water reactors average only about 1.3 percent utilization of natural uranium. The U^{235}, which constitutes only 0.7 percent of natural uranium, is readily fissionable, and only a small part of the U^{238} is converted to fissionable material in the simple types of reactors. Hence, improvements in fuel utilization must be achieved if nuclear energy is to become capable of supplying low-cost energy in the amounts that projected future demand indicates. Breeder reactors can convert the U^{238} portion of natural uranium into energy-producing fissionable material and might obtain 50 to 100 times as much energy from a given quantity of natural uranium as present-day reactors. However, breeder reactors are still in an early stage of development, and their successful practical application is half hoped for, half expected, in the decade 1970–80. In an efficient breeder operation, about 80 percent of the uranium will be utilized because of unrecoverable losses in processing reactor fuel and the production of unfissionable higher isotopes during breeding.

CONSERVATION

The mining of uranium ore deposits has, in general, been done very efficiently. The development of room-and-pillar and panel mining systems together with the use of roof bolts and wire mesh have resulted in almost complete recoveries of ore. A few mines have successfully developed and used beneficiation methods for upgrading economically submarginal ores, and some attempts have been made to heap-leach subgrade ore piles or to leach in place, sometimes called solution mining.

Once made into concentrate, uranium passes into custody of AEC and is accounted for very strictly. Because uranium products are very expensive, losses are kept to a minimum. For the same reason, all uranium from scrap or spent fuel is reclaimed. Even if present-day economics does not favor reprocessing, spent fuel is stored, usually in underground places, where it can be reclaimed if future generations find it feasible to rework the material.

Uranium is wasted in a few low-grade materials being mined for other uses, the most significant being the Florida phosphate rock which is mined on a large scale, but recovery of the uranium is uneconomic. The uranium dissolves and becomes a part of the phosphoric acid and eventually ends up in the fertilizer product.

SOURCES OF STATISTICAL INFORMATION

AEC provides the Bureau of Mines with quarterly reports, showing delivery of crude ore and uranium oxide content to processing plants and monthly operation reports of the processing plants. From these data and the annual Bureau of Mines canvass for mine and quarry information from mine operators annual compilations are made showing the quantity of ore and content of uranium oxide shipped to processing plants. The value of mine shipments for each shipper is based on AEC Circular 5 and Circular 5 revised. The provisions of these circulars are no longer in effect, however, payments for purchases of crude ore by mill operators are very similar to those that prevailed when they were in effect. The quantity and value of the uranium oxide recoverable from crude ore shipped to processing plants also is calculated and the data are published in the Minerals Yearbooks.

The annual mine-and-quarry information canvass also gives information on total material handled, mining methods, and exploration and development conducted, which appears under Technologic Trends in the Mineral Industries of the Minerals Yearbook, Volume I, Metals and Minerals (Except Fuels).

AEC publishes information in its annual report on the amounts of U_3O_8 received each year from domestic and foreign suppliers and also issues press releases showing the U_3O_8 content and cost of concentrate purchased. Both AEC and the Bureau respect the confidentiality of company operations, and individual company data are not published unless permission of the company has been given in writing. AEC also maintains records of ore reserves and mill stockpiles at the end of each year and publishes this information in their annual report. These AEC data are published in daily newspapers in areas where interest lies, in the technical journals, and are included in the Bureau of Mines Minerals Yearbook.

PRODUCTION, CONSUMPTION, AND TRADE

AEC has announced that it would not build up a significant stockpile of unprocessed uranium concentrate, therefore, production and consumption of uranium may be considered synonymous. Hundreds of tons of uranium are tied up by inprocess inventories, and even the uranium that enters reactors is not consumed, although it is placed in useful service. For instance, 50 tons of natural-uranium loaded into a production reactor and operated for 1 year at 28,000 kilowatts will consume about 23 pounds of U^{235} and produce almost an equivalent amount of Pu^{239}. Only about 0.1 percent of the uranium can be converted before the charge must be removed and reprocessed. Power reactors consume uranium in a similar manner, but a higher burnup (5 to 6 percent) is possible.

Table 8 shows the production and average grade of uranium ore by States from 1959 to 1963, and table 9 lists the domestic ore production and grade, the concentrate purchased by AEC of domestic and foreign origin and the total cost and per pound cost of domestic concentrate from 1943 through 1963. The data in table 9 from AEC are for fiscal years and will not match data of the Bureau of Mines in the other tables which cover calendar years. Purchase of foreign uranium by AEC is based on contracts some of which date back as far as 1947.

Uranium deliveries in short tons of U_3O_8 anticipated by AEC on existing contracts are as follows:

Fiscal year	Domestic	Canada	Overseas	Total
1964	12, 200	2, 200	3, 850	18, 250
1965	11, 600	1, 250	2, 800	15, 650
1966	10, 500	700	1, 600	12, 800
1967	8, 900	300	650	9, 850
1968	7, 800	----------	----------	7, 800
1969	7, 800	----------	----------	7, 800
1970	7, 800	----------	----------	7, 800
1971	3, 900	----------	----------	3, 900

The free-world production of U_3O_8 by countries, listed in the order of their importance, from 1956 to 1963 is shown in table 10.

Ores and concentrates are duty-free. Metals and alloys have an effective tariff rate of 25 percent ad valorem.

STRATEGIC CONSIDERATIONS

Uranium is the basis for the atomic energy program, because uranium is the only material occurring in nature that is fissionable. Defense of the Nation as well as ultimate success in armed conflict are largely based on the availability of raw materials for, and the ability to produce, atomic weapons. It also seems certain that nuclear power and other benefits of the atomic age will soon become an essential element of economic strength in the United States and in other nations.

Stockpiles of uranium in various forms are distributed throughout the uranium-production process. An inventory of concentrate will al-

ways be stockpiled at the refineries, and various quantities of orange oxide, green salt, and metal will be in process inventories, or in transit between the various feed material plants. At the reactor sites, several thousand tons of uranium are undergoing irradiation. It is necessary before chemical separation to allow substantial time for decay of highly radioactive products in the irradiated metal; thus, additional hundreds of tons of uranium are in storage awaiting chemical separations. At the gaseous diffusion plants, many hundreds of tons of uranium are in various processing stages.

Practically all the uranium procured by AEC is still on hand in some form or another, assuming that plutonium is the equivalent of the U^{235} used in its production. Uranium goes so far that probably only a few percent of that procured has actually been fissioned or consumed. It has been separated or changed in form, perhaps, and stocks of source material can be classed as follows: (1) inprocess inventories, (2) plutonium produced by irradiating U^{238} in production reactors, (3) highly enriched U^{235} separated from natural uranium and delivered to the weapons stockpile, (4) enriched uranium withdrawn from the weapons circuit for research, reactor fuel, and distribution to foreign Governments, and (5) large quantities of depleted uranium for which little use is found today but which may be useful in breeder reactors in the future.

Eventually nuclear energy will be needed to meet the nation's expanding energy requirements. Present resources of coal, oil, and oil shale—with research unquestionably in time lowering their recovery costs—should last beyond the next 100 years. Nevertheless, nuclear-power development should proceed because it may require 30 or 40 years to develop breeder reactors to the point where they can become the principal source of economic nuclear power. After the introduction of breeder reactors, it will take many years to provide sufficient fissionable material to permit a fast rate of growth. It takes about 10 years for a breeder reactor to produce sufficient plutonium (or U-233, if thorium will be the fertile material used) to double reactor capacity.

Prior to the development of the nuclear bomb, uranium was an unimportant metal used in very small quantities as a ceramic coloring agent. With the development of nuclear weapons it became a prime strategic metal, and the self-sufficiency of the United States was very low. An intensive prospecting and development program was initiated, and a very successful series of bonuses, premiums, and long-term contracts built up the uranium mining industry from almost nothing in 1950 to the largest in the free world. The country is now self-sufficient in uranium and need not depend on foreign sources.

Present AEC contracts with mill operators, which carry to 1966 in most cases and to 1970 in others, will probably result in a moderate surplus of material by 1966. Means of production is vital to the future interests of the country, and the problem is to determine how best to sustain the uranium industry during the slack period.

GOVERNMENT PROGRAMS

Uranium production, like most other phases of the atomic energy program, has been developed primarily to meet a military requirement, which is still the predominant factor in determining the AEC procurement program.

Production of nuclear weapons continues at the rate authorized by the President with research directed toward improvement of current weapon models and development of new ones to meet the requirements of the Armed Forces.

The AEC was given the responsibility for regulating the possession and use of source, by-product, and special nuclear materials, under the Atomic Energy Act of 1954. Licensing arrangements permit industrial participation in programs involving source or fissionable materials. All information on military application programs is controlled by the AEC, which also regulates the construction and operation of certain nuclear facilities and the operators of these facilities.

Principal objectives of the uranium program are as follows:

1. Maintenance of uranium production for military and atomic-power requirements
2. Protection against a possible major overproduction with rapid exhaustion of large ore reserves.

When uranium was in short supply, it was necessary for AEC to make long-range commitments wherever possible and to develop new sources of production to assure requirements for the military demand. By 1958, domestic uranium production and reserves attained self-sufficiency, and it was no longer necessary to expand production. In November 1962, AEC announced a new program for domestic procurement to extend procurement time from December 31, 1966, when the present program ends. This program invited milling companies to defer a portion of the concentrates contracted for delivery before 1967 for delivery in 1967 and 1968. An additional quantity of concentrates, equal to the quantity deferred, would be purchased in 1969 and 1970.

In June 1958, AEC removed certain prohibitions on nonnuclear uses of uranium and made depleted uranium available for sale on an un-

classified basis. In August 1964, the Atomic Energy Act of 1954 was amended to permit private ownership of nuclear materials. The amended Act provided that by January 1, 1969, private power producers may buy raw uranium from mines and enrich it themselves. By January 1, 1971, all new distributions of nuclear materials must be by sale, rather than by lease as at present. By June 30, 1973, any materials leased from AEC by private firms must be purchased by those firms or returned to AEC; however, AEC will still retain its licensing and regulatory functions.

The Atomic Energy Act also directed AEC to conduct research, educational, and training programs and to otherwise develop the peaceful uses of nuclear energy. This is discussed in more detail in the section under Research.

Uranium was included in the list of minerals that were eligible for financial assistance under the Defense Minerals Exploration Administration (DMEA) program. This agency was superseded by the Office of Minerals Exploration (OME) on June 30, 1958. DMEA was authorized to contribute 75 percent of the allowable costs of the exploration specified in acceptable projects. With OME the contribution was reduced to 50 percent. Under DMEA, 209 contracts were approved in 16 States, and these totaled $6,505,111 in Government assistance. Only one project was approved under OME for $46,725 in Government assistance. By the end of 1963 $1,364,785 had been repaid on the loans.

PRICES

AEC encouraged the growth of the uranium industry by incentives which included bonuses and guaranteed prices for ores of various grades. The last price schedule, known as Circular 5, was issued in March 1951 and expired on March 31, 1962. After this date AEC contracted with mills for concentrates, and the mills purchased part of their ore supply on an open market basis. Nevertheless, the old Circular 5 prices continued to form the basis of ore purchases. Circular 5 stipulated a base price ranging from $1.50 per pound of U_3O_8 on ore grade of 0.10 percent to $3.50 per pound on ore containing 0.20 percent U_3O_8 or better. In addition premiums were allowed for ores over 0.25 percent, and a development allowance was paid on all ores. Thus, ores containing 0.15, 0.20, 0.25, and 0.50 percent U_3O_8 aggregated $3.00, $4.00, $4.15, and $4.45 per pound of U_3O_8. In 1962 and 1963, average price for ore, which averaged about 0.25 percent U_3O_8, was $4.05 per pound of contained U_3O_8. Under present contracts, mills are paid $8 per pound for specification-grade concentrates.

After 1968 concentrates will be purchased by AEC on the basis of 85 percent of audited allowable 1963–68 production costs per pound of U_3O_8 plus $1.60, but not to exceed a maximum price of $6.70.

Natural uranium metal has been quoted at $24 per pound for several years. Depleted uranium, in the form of UF_6, varied from $2.50 per kilogram of contained metal for material containing less than 0.38 percent U^{235} to $22.60 per kilogram for uranium containing 0.7 percent U^{235}.

Base charges for enriched uranium in the form of uranium hexafluoride (UF_6) varied with the degree of enrichment from $4.77 per gram of U^{235} content for 0.010 weight-fraction (1.0 percent) to $9.59 per gram for 0.050 weight-fraction and $12.01 for 0.90 weight-fraction material.

Base charges established by AEC for plutonium and for uranium enriched in the fissionable isotope U^{233} were—$43 per gram of contained Pu^{239} and Pu^{241}, the isotopes readily fissionable by thermal neutrons; and $82 per gram of contained U^{233}, subject to adjustment for the presence of other uranium isotopes. These charges apply to material distributed within the United States for research and medical therapy and to nations having cooperative agreements with the United States. They determine the payments due AEC for use, consumption, and loss of leased material, as well as sales prices for material sold.

Reduced base charges were established for these materials for use in certain research and development activities under domestic lease agreements. These charges are equal to estimated fuel values in thermal power reactors and were $10 per gram of Pu^{239} and Pu^{241} and $14 per gram of U^{233}, subject to adjustment for the presence of other uranium isotopes.

Prices on radioisotopes produced by AEC are listed in a Radio and Stable Isotopes Catalogue published by Isotopes Development Center at Oak Ridge National Laboratory, Oak Ridge, Tenn. Cobalt 60, the most widely used radioisotope, ranged from $2 per curie for specific activity of 1 through 25 curies per gram to $7.20 per curie for that having specific activity of 191 through 205 activities per gram. Discounts are made for quantities above 5,000 curies.

TAXES

The mining of uranium from domestic or foreign deposits is eligible for a 23-percent depletion allowance under the Internal Revenue Code of 1954.

TRANSPORTATION

Transportation of radioactive materials in interstate commerce by land or water is subject to Interstate Commerce Commission regulations. In aircraft, transportation of such material is regulated and prescribed by the Federal Aviation Agency. Pertinent regulations are also promulgated by the Coast Guard, and Post Office authorities. Detailed information on many of the basic problems involved in the transportation of radioactive material is contained in a preliminary report 2–5, Physical, Biological, and Administrative Problems Associated with the Transportation of Radioactive Substances, published by the National Research Council, Washington, D.C.

RESEARCH

Nuclear energy inspired worldwide research on a scale that was never before known. The Atomic Energy Act of 1954 directed AEC to promote the conduct of research and development—both within Government-owned facilities and by private and public organizations—that will assist in acquiring theoretical and practical knowledge about nuclear energy and its application. Research is conducted in Government-owned facilities and under contract with private and public organizations, such as colleges, universities, medical centers, and industrial firms. All phases of research are covered—basic, applied, and exploratory development.

Primary objective of AEC-sponsored research and development is to attain new knowledge about the nature of nuclear forces and their effects and how to put these effects to use for the good of mankind. Annual reports of this research are published and a listing of projects covered in the table of contents for 1963, occupied 13 printed pages (*17*). Broadly speaking, the type of research may be divided into five groups: (1) research in the medical and life sciences; (2) environmental radiation studies in ecology on land, fresh-water, and marine systems; (3) Plowshare program and fundamental science of nuclear detonations; (4) basic physical research in physics, nuclear physics, mathematics, chemistry, metallurgy, and controlled thermonuclear science; and (5) nuclear reactor research and development, including fuels, materials, reactor-component development, reactor physics, and chemical process development.

The 12 principal research and development installations of AEC (contractors are shown in parentheses) are as follows:

1. Ames Laboratory (Iowa State University), Ames, Iowa.
2. Argonne National Laboratory (University of Chicago), Lemont, Ill.
3. Bettis Atomic Power Laboratory (Westinghouse Electric Corp.), Pittsburgh, Pa.
4. Brookhaven National Laboratory (Associated Universities, Inc.), Upton, N.Y.
5. Hanford Laboratories (Battelle Memorial Institute), Richland, Wash.
6. Knolls Atomic Power Laboratory (General Electric Co.), Schenectady, N.Y.
7. Los Alamos Science Laboratory (University of California), Los Alamos, N. Mex.
8. Mound Laboratory (Monsanto Research Corp.), Miamisburg, Ohio.
9. National Reactor Testing Station (Phillips Petroleum Co., Aerojet General Corp., and General Electric Co.), Idaho Falls, Idaho.
10. Oak Ridge National Laboratory (Union Carbide Corp.), Oak Ridge, Tenn.
11. Sandia Laboratory (Sandia Corp.), Albuquerque, N. Mex.
12. University of California, E. O. Lawrence Radiation Laboratory (University of California), Berkeley and Livermore, Calif.

Other AEC research was conducted in 1963 under about 1,380 contracts, 668 were in biology and medicine, 568 were in physical research, and 144 were in reactor development and waste management. Table 11 lists AEC research and development costs for fiscal years 1959 to 1963. For comparison, the net cost of all AEC operations is included. AEC investment to June 30, 1963, for research and development totaled $1,886 million acquisition cost or a net after depreciation of $1,388 million. Comparative investment in production facilities was $5,447 million and $3,706 million, respectively.

For all practical purposes, most of this research is brought to fruition in the AEC Reactor Development Program, which was established in 1948 as a strictly governmental effort; the law then prohibited private ownership of any facilities capable of producing significant quantities of fissionable materials. In 1951, AEC invited private industry, at its own expense, to study reactors. The Atomic Energy Act of 1954 encouraged private initiative to enter into nuclear power development, and the first invitation issued in December 1953 led to the Shippingport Atomic Power Station. In 1955, AEC announced its Power Demonstration Reactor (PRD) Program which offered to assist in defraying the research and development costs of nuclear power reactors and to waive the use-charge for leased fuel during

TABLE 11.—*AEC research and development costs for fiscal years*

[Thousand dollars]

	1959	1960	1961	1962	1963
Development of nuclear reactors:

Source: AEC annual financial reports for 1960–63.

early years of the plant operation. Since 1955, AEC has invested about $3.5 billion in the development of nuclear reactors and has also engaged in a series of cooperative agreements with industry for civilian power development (*11*).

The first invitation of the PDR Program, issued in January 1955, offered technical and financial assistance including the waiver of normal charges for special nuclear materials and the support of research and development. From this the Yankee Atomic Power Plant, the Hallam Nuclear Power Facility, and the Enrico Fermi Atomic Power Station (see table 3) were undertaken.

The second invitation, issued in September 1955, requested proposals for small-scale nuclear power plants in which AEC owns the nuclear steam supply system and paid the cost of fabricating the first core as well as related research and development costs. The utility provides plant site, furnishes the nonnuclear power facilities, operates the nuclear portion under contract with AEC, purchases from AEC the steam produced by the reactor, and has an option to purchase the reactor. Under this arrangement, the Piqua and Elk River reactors were constructed.

The third invitation extended in 1957 was in most respects similar to the first invitation, but placed no limit on the type or size of plant. This led to the planning of the Carolinas-Virginia and Pathfinder reactors. A modification of the invitation led to the planning of the Malibu and Haddam Neck plants. The Peach Bottom reactor, using uranium-thorium fuel was in response to a separate invitation.

Unsolicited proposals from industry for cooperative nuclear power-plant projects were included in AEC 1960 authorization acts and led to the construction of the Big Rock, Puente Higuera, LaCrosse, and San Onofre nuclear prototype plants.

The Dresden, Indian Point, Humboldt, Oyster Creek, and Nine Mile Point reactors were initiated by utility companies without AEC assistance.

Early in 1964, AEC invited electric utilities to submit proposals for the design, construction, and operation, in cooperation with the Government, of a number of prototype advanced converter reactor plants. Two proposals were accepted as a basis for seeking authorization and funding. One was for a 260,000-kilowatt high-temperature gas-cooled reactor proposed by Rochester Gas & Electric Corp. and General Dynamics Corp., to be built near Rochester, N.Y. The other was for a 525,000-kilowatt seed-blanket reactor employing the thorium fuel cycle. This was proposed by the California Department of Water Resources and, if located on the coast, the plant may include a sea-water desalting facility.

Most companies interested in nuclear developments also maintain research and development facilities at their own expense, some of which are very large. It would be impossible to cover even a token reference to research activities in this chapter, as the annual AEC reports of some 400 pages profess only to be able to cover the highlights of their research activities. The results of most research activities, except for secret and proprietary information, is published in technical journals. AEC publishes abstracts of the international literature on nuclear science and technology issued twice each month since 1947 as Nuclear Science Abstracts (*16*).

Basic research has lead to the development of more versatile, efficient, and economic ore treatment and chemical separation methods. Techniques, such as ion exchange and solvent extraction used mostly on a laboratory scale before 1950, came into wide use in large-scale plant operations. The Bureau carried out an extensive program of ore-sample analysis, process development, and ore-amenability testing under a cooperative arrangement with AEC. The Bureau also worked with the Battelle Memorial Institute and Rohm & Hass Laboratories in developing amine extractants. The Bureau has contributed to reactor development and waste management in such widely diversified fields as metal-melting research, alloy development, thermodynamics, high-temperature heat transfer, and application of gas bearings to turbocompressors. Metallurgical work has extended to other metals, such as zirconium, columbium, hafnium, and rare-earth metals, which have specialized applications in reactors.

OUTLOOK

Uranium production probably will lag appreciably behind the general metal industry and national rate of growth until 1970 or 1980. After that the adoption of nuclear power is expected to accelerate, overtaking the national growth trend and possibly reaching boom proportions. Nuclear weapons will continue to be the major factor in requirements over the next decade. Uranium requirements for nuclear power plants between now and 1966 will total only a few thousand tons. The AEC estimates of domestic civilian uranium requirements range from 1,600 to 4,000 tons of U_3O_8 per year in 1970, 8,900 to 14,000 tons in 1975, and 19,000 to 27,000 tons in 1980. Foreign requirements for uranium enriched in AEC facilities might be of the same magnitude.

The short-term outlook for mine and mill production of uranium oxide (U_3O_8) is closely circumscribed by AEC procurement contracts which extend through 1966 in most cases and through 1970 in some cases. Domestic procurement as planned by AEC will gradually decrease from the 17,000 tons of U_3O_8 produced annually in 1960–62 to 7,800 tons in 1968–70. Procurement from foreign sources, which was higher up to 1960 than domestic production, will decrease rapidly and cease after 1967.

Development of peaceful uses for nuclear explosives is the objective of the AEC Plowshare program in which the Bureau cooperates. Civil works applications under consideration include excavation of harbors, canals, highway and railroad cuts, and other similar works; mining applications being studied include stripping of overburden prior to open pit mining, breaking of ore underground for mining by methods similar to block caving, and fracturing of low-grade ore deposits for in-situ leaching; petroleum applications include fracturing of low permeable gas and oil beds to stimulate products movement, fracturing of oil-shale for in-situ retorting, and recovery of oil from tar sands. Production of chemicals and radioisotopes on a large scale in underground formations appears possible and preliminary results of tests are favorable. Plowshare activities include research to develop nuclear devices for special application where very low radioactivity is required or where high neutron flux is required. Studies of product contamination and methods to prevent contamination or to decontaminate such products are being made.

The present AEC contract price of $8 per pound of U_3O_8 in concentrate form will remain in effect until 1969 when the price will be limited to a maximum of $6.70 per pound. World prices then are expected to stabilize probably around $5 per pound of U_3O_8 until such time that demand begins to approach production ability.

Legislation enacted in 1964 amended the Atomic Energy Act of 1954 to permit full private ownership of special nuclear materials and eliminated mandatory Government ownership. One of the principal effects of this legislation will be the establishment of open-market prices for all nuclear materials based on fuel value rather than weapon value or military exigency. After 1970, when the present procurement contracts expire, the industry will be ruled by the same economics of supply and demand as any other mineral commodity. Domestic producers may be faced with strong foreign competition.

Aside from nuclear weapons, uranium will continue to be used mainly for nuclear applications, the principal ones being heat and power reactors, both civilian and military, including naval propulsion. The world has such need for power sources that the incredible energy of nuclear fission is already at work in many countries around the globe. The only indeterminate factor is the future date at which nuclear power will be ready for general acceptance and begin its ascendency. Long-term projections on the demand for uranium depend on an evaluation of the trends of basic research and development both in reactor technology and in power production from fossil fuels. Since progress is dynamic in all these fields, forecasting is exceedingly difficult, and continuous study and revaluation will be required for the guidance of industry. Nuclear power development has

proceeded rapidly, and the imminence of economic nuclear power has stimulated the coal and coal-transport industries to greater efficiencies. For some time yet to come, nuclear power plants will be justified only in locations where fossil fuel costs are high. A faster rate of nuclear power development will probably take place in Great Britain than in the United States, because the English coal measures are declining in productivity and coal prices are rising. On the other hand, unpredictable discoveries of large pools of oil or gas can upset the best of calculations. Typical of this is the recent discovery of natural gas in Holland, which apparently will provide low-cost fuel in that area for many years.

Nonnuclear applications of depleted uranium are being developed and will provide a small supplemental market. Research in this field has been intensive, both in this country and abroad, and has produced many prospective useful applications.

The utilization of radioisotopes will continue to increase as new applications are found and old ones are broadened. Radioisotope production in special reactors will decline as the reprocessing of nuclear fuel from power reactors increases, when the supply of many of the long-lived isotopes will be far in excess of demand.

The U.S. Government, as well as many other governments, will continue to assist in the research and development of nuclear energy for both peaceful and military uses. The long-term plans of AEC include an extensive nuclear-reactor research and development program predominantly concerned with advanced nuclear systems, developing and improving nuclear power and propulsion systems, and improving engineering safeguards for all nuclear applications. Reactor development includes cooperative assistance in constructing plants, utilizing presently most competitive reactor types and the development, construction, and demonstration of advanced converter and breeder reactors which will fill the long-range needs of utilizing fertile as well as fissile fuels. The advanced types of reactors on which development can be expected include those moderated with heavy-water, the sodium-cooled graphite-moderated type, the gas-cooled high-temperature reactor, the seed-blanket type, and the nuclear superheat concept, all of which are classed as converter reactors that produce almost as much fissionable material as they consume in their operation. Breeder types, that produce more fissionable material than they consume, also will continue to be investigated intensely in a long-range effort to develop the utilization of the full potential energy available in nuclear fuels.

AEC will also continue its other major activities including basic research in physics, biology, and medicine; the applications of nuclear explosives to excavation and mining (Plowshare program); the application of nuclear energy to the desalination of water; the development of radioisotopes; and its support activities which include educational assistance, industrial relations, public and technical information programs, and, of course, the regulatory activities of licensing, compliance, and radiation protection.

The use of uranium will not suffer materially from competition by thorium breeder reactors. Thorium reactors offer certain theoretical advantages, but they also have many disadvantages that must be overcome by research and development. It is probable that both uranium and thorium will find specific applications and, in the distant future, will complement each other. In any case, fissionable U^{235} will be required to initiate and maintain a thorium breeder until such time (probably around 10 years) that sufficient U^{233} has been produced to replace the U^{235}.

Thermonuclear energy produced by the nuclear fusion of the light nuclei deuterium and tritium does not appear to threaten the uranium industry, barring some senational unpredictable discovery. While fusion has been accomplished on a very small scale, many difficult problems must be solved to arrive at its practical application, and for some of these a means of approach have not been developed.

780-887 O—65——66

PROBLEMS

The uranium industry has the problem of adjusting to a very low level of activity until market growth resumes, possibly after 1970. Producers also face the necessity of making a transition and adjustment from a guaranteed market to a free market. Planning is difficult because demand, prices, and the nature of foreign competition are difficult to assess with any degree of certainty.

Relatively little exploration has been done in the major uranium-producing countries since 1958, and production has depended largely on reserves developed in the 1950's and has depleted and probably will continue to deplete known reserves for some time. Many experts believe that nuclear-power developments will surge ahead rapidly by 1970 or 1980. Since new reactors require a large initial charge of uranium, an extensive program of reactor building could exhaust reserves rapidly and result in a shortage. There need be no concern about a shortage if exploration is undertaken well in advance of the expanding requirements.

The extremely varied aspects, attitudes, and distribution of uranium ore deposits present many mining problems. Likewise, complex mineralogical associations pose metallurgical problems. Constant research and development in these areas will be necessary for those who wish to stay in business in the face of competition, rising costs, and lower grade and deeper ores. Mining of incompetent ground, control of ground water, and combating the hazard of radioactivity, particularly from radon, are major factors that tend to increase mining costs. Means of simplifying or improving ore processing as applied to increasingly more complex lower-grade ores will be essential to maintaining an adequate supply and a stable industry.

Uranium ores contain many potential by-products, including vanadium, molybdenum, selenium, scandium, and radium, some of which are incompletely recovered or not recovered at all. Economic methods of recovery need to be studied to recover and conserve these elements.

Acquiring comprehensive knowledge on the application of nuclear explosives to mining and excavation present a broad field for research and investigation.

Problems associated with the application of nuclear energy and radiation involve almost every scientific and engineering discipline and range from basic or fundamental principles to the practical design, construction, and operation of reactors. Even those involving nuclear reactor research and development are too numerous to list herein. Those of primary interest to the mineral industry include the study and improvement of reactor components, particularly fuels and fertile materials, fuel reprocessing, and cladding and structural materials. A major problem is the development of structural reactor components suitable for operating above 2,000° C.

Reactor accidents can result in serious explosions or in release of fission products, either of which can create radioactivity hazard over a wide area. The safety record with reactors has been excellent, largely because of the safety measures employed. Engineering design must include multiple precautions against any conceivable eventuality. At the same time, the public, often confused by publicity regarding fallout from nuclear explosions, must be kept informed of these safeguards; otherwise suspicion and fear can create serious problems in choosing sites for nuclear reactors.

The disposal of radioactive waste poses problems in all operations from the mining and milling of uranium ores to its refining and the fabrication of fuel elements. However, fission products contained in irradiated fuel elements constitute the dominant waste disposal problem. Present methods of disposal consist mainly of deep burial, either in the sea or underground, of variously compounded forms containing the radioactive materials. Some more useful method should be devised, and one of the more favorable avenues of attack would be to develop methods of utilizing either the heat or radiation being generated by these wastes.

Large stocks of depleted uranium, mainly uranium 238 from which most of the fissionable uranium 235 has been separated, have been accumulated. Means of utilizing this depleted uranium are urgently needed.

VANADIUM

By Gilbert L. DeHuff [1]

VANADIUM is an important alloying element in steels and other metals and an important catalyst for various industrial processes including sulfuric acid production and petroleum refining.

For more than two decades the United States has been the largest producer of vanadium with most of its production coming from the Colorado Plateau area in association with the production of uranium. The Republic of South Africa and the U.S.S.R., both with very large vanadium resources, are becoming important producers. U.S. reserves of high-grade material are limited, but relatively low-grade resources are large. The principal domestic resources are contained in the vanadiferous shales and phosphate rock of the Phosphoria formation in Idaho.

The chief use of vanadium is as an alloying agent for steels and irons, usually in small quantities and in company with other alloying elements. In this connection it is used to reduce and control grain size; to impart toughness, strength, and resistance to impact and abrasion; and to maintain hardness at increased temperatures. Furthermore, it is an important constituent of titanium and aluminum alloys. It has numerous chemical uses, one of the most important being in the preparation of catalysts for various industrial processes including the production of sulfuric acid.

Consumption of vanadium is growing rapidly. With decline in production from Colorado Plateau ores, the United States will need to turn more toward other sources for its vanadium. It will need more economical methods for recovery of the vanadium from large low-grade resources if it is to meet the demand without depending on foreign sources.

BACKGROUND

Vanadium was identified as a distinct element about 1830, and its salts had found uses by 1860 in coloring fabrics, leather, glass, and pottery. Its employment as an alloying element in steels was recognized by the U.S. automobile industry by 1905 and was advertised as a feature of the 1908 Ford. In 1896, French scientists had experimented with vanadium as an alloying agent in armorplate, and work at Sheffield, England, in the following years determined that it improved cutlery, tools, and constructional steels as well as armor.

Some vanadium-uranium ores were mined in Colorado as early as 1902, but discovery of the rich Peruvian deposit of Mina Ragra in 1905 appears to have launched the vanadium industry in the United States on a significant scale.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

For more than 20 years the United States has been the largest producer and apparently the largest consumer of vanadium, but production has decreased since stretchout of the Atomic Energy Commission's (AEC) buying program for uranium. The great bulk of the Nation's production in recent years has been as a coproduct or byproduct of uranium mining and processing operations, and more vanadium has been available from these mined ores than could be used or exported. This has resulted in some accumulation of intermediate sludges, tailings, and other materials which have had the uranium removed but not the vanadium. Although this vanadium production has been dependent

[1] Commodity specialist.

on uranium production, a substantial quantity of uranium has been produced during this period from ores too low in vanadium to warrant treatment for its recovery. Before becoming dependent on uranium output a large portion, perhaps more than half, of U.S. production of vanadium was from Colorado Plateau ores which were of relatively low uranium content—too low, for the most part, to be of continued interest when the uranium market developed.

At the end of 1963, four companies (table 1) were operating one mill each to recover vanadium in the form of vanadium pentoxide from western uranium-vanadium ores, which were obtained both from company mines and from independent operators. Two of these companies also were producing ferrovanadium, but each at locations other than their oxide mills. Two other companies were significant producers of ferrovanadium. In all cases, production of ferrovanadium was accomplished in plants producing other ferroalloys as well. Several firms recovered relatively small quantities of vanadium pentoxide or ammonium metavanadate from miscellaneous sources such as ferrophosphorus, foreign chrome ores, and oil residues.

TABLE 1.—*Principal producers of vanadium oxide and ferrovanadium in the United States, in 1963*

Company	Location	Product
American Metal Climax, Inc.	Grand Junction, Colo.	Oxide.
Mines Development, Inc.	Edgemont, S. Dak.	Do.
Reading Alloys Co., Inc.	Robesonia, Pa.	Ferrovanadium.

Union Carbide Corp., Nuclear Division.	Rifle, Colo.	Oxide.
Vanadium Corp. of America.	Cambridge, Ohio	Ferrovanadium.
Do.	Shiprock, N. Mex.	Oxide.

The European market is supplied by vanadium pentoxide from Finland, South-West Africa, the Republic of South Africa, and the United States. Extensive iron ore deposits having a vanadium pentoxide (V_2O_5) content of 0.02 to 0.20 percent, occurring in Germany, France, Luxembourg, and Belgium, provided vanadium for Germany in World War II. Vanadium was also obtained by Germany at that time from Swedish and Norwegian iron ores and from steel mill slags. These slags, bauxite residues, and iron ores possibly still contribute some vanadium to the European supply.

The Finnish production comes from vanadiferous, titaniferous magnetite of the Otanmäki mine at Otanmäki in central Finland. The Otanmäki company is a wholly government-owned corporation.

South-West African shipments are obtained from oxidized ore of the upper levels of the Berg Aukas lead-zinc mine of South West Africa Co., Ltd.

Transvaal Vanadium Co. (Pty.) Ltd., a subsidiary of Anglo American Corp., was the only producer in the Republic of South Africa in 1963. However, another subsidiary of Anglo American Corp., Highveld Development Co., Ltd., was seriously investigating the possibilities for a steelmaking project which would produce 12,500 short tons of coproduct vanadium pentoxide annually. African Metals Corp., Ltd., also was engaged in exploratory work in 1963 looking to possible production of vanadium pentoxide for export.

The U.S.S.R. appears to have satisfied its needs for vanadium, at least in part, from small vanadate deposits and from certain vanadiferous iron ores. Plans for increasing regional steel production, using iron ore from large vanadiferous deposits which until now have been relatively untapped, are expected to result in a big increase in vanadium production.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Technical-grade vanadium pentoxide is the most common product of the vanadium mills and is the feed material generally used for production of ferrovanadium, other vanadium alloys, and metal. It also has chemical uses. Relatively small quantities are used for direct additions to electric-furnace steels. It is available as the fused oxide (flakes generally containing 86 to 99 percent V_2O_5), also called black flake, fused black oxide, and black oxide, or even loosely referred to as vanadic acid; or it may be obtained as air-dried oxide (a powder analyzing 83 to 86 percent V_2O_5). National Stockpile Specification P–58–R, December 11, 1957, "Vanadium," specified that grade A fused black vanadium oxide procured for the national stockpile shall have a minimum V_2O_5 content (dry basis) of 86.00 percent. The maximum limits for eight elements other than vanadium or oxygen were each set at 0.15 percent or less, and for insolubles at 1.00 percent.

Chemical grades of vanadium pentoxide, variously referred to as high-purity, purified, or C.P. yellow air-dried, have typical V_2O_5 contents of 99.5, 99.7, and 99.94 percent, respectively.

Ammonium metavanadate (NH_4VO_3), another form in which vanadium is marketed, particularly appeals to the chemical industry's requirement for vanadium. It is available commercially in both technical and chemically pure grades. Other oxides include sodium

metavanadate, sodium orthovanadate, and red cake (sodium polyvanadate). The latter is the mill-product oxide immediately before the final step of fusing to obtain the technical-grade pentoxide product.

Ferrovanadium, an alloy of iron and vanadium, is marketed in a number of grades. Those for use in steelmaking are the large-volume items. They consist of the open-hearth grades, containing 50 to 57 percent vanadium, with maximums of 8 percent silicon and 1 to 3 percent carbon; the crucible or special grades, containing 50 to 57 or 70 to 80 percent vanadium, with maximums of 2.25 percent silicon and 0.50 percent carbon; and the refined, primos, or high-speed grades, containing 50 to 57 or 70 to 80 percent vanadium, with maximums of 0.50 to 1.50 percent silicon and 0.20 percent carbon. Foundry-grade ferrovanadiums are available with 38 to 42 percent vanadium, 7 to 11 percent silicon, and 1 percent carbon; or with 50 to 55 percent vanadium, 10 percent silicon, and a maximum of 3 percent carbon.

Vanadium metal is produced as a 90-percent grade, used for alloying purposes, or as a high-purity, ductile metal containing 99.5 percent or more vanadium. The latter can be obtained as crushed material, as ingot metal, or as wire, rod, sheet, foil, and other fabricated forms.

TECHNOLOGY

Geology

Among the more important of the discrete vanadium ore minerals have been the complex sulfide, patronite; the vanadium mica, roscoelite; the hydrous potassium uranium vanadate, carnotite; and the lead vanadates, vanadinite and descloizite.

The most productive source of vanadium in the past 20 years has been the uranium-vanadium deposits in the sandstones of the Colorado Plateau. They have consisted for the most part of numerous, widely distributed, relatively small, tabular deposits; carnotite and roscoelite have carried much of their vanadium content.

At Mina Ragra, in the Andes of Peru at 16,500 feet, a lens-shaped body of asphaltite and patronite, dipping 75° and occupying a fracture in shales and thin-bedded limestone of Cretaceous age, was mined for its vanadium content from 1907 until August 1955. A variety of vanadates, together with vanadium sulfate, occurred as alteration products in the oxidized zone near the surface (*6*).[2] Other similar asphaltic veins are found in the same sedimentary beds of the region but contain only about 1 percent V_2O_5—a much lower vanadium content. Vanadiferous asphalts also are known in other countries (*4*).

Vanadates of lead, zinc, and copper found in the oxidized portions of certain base metal deposits have been the source of the vanadium produced in South-West Africa and Northern Rhodesia. Minor production has come from the Southwestern United States and from Mexico. Other occurrences have been reported from Spain, Africa, and Australia.

Vanadium is a constituent of many iron deposits, vanadium ions replacing those of iron in iron and other minerals rather than occurring as distinct, identifiable, vanadium minerals. Vanadiferous titaniferous magnetites in South Africa and Finland have become important sources of vanadium, and large deposits are known in the U.S.S.R. and the United States. Although these magnetites are associated with both anorthosites and gabbros, the most promising for vanadium are those associated with the anorthosites. The vanadium is linked principally to the magnetite rather than the ilmenite mineralization of these bodies. Vanadium is also a constituent of some sedimentary iron ores to the extent that they can be considered a source, or potential source, of vanadium. Deposits of this kind are under development in the U.S.S.R.

Vanadium occurs as a constituent of certain clays and shales. The vanadium content usually increases with increase in the content of organic material, and certain phosphatic shales and phosphate rock of the Phosphoria formation of Idaho and Wyoming represent a large resource. Some coals also contain sufficient vanadium to yield several percent vanadium in the ash; others are virtually without vanadium. Certain petroleums, particularly in Venezuela and Mexico, have sufficiently high vanadium content to justify its recovery from the oil's residues and soots.

Some bauxites and laterites contain vanadium, as do some titaniferous magnetite beach sands. Although the vanadium content of most bauxite is low, in certain European countries vanadium is sufficiently concentrated in the red muds of the Bayer-alumina process to warrant its recovery.

Mining

Prior to 1948 Colorado Plateau ores were mined underground at shallow depths, on a highly selective basis, and on a small scale. The small pods or lenses which constituted the ore being mined were developed by adits or inclines, and there was little mechanization. Since emphasis has shifted to large-scale uranium production, large low-grade deposits have yielded

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

the bulk of the ore; some contain commercially recoverable vanadium and some do not. Mining is by both open pit and underground open stope or room-and-pillar methods. Vertical shafts as deep as 600 feet have been employed to reach the deeper bodies not outcropping in canyon or rim rock walls.

Vanadium mining in Peru has been both by open cuts and underground from adits.

Metallurgy

Before 1948 recovery of vanadium from carnotite and roscoelite ores employed a salt roast from 825° to 850° C to produce sodium vanadate soluble in water or in a sodium carbonate solution. After adjusting the pH of the leach solution with acid, red cake (sodium polyvanadate) was precipitated, which upon filtering, washing, and subjecting to a direct flame, yielded the fused vanadium pentoxide product containing approximately 86 percent V_2O_5 (*2*).

With development of the demand for uranium, milling was altered by the addition of circuits to provide for recovery of that element. Uranium recovery soon became the controlling factor in mill design with vanadium recovery assuming a subordinate position. Flowsheets for the mills treating western uranium-vanadium ores have become more complex with variations in the leaching processes and adoption of solvent extraction or ion exchange procedures.

Finland pioneered in the commercial recovery of vanadium from vanadiferous titaniferous magnetite. As originally processed in 1956, a magnetite concentrate was obtained which was cleaned, dried, and mixed with sodium salt for pelletizing in a round-shaft furnace designed to promote reaction between the sodium and the vanadium contained in the magnetite. By countercurrent leaching of the pellets with hot water, a pregnant leach liquor was obtained containing the vanadium as sodium vanadate, while the leached pellets constituted a high-grade iron concentrate product. The pregnant solution was treated with sulfuric acid to precipitate the vanadium as vanadic acid, which was recovered from the solution by pressure filters, cleaned of impurities, smelted, and cast into cakes containing 90 to 92 percent V_2O_5 (*2*).

Ferrovanadium is the principal form in which vanadium is used by the steel industry. The alloy is produced by reduction, utilizing a thermic process or an electric furnace. Reduction may be accomplished with silicon, aluminum, or carbon; the type of reductant and method used are affected by the grade of ferrovanadium to be produced. A typical charge for an electric furnace, using carbon as the reductant, might consist of technical-grade vanadium pentoxide, or less commonly some other form of vanadium-bearing material such as slag, ore, or concentrate; steel scrap, coke, and fluxes would make up the balance of the charge. When aluminum is the reductant, an exothermic reaction takes place and no carbon is required in the charge. Ferrosilicon may be used for reduction of the vanadium pentoxide in a two-stage process employing lime and fluorspar in a magnesite-lined furnace. Carbon, although the least expensive, is least satisfactory of the reductants (*2*).

Vanadium metal of 90 percent purity, used for alloying purposes where low-iron or other low-impurity features are desired, is produced commercially by the aluminothermic process; high-purity, ductile vanadium metal is produced by bomb reduction of vanadium pentoxide with calcium.

USES

Small quantities of vanadium added to steels and irons impart beneficial qualities to the product. Vanadium's chief functions are to reduce and control grain size (*14*) and to provide various other alloying effects. Among the benefits achieved are—toughness, strength, improved machinability and weldability, reduced distortion, simpler heat treatment, increased wear and impact resistance, uniformity, better finish, reduction of flaking of carburized surfaces, and ability to maintain high hardness to nearly 1,200° F (*11*). Tool steels, engineering and constructional steels in both light and heavy sections, heat-resistant stainless steels, spring steels, steel and iron castings, steel mill rolls, nonaging rimming steels, and nitriding steels are among the beneficiaries. As an alloying agent for steels and irons, vanadium usually accompanies other alloying elements rather than being used alone (*3*).

Vanadium is employed as an alloying agent in nonferrous alloys, chiefly those of aluminum and titanium, to control thermal expansion, grain size, and electrical resistivity and to improve high-temperature strength. Titanium-base vanadium alloys, having high-temperature strength qualities and good weldability, have become of interest to the aerospace industry. Vanadium is a constituent of permanent magnet alloys and of welding rods and coatings, and it is of interest as a structural material for nuclear reactors.

Compounds of vanadium are important to the chemical industry as catalysts for many industrial processes, including the production of sulfuric acid and the cracking of petroleum. Other chemical applications include use as coloring in glass and ceramic glazes, as driers in paints and varnishes, and in the processing of colored film (*2*).

ALTERNATE MATERIALS

Chromium-vanadium steels have been substituted for nickel-bearing steels. Manganese-titanium steels and molybdenum or molybdenum-silicon steels with a grain-refining addition of aluminum have served as substitutes for vanadium steels. For many of its alloying purposes vanadium is interchangeable to some extent with other alloying elements such as molybdenum, tungsten, and columbium. Platinum can substitute for vanadium compounds as a catalyst.

RESERVES AND RESOURCES

Both free world and Communist nation resources of vanadium are large, and an appreciable part of these resources may be considered in the reserve class when coproducts become part of the scheme of exploitation. The United States does not now have long-range self-sufficiency in coproduct vanadium reserves, but its resources are large.

Owing to the extensive mining stimulated by the AEC buying program of the fifties and sixties, the known vanadiferous uranium ores of the Colorado Plateau cannot be relied upon as a substantial reserve after 1970. Other vanadium reserves of the United States lie in those vanadium ores of the Colorado Plateau that are low in uranium content and in the byproduct vanadium to be obtained from the vanadiferous phosphate rock of Idaho (*4*).

The Colorado Plateau deposits low in uranium content were mined for vanadium before the great demand for atomic energy materials focused attention on other deposits of the Plateau. The ore of the low-uranium deposits, near Placerville, Rico, and Rifle, Colo., contains 1.5 to 2.0 percent V_2O_5 (0.8 to 1.1 percent vanadium) with a developed reserve reported in 1961 as approximately 500,000 tons of ore, or 10 million pounds of vanadium. The potential of these deposits as a resource, largely near Placerville, Colo., is probably several million tons of ore of comparable grade.

The vanadium-bearing phosphate rock of Idaho, containing 0.1 to 0.3 percent V_2O_5 (0.06 to 0.17 percent vanadium), represents a very large resource—conceivably measured in billions of pounds of vanadium. As a reserve, these deposits are dependent on the capacity to produce, and the demand for, phosphorus and its compounds.

The titaniferous magnetites of Lake Sanford, N.Y., and of Iron Mountain, Wyo., with a V_2O_5 content of 0.4 to 0.45 percent (0.2 to 0.25 percent vanadium), constitute other domestic vanadium resources. Other titaniferous magnetites, and vanadiferous phosphatic shales in Idaho and Wyoming of higher vanadium content than the rock now being mined for phosphates, also represent substantial resources of vanadium but have less attractive possibilities for the coproducts needed for favorable consideration of exploitation in a peacetime economy. In addition, vanadium of Colorado Plateau low-vanadium uranium deposits (roughly 0.07 percent vanadium) remains a significant resource, although not attractive for recovery under current conditions.

Large reserves of vanadium occur in the outcropping titaniferous magnetites of the Bushveld complex of the Republic of South Africa. These deposits have been estimated to average 1.8 percent V_2O_5 (1.0 percent vanadium) and to have at least 4 billion pounds of vanadium easily accessible at surface, or over 10 billion pounds to "reasonable mining depths" (*13*).

Titaniferous magnetites in Finland, containing approximately 0.25 percent vanadium, constitute a vanadium resource estimated to have from 150 million to 250 million pounds of vanadium content; the availability of the vanadium content is dependent on the demand for iron ore and titanium.

The U.S.S.R. has large reserves of vanadium which occur as a constituent of titaniferous magnetite at Kachkanar in the Urals and as a constituent of high-phosphorus brown ironstones in the Urals and at Kerch in the Crimea. Resources may be 13 billion pounds or more of recoverable vanadium. Active plans for development of these iron ores include recovery of the vanadium content as a coproduct, linked to steel production targets for 1965 and 1970 (*1*, *7*, *10*). Mainland China is reported to have reserves of vanadiferous titaniferous magnetite which are probably about 10 million tons of ore containing 0.15 to 0.3 percent vanadium.

SOURCES OF STATISTICAL INFORMATION

Statistics for domestic production and consumption of vanadium ores, concentrates, oxides, alloys, and metal are obtained on a voluntary reporting basis by periodic canvasses of the Bureau of Mines. U.S. import and export statistics are compiled by the Bureau of the Census from data filed by the importer or exporter with the Bureau of Customs. Data on foreign production are obtained by the Bureau of Mines largely from questionnaires sent to U.S. consular offices abroad, whose principal sources of information are the official statistical releases of the particular foreign governments concerned. This information is supplemented by data from other sources, including special State Department dispatches.

PRODUCTION, CONSUMPTION, AND TRADE

Table 2 shows mine production of vanadium in the United States as measured by receipts at the mills, and the recoverable vanadium that could have been obtained from those mill receipts if they had all been run through the mill. Recoverable vanadium may be defined as the quantity of vanadium that it is possible to extract from the ores (or concentrates) received at a mill, as calculated by using the recovery factor actually obtained by that mill from the ores (or concentrates) that it actually processed in the same year.

TABLE 2.—*Mine production and recoverable vanadium in ore and concentrate produced in the United States*

[Short tons]

Year	Mine production [1]	Recoverable vanadium
1954–58 (average)	6,022	3,380
1959	7,392	3,719
1960	8,047	4,971
1961	6,359	5,343
1962	7,647	5,211
1963	6,047	3,853

[1] Measured by receipts at mills, vanadium content.

Table 3 shows production of vanadium pentoxide in the United States from all sources, including that recovered from ferrophosphorus, oil residues, and imported chromium ores in the course of producing chromium chemicals.

TABLE 3.—*Production of vanadium pentoxide in the United States*

[Short tons]

Year	Gross weight	V_2O_5 content
1954–58 (average)	6,890	6,128
1959	7,906	7,305
1960	10,767	9,812
1961	10,796	10,387
1962	6,876	6,403
1963	7,347	6,959

Foreign production (short tons) of vanadium in ores and concentrates in 1963 was reported as follows: Republic of South Africa, 1,381; South-West Africa (recoverable vanadium), 1,134; and Finland (estimated), 617. In addition, the U.S.S.R. produced vanadium for its own use, and Argentina is believed to have continued to produce a small quantity.

U.S. consumption of vanadium materials is shown by type of material in table 4 and by end use in table 5.

TABLE 4.—*Vanadium consumed in the United States, by type of material*

[Short tons, vanadium content]

Material	1962		1963	
	Quantity	Percent of total	Quantity	Percent of total
Ferrovanadium	1,710	74	2,302	79
Oxide	165	7	135	5

Source: Bureau of the Census.

Imports of vanadium into the United States halted in, or previous to, 1955. They had consisted of ore or concentrate from Peru; flue dust from Canada, Venezuela, Peru, and Curacao; and ferrovanadium from Japan, France, Germany, and the United Kingdom. Imports resumed on a small scale in 1959. Ferrovanadium imports became appreciable in 1962 (88 short tons), and in 1963 general imports of ferrovanadium totaled 481 short tons. Exports of vanadium from the United States are shown in table 6. The largest recipients of U.S. oxide in 1963, Japan and Belgium-Luxembourg, also were important suppliers of the U.S. imports of ferrovanadium in that year.

According to the Tariff Schedules of the United States, effective August 31, 1963 (U.S. Tariff Commission, TC Publication 112), vanadium ore and concentrate enter the United States duty free; for ferrovanadium, a rate of 12½ percent ad valorem applies to the product of most nations, and 25 percent ad valorem to that of the U.S.S.R., mainland China, and certain other specified Communist countries; for unwrought vanadium metal, the respective rates are 10 and 25 percent ad valorem.

STRATEGIC CONSIDERATIONS AND GOVERNMENT PROGRAMS

Vanadium is classified as a strategic and critical material and is held in the national stockpile. During the 10 year period of AEC uranium procurement, the domestic vanadium supply as a byproduct of uranium was so large that the United States became a net exporter. As this byproduct source declines the United States could become more dependent upon overseas vanadium sources. On June 30, 1964, government inventories in the national (strategic) stockpile totaled 7,865 tons.

PRICES

A price of 31 cents per pound of contained V_2O_5 continues to be quoted, nominally, for domestic vanadium ore. Quotations for technical-grade vanadium pentoxide, $1.15 per pound of contained V_2O_5, are for small quantities; actual prices for large lots dropped to about 80 cents per pound by the end of 1963. These had recovered to about 95 cents by the beginning of 1965. Between 1941 and 1959, the price for technical-grade vanadium pentoxide ranged from $1 to $1.38. It was quoted at $1.38 from 1959 through 1962.

Ferrovanadium prices increased from $2.70–$2.90 per pound of contained vanadium in 1940 to $3.20–$3.45 in 1962. By the end of 1963, quotations for the open-hearth, crucible, and primos grades containing 50 to 55 percent vanadium had dropped to $2.85–$3.05 per pound of contained vanadium, depending on the grade. At the end of March 1964, the price was down to $2.50 per pound of contained vanadium for all three grades, a price improving vanadium's competitive position with other alloying elements.

Vanadium metal of 90-percent purity has been quoted from $3.45 to $3.65 per pound for 100-pound lots since 1954. There are no published quotations for high-purity vanadium metal, but the price has been about $30 to $40 per pound since 1954.

RESEARCH

Research continues in government and industry on the extraction of vanadium from different materials and on application in various forms. Recently, interest has been generated in research on vanadium alloys for aerospace applications and on coatings for protection of such alloys against oxidation at high or moderately high temperatures. Current Bureau investigations include studies for an improved process for recovering vanadium from ferrophosphorus obtained as a byproduct, or waste product, of elemental phosphorus production from western phosphate rock; application of fused salt electrorefining techniques to preparation of high-purity ductile vanadium from commercially available vanadium materials; purification of vanadium with an electron-beam furnace; and basic research studies of the physical metallurgy of electrolytic vanadium and of vanadium-base chromium and tungsten alloys.

OUTLOOK

The vanadiferous uranium ores of the Colorado Plateau can no longer be expected to provide a surfeit of vanadium. However, considering other U.S. resources and the large deposits of South African vanadiferous magnetite, the supply will continue to be more than adequate. In addition, large Soviet supplies of vanadium may begin to appear on the world market by 1970.

Consumption of vanadium should continue to increase, possibly accelerating appreciably. New developments in the steel industry will account for the greater part of the increased demand. Greater use of the continuous casting

process will substitute vanadium for aluminum for killing deep-drawing steels such as are used in automobile bodies, shell cases, can tops, etc.; growing use of vanadium-bearing high-strength low-alloy steels by the construction industry will consume more vanadium; and the use of vanadium in line pipe and oil-drilling pipe will probably increase. Increased use of vanadium in various high-temperature and cryogenic applications can be anticipated, but it is doubtful that the quantity used will be of much significance compared with the aforementioned uses. Normal growth of the use of vanadium as a catalyst is expected. If a vanadium catalyst is found to be the answer to the automobile exhaust-smog problem, a large and continuing increase in demand would result. At present, however, there is no firm indication of such a development.

PROBLEMS

As the Colorado Plateau uranium ores of relatively high vanadium content become exhausted, the United States will have to turn increasingly toward one or more of the following sources: (1) vanadium ores of the Colorado Plateau with little or no recoverable uranium, (2) vanadium obtained as a byproduct or coproduct of Idaho phosphate or certain titaniferous magnetite mining operations, and (3) foreign sources of supply.

If the United States is to maintain self-sufficiency in vanadium, it will need to develop more economical methods of recovery so that this element can be obtained from the country's large low-grade deposits without dependence on coproducts.

The strong possibility of Soviet vanadium appearing on the market in substantial quantities can pose serious problems for present and prospective producers. The problem of continued ready availability of this vanadium becomes a concern for the consumer and those charged with government planning.

Cost is an important factor with regard to the position vanadium holds in competition with other alloying elements, particularly molybdenum and columbium.

Temperature and oxidation problems of vanadium and its alloys limit applications and present problems in working that challenge the research metallurgist.

VERMICULITE

By Timothy C. May [1]

VERMICULITE expands into worm-like forms when suddenly subjected to heat. This curious bloating effect, known as exfoliation, is often so great that a plate of vermiculite, on heating, may swell up to 20 times its original thickness in a manner resembling the opening out of an accordion. The expanded vermiculite has many uses.

The first commercial production of vermiculite in the United States was in Colorado in 1915. There were five domestic producers in 1963, one of these accounting for nearly all of the output. The value of the exfoliated product was $14 million. The largest reserve is in Montana. In 1963, Montana and South Carolina were the largest producing States. Several foreign countries produce vermiculite, the largest foreign output coming from the Republic of South Africa.

Nineteen varieties of vermiculite have been identified and named, all hydrous magnesium aluminum silicates, mica-like minerals which can be exfoliated to as much as 20 times the original bulk on heating. Vermiculite is a secondary mineral, associated with basic host rocks and formed by hydrothermal alteration.

Mining is by open cut. The most advanced beneficiation is a wet method using hammermills, rodmills, classifiers, screens, table, and other standard beneficiation equipment and practices. Exfoliation is usually done in a vertical furnace, the ore falling by gravity against a series of baffles through a temperature zone ranking from 1,600° F to 2,000° F.

Uses are principally in construction as plaster and concrete aggregate and for loose fill insulation. Resources are large in the Western United States but are relatively small in the East. Substantial quantities of crude vermiculite are imported from the Republic of South Africa.

The outlook for vermiculite in the next few years is for a slight increase in production. Problems of the vermiculite industry include production of excessive fines and lack of market for these fines and byproduct biotite, health hazards and dust nuisance, high transportation costs, specification standards, and limited information on marketing and use.

BACKGROUND

In 1824, Thomas H. Webb, a mineralogist, described vermiculite from a deposit near Worcester, Mass. A variety of vermiculite first found in a serpentine quarry near West Chester, Pa., in 1851 by W. W. Jefferis was named jefferisite. Another variety was discovered in 1873 near the Culsagee River in Macon County, N.C., and named culsageeite. Since then other varieties have been found and named.

It was not until 1913 that deposits were discovered in Chaffee, Fremont, Custer, and Gunnison Counties, Colo. The first of these discoveries was by W. B. Thomas, in Chaffee County, 14 miles north of Salida, Colo. Only a small tonnage was produced from this source.

In 1915, the Denver Mining and Manufacturing Co. marketed vermiculite from a mine near Hecla, in Chaffee County. The product was sold under the trade name "Tung Ash" and classified at that time as a hydrated biotite mica (*4*).[2]

The most important domestic deposits were discovered in Montana by E. N. Alley, in 1916, while prospecting for vanadium. Continuous Montana production on a commercial scale began in 1921.

[1] Commodity specialist.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

Production from eastern deposits was first reported in 1929, from the Brinton quarry at West Chester, Pa., by the John Warren Watson Co. of Philadelphia, but the enterprise was not profitable. In 1933, deposits in North Carolina were opened near Ellijay in Macon County, but by 1959 all eastern vermiculite production came from South Carolina.

Important deposits in northeastern Transvaal, Republic of South Africa, became productive about 1938 (*9*).

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Five domestic operators mined vermiculite ore in 1963. They produced a total of 226,000 short tons of crude vermiculite valued at $3.6 million. The industry also has imported an average of 12,700 tons of crude annually during 1959–63.

In 1963 there were five domestic producers of vermiculite, American Vermiculite Co. and Patterson Vermiculite Co. operating in Laurens County, S.C.; W. R. Grace & Co., Zonolite Division, with several mines in South Carolina and one near Libby, Lincoln County, Mont.; Insuplast Inc., operating in Custer County, Colo.; and D.C. Howe in Platte County, Wyo. The W. R. Grace & Co., Zonolite Division, produces more than 90 percent of domestic crude vermiculite.

The ore mined is beneficiated and sized in the general vicinity of the mines and shipped to consuming centers in cities for exfoliation, bagging, and local distribution.

The largest domestic deposits are in Lincoln County, Mont., about 7 miles northeast of Libby (*1*). The Colorado deposits are probably next in potentiality, but as Montana now supplies the western and midwestern markets, and South Carolina, together with imports from the Republic of South Africa, serves the East, there is little current production from Colorado.

South Carolina has a number of relatively small developed deposits in Greenville, Spartanburg, and Laurens Counties, near Travelers Rest and Enoree. The Enoree area is currently the most active. North Carolina production came from deposits at Ellijay, Macon County, and from Swannanoa in Buncombe County.

By far the most important foreign vermiculite deposits discovered are in the Palabora region of northeastern Transvaal (*10*). The U.S.S.R. claims extensive deposits in the Ural Mountains, and production from this source has been confirmed.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Vermiculite is the name of the specific mineral and is also the commercial term applied to a group of micaceous minerals that expand greatly on rapid heating. The term also is used to denote the exfoliated product. In this report *crude vermiculite* means any of the vermiculite group minerals, beneficiated and sized, ready for the exfoliation furnace. They are all hydrous magnesium-aluminum silicates containing iron and other elements and have the characteristic micaceous lamellar structure and basal cleavage.

Nineteen varieties of vermiculite have been identified. Although there is some disagreement as to whether vermiculites constitute a distinct species, X-ray studies tend to confirm this as the defraction patterns of the vermiculites differ from the true micas or chlorite. Only the vermiculite and jefferisite varieties have been mined commercially.

Hardness ranges from 1.5 to 3.0 on Mohs' scale, and specific gravity of the crude material varies from about 2.30 to 2.80. In the crude state the color may be light brownish-yellow, dark yellowish-brown, or greenish, to almost black, often with a bronze cast. The streak is white, tenacity elastic to pliable, exfoliation temperature between 300° F and 1,500° F, and melting point between 2,425° F and 2,480° F. When heated in an open tube, the color changes to a gold, golden brown, or bronze, often with a metallic lustre. Heating in a reducing atmosphere gives crude vermiculite a silvery or almost white appearance.

Chemical composition is of little value in determining the expandability of vermiculite, and exfoliation tests provide the only satisfactory evaluation. The mineral can be identified in prospecting by heating with the flame of a candle or even a match.

When used for loose fill insulation, exfoliated vermiculite is sized to minus 3- plus 14-mesh and weighs 5 to 6 pounds per cubic foot. For concrete aggregate, a minus 5- plus 20-mesh exfoliated vermiculite is usually recommended, replacing sand, gravel, or crushed stone. Other commercial screen size ranges are minus 8- plus 65-, minus 10- plus 65-, and minus 20- plus 100-mesh (Tyler standard screen sizes) (*8*). Vermiculite concrete weighs from 16 to 50 pounds per cubic foot and has a compressive strength of 50 to 500 pounds per square inch compared with 150 pounds per cubic foot for concrete made with sand and gravel aggregate having compressive strength of 1,300 to 3,000 pounds per square inch. The thermal conductivity (k-factor) is

0.60 to 1.9 Btu per square foot per inch thickness, per hour, per degree F, depending principally on the mix ratio, which governs the unit weight of the concrete. The proportions of the mix usually are 1 cubic foot portland cement (1 bag), 3 cubic feet of stabilized vermiculite concrete aggregate (¾ bag), and 2 cubic feet of sand. The lighter the concrete, the more sealed air spaces are present, with a corresponding lowering of the k-factor and greater efficiency as insulation. Air-entraining agents are used with vermiculite concrete and are introduced as a dry additive in the proportion of about 5 ounces per 4-cubic foot bag of exfoliated vermiculite.

The finer exfoliated sizes, down to 100-mesh, are used in vermiculite plaster for walls and ceilings to insulate against heat and sound and as fireproofing around beams, girders, and columns. Vermiculite base-coat plaster is made by adding 6 bags of vermiculite aggregate to 9 bags of gypsum plaster. The finish coat is composed of 1 bag vermiculite aggregate, 2 bags unfibered gypsum plaster, and 16 gallons of water. A 4-hour fire rating was issued in 1939 on a ⅞-inch thickness of vermiculite plaster on metal lath to fireproof a steel floor assembly. Since then many fire ratings for various types of construction and fireproofing have been developed. Vermiculite has contributed materially to the improvement of modern lightweight building construction (*11*).

TECHNOLOGY

Geology

Vermiculite is associated with basic rocks such as pyroxenite, peridotite, dunite, and serpentine, often in the vicinity of pegmatite dikes or other acid intrusives. Associated minerals frequently are quartz, feldspar, apatite, kyanite, corundum, biotite, chlorite, phlogopite, asbestos, talc, and clay minerals. A few occurrences have been reported unassociated with basic rocks, but in such instances the deposits were small, and the vermiculite did not exfoliate satisfactorily. Extensive "horses" of unaltered biotite are found in the South Carolina vermiculite deposits.

The vermiculites are believed to be formed by hydrothermal action on the ultrabasic igneous host rocks or by the alteration of biotite, phlogopite, chlorite, or other minerals of similar chemical composition. Weathering may play an important part in the alteration cycle.

The following chemical analyses are typical of the three major vermiculite deposits (*8*):

TABLE 1.—*Analyses of unexfoliated vermiculite*

[Percent]

	Source of material		
	Libby, Mont.	Enoree, S.C.	Palabora, Transvaal, Republic of South Africa

Cl	.28	.52	
H_2O	5.29	8.71	11.38

Mining

Although some underground mining of vermiculite has been done, all 1963 production was from open-cut mines. The usual practice is to strip the overburden with hydraulic scrapers and dig the vermiculite ore from the face with power shovels loading into trucks. Benches are established if the ore has a vertical thickness of over 25 feet. Although some blasting of dikes and barren rock may be needed, the vermiculite ore is soft and easily handled by the shovel or dragline excavator without blasting. The ore carries from 25 to 95 percent vermiculite, the gangue consisting principally of clay and boulders from the dikes and country rock with which the vermiculite is associated.

Beneficiation

Until recently domestic vermiculite ore was beneficiated by dry methods using screens, direct-fired dryers, pneumatic tables, and air separators. Partly because of the dust hazard, wet methods are now used in the mills of the largest mines. Hammer mills, rod mills, rake classifiers, screens, wet cyclones, and tables are used to separate the vermiculite flakes, remove adhering clay and other impurities by scrubbing and washing, and to concentrate and size the vermiculite. Drying is done by centrifuge and direct-fired rotary drier.

Exfoliation has been done in furnaces of only slight inclination and also those of vertical design. The latter type now is used predominantly in commercial expanding operations. The inner walls are of fire brick with an outer wall of insulating brick. Baffles in the heating chamber impede the fall of the crude ore which is fed in near the top of the furnace. Gas or fuel oil is used for heating,

and the charge is usually exposed to a temperature of between 1,600° F and 2,000° F for from 4 to 8 seconds.

Exfoliation is caused by the pressure of steam generated when the water of composition is heated to a high enough temperature. This forces the laminae apart in a direction at right angles to the cleavage planes, in an accordion-like form. This is also accompanied by considerable warping of the individual laminae. Innumerable air spaces are thus developed throughout the heated vermiculite, imparting to the mass the great bulk and insulating qualities which give it commercial value. The ultimate crystalline sheet into which vermiculite can be split measures only 10 angstrom units (25 such sheets piled on top of one another would measure about 1 millionth of an inch) (*5*). This provides a great expansion potential as the water of crystallization is turned to steam between the lamellae.

Too much time in the hot zone of the furnace removes additional combined water after optimum exfoliation has been achieved. This has a deleterious effect on the vermiculite, reduces toughness and pliability, and causes brittleness.

An airlift separates the exfoliated vermiculite from rock and other unexpanded waste material, and an air current then carries the exfoliated material to the bagging department. It also cools the vermiculite so packaging can be done without scorching the bags.

The friable nature of vermiculite is the cause of considerable dust in the plant during exfoliation, sizing, and bagging.

The usual exfoliating furnace has an hourly capacity of over seventy 4-cubic-foot bags, the standard packing unit. Although fines are necessarily produced, little minus 100-mesh vermiculite is marketable. The matter of fines is a serious major problem with all producers.

USES

It is estimated that over 50 percent of all exfoliated vermiculite is used in building and construction, and much of this is used as concrete aggregate. Lightweight-plaster aggregate and loose-fill insulation are also important uses. In plaster, vermiculite improves insulation and fire resistance and reduces fuel costs. The innumerable minute air cells within the exfoliated vermiculite retard the passage of heat and sound through the mass. Standard mixtures for vermiculite plaster and concretes with approximate corresponding coverages, are available from The Vermiculite Institute (*11*).

One ton of loose exfoliated vermiculite will cover about 1,120 square feet of area to a depth of 3 inches and provide excellent thermal insulation.

Vermiculite is used for packing refrigerators, cold storage rooms, incubators, fireless cookers, thermal jugs, ovens, safes, and water heaters. As a refractory, vermiculite with a suitable binder and applied as a plastic mass can withstand furnace temperatures to 1,800° F.

Other uses include horticulture, carriers for herbicides, insecticides, fungicides and fumigants, hatchery litter, refractory fire brick, and beds for transporting hot steel ingots.

As a filler, vermiculite has applications in plastics, rubber, paints, printing inks, and oil well cements. For other uses, it is bonded with many binders, including dextrin, casein glue, wood pulp, clays, plaster of paris, portland cement, synthetic resins, and waterglass. In combination with asphalt, vermiculite is used in roofing and flooring compositions.

Exfoliated vermiculite is used as a soil additive for rooting cuttings and tubers in hotbeds, for sprouting seedlings, and as a general soil conditioner mainly to lighten clay soil or to improve the moisture-retention qualities of sandy soils.

The coarsest exfoliated vermiculite, around ½-inch particle size, is used in poultry hatcheries as a litter. The medium-size range is marketed as a loose fill insulation between the studding and beams of walls, floors, and roofs, for lightweight aggregate, plaster and concrete, and as a soil conditioner. Some applications for sizes below 100-mesh are:

- Grease lubricants
- Filler in plastics
- Tire and rubber goods
- Wallpaper printing
- Outdoor advertising paints
- Anti-caking agent in fertilizers
- Increasing viscosity of oil
- Fireproof containers for photographic films
- Extender for gold and bronze printing inks and for paint
- Carriers for agricultural chemicals, insecticides, herbicides, and fungicides

A data book has been published listing uses for vermiculite, including information on absorption, resiliency, thermal expansion, and other characteristics in filler, lubricant, catalyst, dielectric, and insulator applications (*12*).

ALTERNATE MATERIALS

Vermiculite encounters several long-established competitive commodities in all its fields of use. As plaster aggregate, it must compete with silica sand, expanded perlite, and pumice. Competitive lightweight concrete aggregates

are expanded clay, slate, shale, and slag, expanded perlite, cinders, pumice, sawdust, organic fibers, foamed glass, and calcined diatomaceous earth. Air-entraining agents which lighten ordinary concrete also can be considered a lightweight aggregate substitute. Mineral wool, expanded perlite, pumice, diatomaceous earth, cork, and sawdust compete with vermiculite as loose fill insulation. In oil well cementing, perlite and clays, including bentonite, are competitive materials.

There are many fillers and extenders with which vermiculite must share the market. Some of these are perlite, feldspar, gypsum, mica, pumice, talc, limestone, kaolin, silica sand, diatomite, barite, and synthetic calcium silicates.

As a soil conditioner, vermiculite competes with perlite, peat, and synthetic soil conditioners.

RESERVES

Substantial vermiculite resources occur in Colorado, North and South Carolina, and Montana, principally in the latter State, in Lincoln County and in the southern extension of the Madison and Gallatin Ranges north of Yellowstone National Park, in the Rocky Boy Indian Reservation in Hill County, and also about 12 miles east of Hamilton in Ravalli County. Other States have potentially important but unexplored resources. Vermiculite deposits have been reported in Arkansas, California, Georgia, Massachusetts, Nevada, Pennsylvania, Texas, and Wyoming.

The largest known foreign resources are in Africa, particularly in Transvaal Province, the Republic of South Africa. Other African deposits are in Tanganyika, Kenya, Uganda, Southern Rhodesia, United Arab Republic (Egypt), and Morocco (*10*).

Vermiculite also occurs in southeastern Western Australia, at Bulong and Kalgoorlie. A Canadian deposit near Stanleyville, Lanark County, Ontario, is said to have commercial possibilities (*3*). Japan has vermiculite in the Kadzua Peninsula and in the Hajikano area, Province of Yamanashi-ken. Other foreign sources are Argentina, India, Brazil, Chile, and Mexico.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines, U.S. Department of the Interior, canvasses producers of crude and exfoliated vermiculite annually, and publishes resultant data in Minerals Yearbook. A Census of Mineral Industries intermittently presents vermiculite industry statistics for single years.

780-887 O—65——67

PRODUCTION, CONSUMPTION, AND TRADE

The quantity of exfoliated vermiculite sold or used in 1963 was 24 percent less than the quantity of crude vermiculite reported produced. This difference was partially due to changes in stocks and loss of fines formed in the exfoliation processes and to the rejection of waste rock and unexfoliated vermiculite during the operation.

Although statistics on producers' or consumers' stocks are not collected by the Bureau of Mines or The Vermiculite Institute, supplies of currently unmarketable fines are known to be substantial.

Colorado was the first State to record commercial production of crude vermiculite in 1915, but Montana has been the leading producer since 1922.

In 1963 the first six States, in order of production of exfoliated vermiculite were California, Illinois, Texas, New Jersey, Minnesota, and Florida.

Vermiculite data are combined with a variety of other nonmetallic minerals in government foreign trade statistics. About 85 percent of the vermiculite exfoliated in Canada came from the United States in 1963. Canada imported almost Can$497,000 of crude vermiculite from the United States and Can$77,000 from the Republic of South Africa in 1963.

The Republic of South Africa ships substantial quantities of crude from several operations to world markets, including the United States. Exports of crude to the United States, in short tons, are reported from the Republic of South Africa for the years 1959 through 1963 as follows: 1959—11,827; 1960—12,396; 1961—12,913; 1962—12,098; 1963—14,337.

Crude vermiculite may be imported duty free under paragraph 1719 of the Tariff Act of 1930. Exfoliated vermiculite carries a duty of 15 percent ad valorem but the bulk of exfoliated vermiculite ordinarily precludes its importation into the United States.

TABLE 2.—*Crude and exfoliated vermiculite sold or used by producers in the United States*

	1959	1960	1961	1962	1963
Crude vermiculite:					
Thousand short tons	207	199	206	205	226
Value, thousands	$3,082	$3,108	$3,350	$3,293	$3,572
Average value per ton	$14.89	$15.62	$16.26	$16.06	$15.81
Exfoliated vermiculite:					
Thousand short tons	153	151	151	152	172
Value, thousands	$9,591	$10,305	$10,787	$11,152	$13,877
Average value per ton	$62.69	$68.25	$71.44	$73.37	$80.68

PRICES

The average annual value of domestic crude vermiculite has been more nearly constant than most other industrial mineral prices. The average for 1949–58 was $12.66 per ton f.o.b. producer's plant. Values of both crude and exfoliated vermiculite for 1959–63 are shown in table 2.

TAXES

Federal tax statutes permit a 15-percent depletion allowance on the value of domestic and foreign crude vermiculite.

TRANSPORTATION

Montana supplies crude vermiculite to exfoliators from the Midwest to the Pacific Coast areas and the Pacific export markets; the South Carolina output is distributed from the Midwest to the eastern seaboard and Atlantic export markets. Imports from Africa compete with some eastern domestic sources for eastern coastal markets. Transportation cost is an important competitive feature in this industry.

Exfoliated vermiculite has great bulk in proportion to its weight. Therefore, the washed and sized crude vermiculite is shipped from the mines to exfoliation plants in the consuming areas.

Packaged exfoliated vermiculite is sold in 4-cubic foot paper bags which range in weight from 24 pounds per bag for very coarse material to 35 pounds for very fine product. The average is about 7½ pounds per cubic foot, dry basis. This compares with an average for expanded perlite of from 3 to 6 pounds per cubic foot, 9 pounds for diatomite, and 100 pounds for ordinary sand. The weight of pumice per cubic foot ranges from 15 pounds to almost that of obsidian.

RESEARCH

The Vermiculite Institute promotes the welfare of the vermiculite industry, publicizes its advantages, advocates its increased use, works for approval of its applications in city building codes, and develops fire ratings. In pursuit of these objectives, research has been conducted by this Institute, assisted by the producers. Many construction designs embodying the use of vermiculite have been published by the Institute (*11*).

Studies and comparisons were made by the Housing and Home Finance Agency of concretes using exfoliated vermiculite aggregates, other lightweight materials, and ordinary dense sand and gravel (*6*).

Studies by the Bureau of Mines have covered a number of aspects including influence of temperature, heating time, moisture and flake size on exfoliation, percentage of voids, hydraulic, air and screen classification, tabling, flotation, and comparative insulating values. Details of the work accomplished are reported in three publications (*2*, *7*, *13*).

OUTLOOK

The growth in the consumption of vermiculite will be influenced largely by the volume of future residence and public building activity. Over the short term period (5 years) production of crude vermiculite is expected to reach 300,000 tons by 1970, or an increase of 5 percent annually during the 1965–70 period.

The trend in construction design is toward the greater use of lightweight aggregate concrete and consumption of vermiculite is expected to increase from that source as well as the use of vermiculite as a masonry fill. Vermiculite for accoustical and fireproofing purposes, pipe covering, and horticulture is expected to maintain the gradual increase in usage.

The large resources of vermiculite presently known indicate that the supply will be adequate to meet foreseeable requirements.

PROBLEMS

Freight rates for shipping the ore from the mine to exfoliating plants are significant in the cost of the expanded material. High transportation costs from present major commercial sources of crude vermiculite to the major market areas are a serious commodity problem.

Inadequate information on the consumption of exfoliated vermiculite has impeded understanding of the demand picture.

Many of the architectural design manuals of the military departments have been revised to permit the use of vermiculite masonry fill. There are some building codes, however, that restrict the full utilization of vermiculite.

Since there are differences in the inherent expandability of different vermiculites, the volume to which a given size will expand is important to the purchaser of vermiculite con-

centrates. Studies are needed of the physical, chemical, and processing characteristics of vermiculites from different sources for determining their commercial potentialities.

Another problem of the industry is to find an outlet for fines produced in processing and for the residual biotite occurring in some vermiculite deposits.

Dust produced in exfoliating plants cause health hazards. Installation of dust collection systems in many plants has relieved this problem to a great extent.

WATER

By William H. Kerns [1]

WATER is recognized as one of the most important natural resources of the world. An adequate supply of this precious mineral, for man's ever-increasing requirements for personal use, for agricultural, mining, and manufacturing industries is essential to the continued welfare and advancement of modern civilization.

This chapter presents the salient facts and problems of water supply and demand with special emphasis on water use and problems in the mineral industry. If the economy of the United States is to continue to grow and prosper, there must be adequate supplies of water available.

The nature, the immediacy, and the gravity of the water resources problems faced by the United States vary greatly from region to region; however, all parts of the country either have or will have water problems. The well-watered Eastern and Southern States are beginning to share a concern about water that has been felt in the arid West since its settlement. As industrial development and urbanization expand in the East, it is becoming more apparent each year that lack of water may deter growth unless action is taken to assure a continued supply.

The withdrawal of water, now about 300 billion gallons daily (bgd), is expected to double or be 51 percent of the streamflow by 1980 and triple or be 81 percent of the streamflow by the year 2000, if present trends are continued. However, most of the water withdrawn is returned to streams and can be reused many times, provided steps are taken to maintain its quality. Consumptive uses and depletions are expected to be 17 percent of the available streamflow in 1980 and 23 percent in the year 2000.

From this, it appears that our overall water resources are abundant and sufficient for many years to come if we concentrate our efforts in certain areas. Five of the more important categories of effort needed in meeting future prospective water demands include (1) maintaining water quality through pollution abatement in order to increase reuse of water; (2) regulating streamflow by means of constructing surface reservoirs and watershed management; (3) making better use of underground storage; (4) increasing the efficiency with which water is used through improved sewage treatment methods, recirculation, increased irrigation efficiency, substitution of air cooling for water cooling, and elimination of wasteful practices; and (5) increasing the natural water yield by desalting, weather modification, and other artificial means.

Of the six principal water-using manufacturing industries that accounted for 81 percent of the total water requirements for manufacturing in the United States in 1959, four—iron and steel, chemical, aluminum, and copper, which represented 72 percent of the total manufacturing—are a part of the mineral industry. The projected total water requirement for these six manufacturing industries for 1980 is 26,500 billion gallons yearly (bgy), nearly three times that in 1959, and is expected to be 61,600 bgy, more than six times the 1959 requirement, by 2000.

For selected nonmanufacturing segments of the mineral industry in the United States in 1962, a total of 1,030 bgy of new water was withdrawn and 2,563 bgy was recirculated, making a total of 3,593 bgy required or used. Of the total new water withdrawn, 774 bgy or 75 percent was discharged for reuse and 257 bgy or 25 percent was consumed by evaporation or by shipment in the product. By 1980 demand for new-water intake for these selected nonmanufacturing segments of the mineral industry is expected to double to more than 2,000 bgy and by the year 2000 to quadruple to more than 4,000 bgy.

The pressing problems concerning water resources in the mineral industry follow closely the national water problems. An adequate quantity and quality of water must be provided or developed at the place and time needed to mine and process minerals to meet the present and future ever-increasing needs for them. In

[1] Commodity specialist.

some areas ways must be provided to handle too abundant water that floods mines or flows from mines or mined-out areas. Ways must be found to reuse or recirculate more water in order to conserve water and to replace some of the new-water intake. Disposal of mining and metallurgical wastes to abate stream pollution is a major problem. Statistical data must be collected through detailed studies in water-short mineral-producing areas, and national canvasses of water use in the mineral industry must be conducted as the basis for understanding and projecting future requirements for this essential industry.

BACKGROUND

Water is mankind's single most valuable natural resource. Science tells us that the earliest forms of life began in the vast oceans of the primeval earth. The human body is over 70 percent water. Without water, life as we know it would perish from the earth. Water has been the key to man's advancement since the beginning of recorded history. The earliest civilizations were established where water supplies were available. Recorded history began in the valleys of the Tigris and Euphrates and along the Nile. According to many historians, the decline and disappearance from the face of the earth of ancient civilizations in many of the arid or semiarid regions began with man's failure to properly use his available water resources.

Water is assuming an ever-increasing importance as civilization's needs for water and water related products and services grow. Areas of this globe that will thrive, or even survive, will be determined by the availability of water and its wise use to serve man. The development of water resources is of strategic importance in nearly every country possessing unused natural resources and having ambitions to secure a higher standard of living for its people.

MAGNITUDE AND GEOGRAPHIC DISTRIBUTION OF WATER SUPPLY

Water is the most abundant substance on our planet. The earth is sometimes called the water planet because it is the only member of our solar system known to contain large quantities of water on its surface. Nearly all of our planet's water is salty, which is satisfactory for the creatures that live in the sea; however, land plants and animals must have fresh water. They can live only because the sun continually distills pure water from the oceans, and this water is carried in the air until it condenses and drops on the land. The flux of water from the ocean into the air, onto the land, and back to the sea is called the hydrologic cycle or water cycle.

The water that falls as rain on the United States averages about 5 billion acre-feet of water per year, sufficient to cover the area to a depth of 2½ feet if it were uniformly distributed. Many parts of this country either have or will have water supply problems. However, with its abundant supply of good water and its advanced technology and skills, the United States need never suffer for lack of water.

The water resource of the United States that is derived from precipitation varies geographically as well as seasonably and yearly. However, it is a perennial supply, which on a long-term basis approaches a constant for the Nation, averaging about 30 inches a year. In many Southern and Eastern States the annual precipitation is considerably above the national average, while in most of the West and Southwest it is below average. For example, average precipitation at Greenland Ranch, Death Valley, Calif., is 2 inches per year compared with more than 150 inches at Wynoochee, near Aberdeen, Wash. At Little Port Walter, Alaska, total precipitation was 269 inches in 1943, while at Mt. Waialeale, Hawaii, the average annual precipitation is reported to be 471.68 inches, the heaviest recorded rainfall in the world.

Of the national 30-inch-average annual precipitation, 21 inches or 70 percent returns to the atmosphere by evaporation or transpiration. This water is not all wasted because a part of it supports cultivated crops, forests, and native grass. The remaining 9 inches, draining from land surface and ground-water seepage, is the manageable supply. From this runoff, 3 inches is withdrawn for all uses, of which 1 inch returns to the atmosphere and 2 inches is returned to the streams, lakes, oceans, or ground. Of the 3 inches withdrawn for use, 80 percent is from lakes and streams and the remaining 20 percent is from wells.

The manageable supply, commonly called the water supply potential, as measured by runoff, is 1,200 bgd. Of this total, 269 bgd is withdrawn for all uses exclusive of water used to develop waterpower. Of this water withdrawn, 62 bgd is consumed. Total dependable supply in 1980 is estimated at 515 bgd and in some water-use regions such as South Pacific (California) and Western Gulf (most of Texas

and New Mexico) the estimated dependable supply for 1980 is less than the withdrawals in 1960. Water-use regions in the United States are shown in figure 1 and water supply potential and use, runoff, withdrawals, and water consumed in 1960, and estimated dependable supply in 1980, are shown by region in table 1 (*20*).[2]

In the 1961 final report (*31*) of the Senate Select Committee on National Water Resources, U.S. Congress, the contiguous United States was divided into 22 water resources regions slightly different from the Federal Geological Survey regions shown on figure 1. According to this committee, substantial areas of water shortages already exist in many of the river basins in the western one-half of the United States. By 1980 or earlier, full development of all of the available water resources in 5 of the 22 regions will be required if the economic development is achieved that is necessary to support the Nation's ever-increasing population. The five regions are (1) South Pacific (lower one-third of California), (2) Colorado River (similar to that shown for Colorado region on fig. 1), (3) Great Basin (as shown on fig. 1), (4) Upper Rio Grande-Pecos River (western one-half of Western Gulf region on fig. 1), and (5) Upper Missouri River (as shown on fig. 1). By the year 2000, three more regions will be added to the list of those in which full development of available water resources will be required if the projected demands are to be met. These regions include (1) Upper Arkansas-Red Riv-

[2] Italicized numbers in parentheses refer to items in the references at the end of this chapter.

ers (as shown on fig. 1), (2) Western Great Lakes (as shown on fig. 1), and (3) Western Gulf (eastern one-half of Western Gulf region as shown on fig. 1).

The Bureau of Mines has a continuing program of cooperation with other Government agencies in the preparation of comprehensive water development plans for all major river basins of the United States along the lines suggested by the Senate Select Committee on National Water Resources.

Water usage data from the Bureau of Mines canvass of selected nonmanufacturing segments of the mineral industry, by States, in 1962 are shown in table 2. Including the metals, nonmetals, coal, and natural gas processing components and excluding the oil well drilling and secondary-recovery operations, the major water-using States were Texas, Florida, Louisiana, California, and Minnesota, which together accounted for 55 percent of the total water usage by the major components covered. For this same grouping of mineral industries, Texas, Tennessee, Utah, Arizona, and Florida were the largest water-consuming States, which together consumed 57 percent of the total.

A comprehensive State-by-State report on the Nation's water resources was published (*22*) that both reassures and cautions all who have an interest in the water situation. It shows that, despite the availability of water reserves underground, the intensity of surface and ground water development in this country has led to local shortages and acute water problems, such as permanent lowering of the water table in certain areas or the encroachment of salt water in coastal streams and wells.

Reports on the mineral and water resources of seven States—Alaska, Colorado, Nevada, Idaho, Montana, South Dakota, and Utah—have been prepared for the Senate Committee on Interior and Insular Affairs and published as committee prints. Detailed data are given for the water situation in each of these States: surface and ground water supply, utilization and storage, waterpower, and selected references. Reports for other States are under preparation.

In the East, where water is relatively plentiful except for some localized areas, there are mounting pollution problems in otherwise usable water supplies. In the West, industry—and with it, population—is moving into precisely those areas where the available water supply already is limited. To ease the water situation in such areas several transmountain water-diversion plans have been proposed.

TABLE 2.—*Water usage in selected segments of the mineral industry, by States, 1962* [1]

[Million gallons per year]

State	Total metals, nonmetals, coal, and natural gas processing industries					Petroleum well-drilling and secondary-recovery operations (total water usage)
	New water	Water recirculated	Total water usage	Water discharged	Water consumed

[1] Data may be slightly different from those shown in vols. I and III of Minerals Yearbook 1963 because of rounding and minor revisions.

Suggestions by the U.S. Department of the Interior include the Southwest Pacific Plan and the Central Arizona Project, which call for diversion of water from northern to southern California, and probably eventually into Arizona. Other proposals by the Department include the San Juan-Chama Project (Colorado to Rio Grande basins) and Frying Pan-Arkansas Project (Colorado to Arkansas basins).

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Water is such a common substance that many of its unusual properties are overlooked. It is one of the two mineral substances that are liquid at ordinary temperatures, the other being mercury. Water is denser as a liquid than as a solid. Without this property lakes and ponds would freeze from the bottom up and life, as we know it, could not have developed.

Water's high specific heat and high latent heat of vaporization make it an excellent substance for transferring heat energy. The kinetic energy of a moving column of water is utilized in spinning turbines for power generation and in hydraulic placer mining. The property of water which enables it to dissolve, entrain, and suspend many substances makes it a convenient tool of industry for transporting, mixing, grinding, separating, and cleaning the many material substances required by modern society.

The fact that water dissolves or entrains many sustances strongly affects its physical and chemical properties. Suspended solids are generally more easily removed than dissolved solids, many of which adversely affect the use of the water. Some of these contaminants cause corrosion and others, such as calcium and magnesium, cause scaling and interfere with the cleansing action of soap in water by precipitating the soap. Water containing appreciable quantities of calcium and magnesium are classed as hard waters.

For drinking water the Federal Public Health Service recommends that the total dissolved solids should not exceed 500 parts per million (ppm), although 1,000 ppm is permitted on interstate carriers when water of better quality is not available. The mineral content of good irrigation water should not exceed 1,400 ppm, with special restrictions on the sodium ion. Radioactivity limits for drinking water were established in microcuries per liter as follows: 3 for radium 226; 10 for strontium 90; and 1,000 for gross beta activity (*33*).

Water having more than about 1,000 ppm of dissolved solids is said to be slightly saline; between 3,000 and 10,000 ppm it is moderately saline; with more than 10,000 ppm it is very saline; and with 35,000 ppm and over it is characterized as brine. Ocean water usually ranges from 33,000 to 35,000 ppm. In most saline waters the sodium and chloride ions predominate; however, significant quantities of Ca, Mg, K, Fe, Mn, SiO_2, HCO_3^-, and SO_4^{--} are also present.

With the rapid growth of nuclear science the term "heavy water" has become common. Heavy water, or deuterium oxide (D_2O), consists of deuterium, a heavy isotope of hydrogen, combined with oxygen in the usual ratio. Although similar to ordinary water, heavy water differs in several of its properties, being slightly more dense and viscous.

Definitions of the terms used in the Bureau of Mines canvass of the selected nonmanufacturing segments of mineral industries in 1962 are as follows:

New-water intake.—Water introduced into the operation for the first time regardless of quality or source.

Recirculated or transferred water.—Water that is returned or transferred for reuse for the purpose of reducing new-water demand.

Water use or usage.—Summation of new water and recirculated or transferred water.

Recycled solvent.—Solutions such as leaching and cyanide solutions, reused for metallurgical processing.

Water discharged.—Water returned to streams, lakes, or to the ground.

Water consumed.—Water evaporated or incorporated and shipped in product.

TECHNOLOGY

An exhaustive study of U.S. water problems covering virtually every aspect of the technology of water—its sources, location, conservation, uses, management, and economics—was made by Resources for the Future, Inc. (*1*). The study treats primarily the proven technology which has influenced water development in the past or which still is effective in shaping its course; however, it also treats the emerging technology of today. It will serve as an excellent factual background or reference for relating technology to water development and water policy decisions.

Abatement of the pollution of our water resources is a pressing technologic problem. Pollution is a threat to public health and to the economic and social welfare of our people. A National Conference on Water Pollution (*34*), called by the President in 1960, assessed the problem of water pollution, determined its effects upon our national welfare, and set realistic goals for its control.

A study of subsurface waste disposal of industrial wastes in the United States revealed that in an area of eight States a wide variety of

industrial wastes is being injected into formations ranging in age from Precambrian to Recent (*10*). In this area more than 30 wells ranging in depth from 300 to 12,000 feet are used for waste disposal into subsurface formations which include unconsolidated sand, sandstone, vugular limestone, and fractured gneiss.

Most uses of water have rather specific quality requirements, and for this reason water treatment is usually necessary. Treatment of water for municipal uses generally consists of settling and filtration to remove suspended matter, chlorination to kill residual microorganisms, and aeration for odor control. In some States water treatment includes the addition of small quantities of fluorine-containing compounds. Water is also treated to reduce its hardness. This treatment removes a high proportion of the calcium and magnesium ions that increase soap and detergent requirements and cause scaling in boilers.

Treatment of waterborne wastes is becoming increasingly complex, not only because of increasing quantities of waste but also because, in the production of many new chemical and medicinal substances, new types of industrial and mineral wastes are being produced. Increasing use of mineral detergents in place of ordinary soap causes difficulties with standard water- and sewage-treatment processes.

New-water intake (1,029,800 mgy), water introduced for the first time in mining, milling and processing operations regardless of quality or source, within scope of the Bureau of Mines survey of water use in the nonmanfacturing mineral industry in 1962, was slightly more than one-half that of fresh water (517,858 mgy), suitable for cooking and drinking. The remainder (417,849 mgy) was primarily low-quality water not suitable for domestic use but not saline, and saline water (94,094 mgy) containing 1,000 ppm or more dissolved solids. Twenty-four percent of the total new water, 51 percent of the total discharge, and 75 percent of the total recirculated water was treated. Of the total quantity of water treated, 12 percent was new water, 83 percent was recirculated, and 5 percent was discharged water. The major methods of treating water were pH control (33 percent), settling (21 percent), bactericide (14 percent), and chlorination (11 percent). Most new water treated was subjected to filtration, settling, or bactericide treatment, whereas recirculated water was subjected to pH control and settling. The major discharge treatment was settling.

The Bureau of Mines, through its Industrial Water Laboratory, provides consulting boiler-water service to Federal agencies operating heating and power plants and financing and requesting this service (*5*). Each year 13,000 to 15,000 water-condensate samples are analyzed from more than 10,000 boilers. These analyses are helpful in spotting and correcting corrosion problems in boilers and condensate return lines.

Disposal of radioactive liquid wastes from uranium mining and milling operations have not posed a major problem primarily because the operations are located in remote areas. Mine water generally can be safely disposed to ground water or to the streams. Waste liquids from milling are diluted and released to streams or to retention ponds from which they gradually seep into the soil. Research conducted by the Bureau of Mines on disposal of radioactive waste from uranium mills indicated that the problem could be minimized by reuse of the waste milling solution, erasing the need for disposal of the liquid waste.

Most organic sewage wastes are treated by biological oxidation methods through which the organic material is ponded and attacked by biological organisms and reduced largely to gases, water, and sludge. Chemical and mineral substances on the other hand often require special chemical techniques in order to neutralize, precipitate, collect, or drive off the waste substances. Each industry has its own waste-disposal problem. Wider dissemination of knowledge and techniques in handling chemical and mineral wastes would be of value not only in controlling chemical wastes but also in recovering valuable mineral and chemical substances otherwise lost.

Wastes of the mineral industry are a special problem in many areas. In addition to acid-mine water, oil well brines are often a disposal problem. All wastes, however, should be examined closely for values which may readily be recovered. The recovery of iodine from oil-well brines is one example.

Cloud seeding to induce rainfall is practiced on a commercial basis in some areas. One procedure consists of burning coke impregnated with sodium iodine. The iodine particles carried upward with the hot gases act as nuclei for the condensation of moisture from rain clouds. Other procedures involve seeding with silver iodine, dry ice, or salt. The main problem in dry areas is to find clouds in the proper stage of supersaturation so that the addition of nuclei will cause rainfall.[3]

In 1934 Harold Urey discovered that the molecules of pure water contained, besides the common atoms of hydrogen and oxygen, an unusual type of hydrogen atom that was twice as heavy as the common variety. This isotope

[3] Committee print 22 (*32*).

of hydrogen, subsequently named deuterium, has an atomic weight of 2 and resembles hydrogen in many ways, combining with oxygen to form the compounds D_2O or heavy water.

The freezing and boiling points of D_2O are 3.8° and 1.4° C higher, respectively, than those of ordinary water (*6*). Besides being slightly more viscous than water, D_2O apparently is not used by plants or animals as readily as ordinary water. Many will die of thirst when supplied exclusively with it.

The largest use of heavy water is as a moderator in nuclear reactors, but it is also employed as a tool in theoretical research. If the less reactive deuterium is substituted for hydrogen in certain compounds, altered chemical properties, from which molecular structure may be studied, may result.

Heavy water may be produced in several ways. In one procedure deuterium is obtained from hydrogen gas by liquefying the gas and fractionating the liquid. Ordinary hydrogen molecules tend to boil off first. The resulting deuterium is reacted with oxygen to produce D_2O. The D_2O content of ordinary water may also be increased by electrolysis and by fractionating steam. To produce heavy water by these processes, large quantities of hydrogen, steam, or cheap electric power are required. It is economical, therefore, to build heavy-water plants in connection with plants that utilize large quantities of hydrogen or steam.

In addition to ordinary hydrogen and deuterium a third isotope of hydrogen, tritium, may be found in water. This material is of great importance in connection with the hydrogen bomb. Three isotopes of oxygen, O^{16}, O^{17}, and O^{18}, are also found in water. While tritium and O^{18} are present only in minute traces, deuterium and O^{17} average 200 and 1,000 parts per million, respectively. These 6 isotopes combine to form 18 different substances that may be found in water (*6*).

Both deuterium and tritium present in water are of great importance in studies of the controlled fusion reaction as an energy source. Although technical problems involved in achieving a fusion reaction with deuterium are more difficult than those raised by the use of tritium, the greater abundance of deuterium rules in favor of the latter.

USES

Water uses are classed as withdrawal and nonwithdrawal and consumptive and nonconsumptive. Domestic, municipal, irrigation, waterpower, and industrial uses are classed as withdrawal uses, as for these purposes the water must be pumped from the ground or diverted from a stream, lake, or reservoir. On the other hand, navigation, waste disposal, recreation, and conservation of wildlife are examples of nonwithdrawal uses. Water that is evaporated or incorporated into a product is said to be consumed or to be used consumptively.

The water withdrawal pattern for three selected years, 1950, 1955, and 1960, is shown in table 3 by the primary withdrawal uses, rural, public supplies, self-supplied industrial, and irrigation (*20*). Including conveyance losses, water used in irrigation in 1960 was the same as that for 1955. The quantity of water withdrawal for industry (self-supplied) increased substantially in 1960 and represented more than one-half of the total for all uses. Although it accounted for only 9 percent of the total water withdrawal, water supplied to the rural and municipal (public supplies) domestic users continued its increasing trend.

TABLE 3.—*Water withdrawal pattern 1950, 1955, and 1960, in the United States* (*20*)

Uses	Water withdrawal (billion gallons per day)			Percent increase, 1955 to 1960
	1950	1955	1960	
Rural	3.6	[1] 3.6	3.6	
Public supplies	14	17	21	24
Self-supplied industrial	77	110	140	27
Irrigation:				
Excluding conveyance losses	79	81	84	4
Including conveyance losses	[2] 110	110	110	
Total, all uses:				
Excluding conveyance losses	174	212	249	
Including conveyance losses	205	241	275	14
Waterpower	1,100	1,500	2,000	33

[1] Revised.
[2] Estimated.

Data in table 4, from the Bureau of Mines canvass of water use in selected segments of the mineral industry in 1962, show that seven industries accounted for 91 percent of the total water usage in that part of the mineral industry covered by the survey. These industries were natural gas processing, phosphate rock, sand and gravel, iron ore, petroleum well drilling and secondary recovery, copper ore, and bituminous coal.

Of the total water used (excluding petroleum well drilling and secondary recovery), 6 percent was used in mining and transporting materials, 64 percent for processing (including natural gas processing), 3 percent for cooling and condensing, and 3 percent for miscellaneous uses such as boiler feed and sanitary purposes.

Mills, preparation plants, sand and gravel washing plants, and natural gas processing plants accounted for 58 percent of the total water usage, 68 percent of the water re-

circulated, and 32 percent of the new water required. Surface mines and associated mills utilized 28 percent of the total water used, 23 percent of the water recirculated, and 41 percent of new water intake. Underground mines and associated mills, chemical or solution extraction, petroleum well drilling and secondary recovery, and natural gas processing accounted for the remaining water usage.

The major users of water for mineral processing by industry include natural gas processing plants and the phosphate rock, sand and gravel, iron ore, copper ore, and coal. Beneficiation methods, such as flotation, jigging, heavy-media separation, and spirals, require large quantities of water.

Major mineral industry users of water in mining, were phosphate ore (transporting), gold (hydraulic stripping, mining, and washing of the placer gold gravels), sulfur (solution mining by the Frasch process), and salt (solution mining of underground salt beds), which together accounted for the more than 90 percent of the total water usage in mining.

Only a small part or 6 percent of the total water usage in the natural gas processing plants was new water; the remainder was recirculated water used to cool the fractionating towers. Water is used extensively in the petroleum industry for well drilling, pressure maintenance of the producing zone, and for secondary recovery of oil. Approximately one-third of this total water usage for petroleum well drilling and secondary recovery was measured as recirculated water; the remainder was new water that usually was not fresh.

The Bureau of Mines has conducted many research projects and has published numerous reports on the subject of water injection and water flooding to maintain underground pressures and for secondary recovery of oil. Although the quantity of water used for this purpose is relatively large, most of it is water pumped with and separated from the crude oil and is reinjected. It should be considered as a form of recharging the ground water reserves even though it is counted as a consumptive use.

Water is being used extensively in pipeline transportation of solid materials as slurry. Solids pipelines are nothing new because they were used in California during the gold rush and the first U.S. patent for pumping solids through pipes was issued in 1889. For short distances they are used extensively in mills and

TABLE 4.—*Water usage in selected segments of the mineral industry, 1962* [1]

[Million gallons per year]

Industry	New water	Water recirculated	Total water usage	Water discharged	Water consumed	New water per dollar value of production
Anthracite	16, 938	14, 930	31, 868	15, 585	1, 353	129

[1] Data may be slightly different from those shown in vols. I and III of Minerals Yearbook 1963 because of rounding and minor revisions.
[2] Not applicable.

processing plants. For many years consolidated Coal Co. successfully operated the longest coal pipeline in the world—108 miles from Cadiz to Eastlake, Ohio, on Lake Erie. In mid-1963 the company placed the pipeline on standby and started transporting its coal by railroad cars when lower rates were offered. American Gilsonite Co. has now operated a 72-mile pipeline in Utah, transporting gilsonite from its mine to mill, for 6 years. The ore is also mined and hoisted hydraulically at this operation. In South Africa more than a dozen pipelines have transported uranium-bearing tailings over long distances since 1956.

Water is a vital raw material in economically mining and processing phosphate ore in Florida. New techniques in hydraulic transportation of phosphate ore by pipeline have been pioneered there. Hydraulic transportation, involving the use of about 360 gallons of water per ton of ore, provides a low-cost and effective method of slurrying, scrubbing, and transporting the ore to the processing plant. Processing this ore requires an additional 3,000 to 10,000 gallons of water per ton of the final product. Less than one-third of the total water used for mining and processing phosphate ore is new water; the remainder is recirculated water.

Exploration and development of natural steam for electric power generation has been extensive in the Western United States in recent years. From 1955 to 1962, approximately 40 wells were drilled in 15 California thermal areas for this purpose (*23*). Geothermal plants are competitive with conventional units. In 1963 a geothermal plant could produce electric energy for 6.70 mills per kwhr, compared with 6.96 mills for coal, 6.74 mills for oil, and 7.04 mills for gas. Potential for geothermal power exists in the Western United States. An economic evaluation of geothermal power was made by the Bureau of Mines (*16*).

In a study made in New Mexico under a grant made to the University of New Mexico by Resources for the Future, Inc., it was found that each acre-foot of water would generate $51 in gross State product if used in farming, $3,041 if used in municipal and industrial purposes, and $2,793 if used for a combination of industrial and recreation (*37*).

A Bureau of Mines study of the water use in the mineral industries of Arizona (*14*) showed that the mineral-product value of copper, lead, zinc, and byproducts was equivalent to $15.27 for each 1,000 gallons, or $4,980 per acre-foot, of new water and $26.29 for each 1,000 gallons, or $8,570 per acre-foot, of consumed water.

BYPRODUCTS

Sea water, certain natural brines, and geothermal steams contain various minor minerals which, under proper conditions, may be recovered at a profit. Among these are bromine, calcium chloride, iodine, and sodium and magnesium compounds. Others such as potash may be economically recovered in the future. Various methods have been suggested for recovery of minerals from sea water (*7*, *28*).

Recent studies (*11*, *18*) were made on the minor elements, dissolved elements that do not generally exceed 1 milligram per liter, in natural water, and chemical data for the river and lake waters of the United States. The principal bulk of dissolved constituents in natural water consists of soluble products of chemical weathering and soil formation.

ALTERNATE MATERIALS

In most populous areas of the earth, water is so low in cost that substitution on a large scale is uneconomic. In areas of water shortage, low-quality water is often used for certain purposes in place of naturally fresh water. For example, sewage effluent is used in some areas for irrigation and industrial uses. Sea water is also used for cooling purposes by plants near the coast and for waste disposal aboard ships. In general, treated and reused water is thought of as the principal substitute for naturally fresh water. However, the trend in alleviating perennial water shortages has been toward importation of high-quality water from distant sources rather than toward substitution.

Air is used for cooling purposes in place of water and to remove heat from water. Air also takes the place of water in classifying and cleaning certain minerals and other commodities in the process called "dry blowing."

For certain specific purposes, such as the cooling of engines for operation at subfreezing temperature, ethylene glycol and alcohols are used in place of water. Mercury vapor has been used in place of steam in turbines designed to operate at high temperatures. Oil has been suggested as a substitute for water in grinding cement materials prior to clinkering.

SECONDARY SOURCES AND RECOVERY

Sewage effluent is used in many areas of the world for the irrigation of certain crops. Not only the water content but also a portion of the nitrogen content of the effluent is believed to be utilized by the crops.

In Baltimore, sewage effluent is utilized by the Bethlehem Steel Co. in the plant for nonsanitary purposes (*15*). The effluent requires no treatment except chlorination and settling.

The use of treated sewage effluent by oil companies for general plant use and for water injection in secondary oil recovery has also been described in many journal articles (*21*, *27*). These are only four examples of many instances where reclaimed sewage is employed.

RESERVES

An inventory of the world's total water reserves and potential resources available within the earth's hydrosphere shows that the overwhelming amount, an estimated 1,060,000 billion acre-feet or 32 times that of fresh water, is in the oceans. This water is presently usable as a transportation and recreation medium, as a natural source of food and minerals (sodium chloride, potash, and magnesium), and in industrial plants. If the oceans could be economically desalted and suitable disposition made of the removed minerals, the supply of fresh water would be virtually inexhaustible. Of the 33,016 billion acre-feet of fresh water in the inventory, 24,668 billion acre-feet or 75 percent is in polar ice and glaciers, and 8,213 billion acre-feet or 25 percent is ground water. All other forms of fresh water in lakes, rivers, soil, plants, animals, and the atmosphere are 135 billion acre-feet or less than 0.5 percent of the total amount of fresh water. Annual precipitation on land is 89 billion acre-feet and annual stream runoff is estimated at 28.5 billion acre-feet.

CONSERVATION

The greatest consumption of water is in irrigation because up to two-thirds of the water used is evaporated. Very little can be done to reduce this water loss; however, losses due to leaks in reservoirs and conduit systems and to phreatophytes are minimized by proper surveillance.

It has been estimated that in the arid and semiarid regions of the Western States phreatophytes waste more than 25 million acre-feet of water annually. Phreatophytes are plants that depend upon ground water for their water supply and that have low economic value. The water they use and return to the atmosphere without substantial benefit to man is defined as consumptive use. In the interest of conserving water to meet an ever-growing demand, more attention has been given to the phreatophyte problem (*25*, *26*).

Water evaporated annually from larger lakes and reservoirs having a combined area of 11 million acres is estimated to exceed the total water withdrawal for public supplies. Farm ponds, which are shallow and relatively warm, are more subject to evaporation loss than the deeper lakes and reservoirs. Loss due to seepage from small ponds and reservoirs has been estimated at three to six times the evaporation loss. However, seepage losses are potentially recoverable as ground water.

The water loss by evaporation from reservoirs and ponds is reduced by maintaining an adequate depth-to-surface-area ratio, thus minimizing the temperature rise. A film of hexadecanol (cetyl alcohol) spread on the water surface also retards evaporation.

Industrial water applications offer many opportunities for conservation. Elimination of leaks in conduit systems and use of shutoff valves to control unnecessary flow reduce waste. Greater reuse of water entails many problems associated with water quality, which usually deteriorates with each reuse.

A western steel firm conserves water by progressive reuse in the several processes of the operation. After water is used for the highest quality needs, a part of it is passed on to the next process that can use a lower quality water; the rest, along with new makeup water, is recirculated. Consequently, this plant consumes only 1,100 gallons of water per ton of steel, compared with the industry average of 65,000 gallons per ton of finished steel. Problems associated with the buildup of organic slimes in recycled cooling water have been attacked by using additives to destroy the organisms and eliminate corrosion caused by their waste products.

SOURCES OF STATISTICAL INFORMATION

Data on water use in selected nonmanufacturing segments of the mineral industry in the United States in 1962 were collected by a national survey conducted by the Bureau of Mines during 1963. Included in the survey were operators of metal and nonmetal mines, mills, and quarries; coal preparation plants and associated mines; petroleum-well drilling and secondary recovery, and natural gas processing plants. Metal smelters and refineries and cement and lime plants were excluded because they are classed in the manufacturing industries ordinarily canvassed by the Bureau of the Census. Stockpile and assessment work operations, natural brine operations, and coal mines without preparation plants were excluded to limit the size and complexity of the canvass and because it was concluded that together they constituted less than 1 percent of the total water

use in the mineral industry within the scope of the canvass. Recycled solvents such as leaching and cyanidation solutions also were excluded.

Primary producers of petroleum and natural gas were excluded because the water usage in these sectors was considered to be relatively small. Petroleum refineries were excluded because they are classed as manufacturing and not in the Bureau of Mines canvassing scope and because recent water-use surveys have been conducted by other Federal agencies and industry associations. Only the contract well-drillers were canvassed because they accounted for about 95 percent of the wells drilled for the petroleum and natural gas industries. The data collected from the contractors were expanded to cover the total footage drilled by contract and by oil and gas companies and operators.

More detailed data from this canvass on quality and source of water, new-water intake, and total water usage by major segments of the mineral industry were published in the Bureau of Mines Minerals Yearbook, 1963 (*17*). In addition, two proposed Bureau of Mines Information Circulars reporting on this canvass are under preparation; one, by Alvin Kaufman, will place emphasis on the water use in the metals, nonmetals, and coal components of the mineral industry, and the other, by Paul M. Buttermore, on the petroleum and natural gas industries. It is anticipated that a similar survey will be conducted by the Bureau once every 5 years to determine the trend of water use in the mineral industry.

WITHDRAWALS, REQUIREMENTS, DISCHARGE, AND CONSUMPTION

Water withdrawals and water consumed in 1960 are shown by water-use regions in table 1. Total withdrawals of 266 bgd in 1960 were more than 50 percent of the estimated dependable supply of 515 bgd in 1980. However, water consumed, 60 bgd, was only 22 percent of the total withdrawals in 1960.

United States water requirement for all uses for 1954, with predictions for withdrawals and consumption for 1980 and 2000, as given in the final report (*31*) of the Senate Select Committee, are shown in table 5. The streamflow in the United States in 1954 was about 1,100 bgd. On an anual basis, the Nation's streamflow has ranged from 50 percent of the average during periods of drought such as that during the 1930's, to nearly 140 percent of average during periods of excess precipitation. Withdrawal of 300 bgd in 1954 was 27 percent of the streamflow in that year. This figure is substantially higher than published estimates by the Federal Geological Survey for 1955 and for 1960 (table 1) because it was computed on the assumption that the optimum amounts of water for irrigation are made available to the growing plants; whereas, in actuality, substantial shortages were felt in 1954.

TABLE 5.—*Water requirements, 1954, 1980, and 2000, for withdrawals and consumptive uses or depletions from streamflow in the United States* [1]

Total	300.3	100	109.5		558.9	100	119.3		888.4	100	156.3	
Onsite uses:												
Watershed improvement programs							4.0				7.0	
Swamps and wetlands for wildlife							66.7				89.9	
Total							70.7				96.0	
Grand total							190.0				253.2	

[1] Based on Resources for the Future, Inc., medium projects and in (*31*); data may not add to totals because of rounding.
[2] Less than ½ percent.

Demands are projected by the Senate Select Committee on National Water Resources to increase to 559 bgd or 51 percent of the streamflow by 1980 and to 888 bgd or 81 percent of the streamflow in the year 2000. These withdrawals or demands must be supplied through an expansion in the water resources development program. However, most of the water withdrawn is returned to the streams and can be reused many times, provided steps are taken to maintain its quality. Consumptive uses or losses for the various purposes, as shown in table 5, ranged from 59 percent of the water withdrawn for irrigation down to one-half of 1 percent for steam-electric power cooling. Water withdrawals for irrigation was 59 percent of the total withdrawals in 1954 compared with a projected 21 percent in the year 2000, while withdrawals for steam-electric power cooling was 25 percent of the total in 1954 and is expected to comprise 48 percent of the total in 2000. With anticipated increased evaporation and transpiration losses due to watershed, swamp, and wetland improvement programs, the total of national consumptive uses and depletions is projected to 190 bgd or 17 percent of the available streamflow in 1980 and 253 bgd or 23 percent in 2000.

Water requirements for 1954 and 1959 and projected requirements for 1980 and 2000 for principal water-using manufacturing industries, accounting for 66 percent of the total for all manufacturing in 1954 and 81 percent in 1959, as shown in the final report (*31*) of the Senate Select Committee, are shown in table 6. Projected total requirements for these industries for 1980 are nearly three times the 1959 requirements and for the year 2000 are more than six times that for 1959. Of these industries, chemicals has the greatest projected increased water requirements; by the year 2000 the chemicals industry will require 48 percent of the total water used by these industries and require more than nine times as much water as it did in 1959. Of the six principal water-using manufacturing industries shown in table 6, that represented 81 percent of the total manufacturing industries in 1959, four—iron and steel, chemical, aluminum, and copper, which represented 72 percent of the total manufacturing reported in table 4—are related to the mineral industry.

Special studies have been made and reports published on the water requirements of selected mineral industries; including the mining and milling, smelting, and refining operations; for copper (*24*), aluminum (*8*), and carbon black (*9*).

In table 4 data are shown for total water intake, recirculated, usage, discharged, and consumed at selected nonmanufacturing segments of the mineral industry in 1962 that were covered by the Bureau of Mines canvass. Of the total water usage in these metal, nonmetal, coal, natural gas processing, and petroleum well drilling and secondary recovery operations, 29 percent was new-water intake and the remainder was recirculated or reused water. Of the new-water intake, 75 percent was discharged or returned to the streams or the ground for reuse and the remainder was consumed through evaporation or shipped in the product. The metals, nonmetals, and coal industries as a group accounted for 47 percent of the total water usage, natural gas processing for 48 percent, and petroleum well-drilling and secondary recovery for the remaining 5 percent. The metals, nonmetals, and coal industries as a group discharged 89 percent of the total water discharged and consumed 44 percent of the total water consumed in those segments of the mineral industry covered by the canvass. Petroleum well-drilling and secondary-recovery operations consumed most of the remaining total water consumed.

TABLE 6.—*Water requirements, 1954, 1959, 1980, and 2000, principal water-using manufacturing industries* [1]

[Billion gallons per year]

Water intake by industry	1954		1959		1980		2000	
	Quantity	Percent of total	Quantity	Percent of total	Quantity	Percent of total	Quantity	Percent of total
Iron and steel	2,812	36.6	3,500	35.7	7,124	26.8	12,827	20.8
Chemical	2,380	30.9	3,210	32.7	10,800	40.7	29,700	48.2
Pulp and paper	1,607	20.9	2,140	21.8	6,893	26.0	16,173	26.3
Food	590	7.7	630	6.4	1,000	3.8	1,500	2.4
Aluminum	263	3.4	278	2.9	605	2.3	1,139	1.9
Copper	42	.5	49	.5	114	.4	247	.4
Total	[2] 7,694	100.0	[2] 9,807	100.0	26,536	100.0	61,585	100.0

[1] Based on Resources for the Future, Inc., median projections and on (*31*); data may not add to totals because of rounding.
[2] Represented 66 percent of the total for manufacturing industries in 1954 and 81 percent in 1959.

The source, adequacy, requirements, treatment, costs, reuse, and disposal of water in Arizona mineral industries was described in a report by the Bureau of Mines (*14*). Detailed schematic flow diagrams were shown for uses of water at many of the operations. Total new water required by major Arizona mineral industry operations in 1960 was 27,995 bgy, of which 14,205 bgy or 50.7 percent was consumed. Similar studies are being conducted in the States of Nevada, New Mexico, Wyoming, and Montana and in the Missouri River basin area of northern Missouri and Kansas.

Results were reported on a survey made of the industrial wastes of mineral origin, water requirements, treatment of wastes, and water-treatment practices of meal-processing and various other industries in the Missouri River basin of Kansas and Missouri (*12*, *36*).

GOVERNMENT PROGRAMS

The importance of national water resources problems has been recognized by Federal Government administrators for many years, and many bodies, commissions, and committees have been established to study the Nation's water supply and needs. Among bodies concerned principally or in part with water are the President's Water Resources Policy Commission established in 1950 and followed in rapid succession by the President's Materials Policy Commission, the House Subcommittee to Study Civil Works, the Missouri Basin Survey Commission, the Commission on Intergovernmental Relations, the Commission on Organization of the Executive Branch of the Government, the Presidential Advisory Committee on Water Resources Policy, and the Senate Select Committee on National Water Resources.

The Senate Select Committee on National Water Resources was established in 1959 to study the relation of water resources activities in the United States to the national interest, and the extent and character of water resources activities, both governmental and nongovernmental, that will be required to take care of needs for water for all purposes between that date and 1980. The published series of 32 committee prints (*32*), on the studies undertaken by and for the committee, comprise one of the most comprehensive reviews and forecasts of water-resources development in the United States ever assembled. The Bureau of Mines contribution to this Senate Select Committee study was published as Committee print 8. It includes information on water use in the mineral industry for 1954 and 1958 and projections for the years 1980 and 2000. The data for the water requirements, source, and discharge of water in the mineral industry were based on figures from the Bureau of the Census canvass of the mineral industries in 1954 conducted in cooperation with the Bureau of Mines and on figures from a Bureau of Mines canvass in 1958.

The final report (*31*) of the Senate Select Committee summarized the findings of the hearings, studies, and reports as published in the 32 committee prints and presents the committee's conclusions and recommendations for meeting growing demands on the Nation's water resources in the most efficient manner consistent with accepted public aims.

As a result of the committee's recommendation for a coordinated Federal Government scientific research program on water, the Federal Council for Science and Technology established a Task Group on Coordinated Water Resources Research to make a study. This task group prepared a comprehensive statement of the objectives and activities of all Federal agencies, comprising 5 departments and including 22 bureaus or equivalent units and 3 independent agencies, engaged in water resources research programs (*13*).

In 1952 the Office of Saline Water (OSW) was established in the Department of the Interior under the Saline Water Act to investigate and evaluate problems relating to large-scale desalting of saline water. In 1955 the Saline Water Act was amended and in 1961 the Anderson-Aspinall Act was passed, both of which continued and expanded the work of the OSW.

The Office of Water Resources Research was established in July 1964 by the U.S. Department of the Interior to administer the provisions of the Water Research Act of 1964, which authorizes annual grants to the State water resources research centers. A major aspect of the Office of Water Resources Research is a continuing program of grants to aid specific water resources research at land-grant universities.

PRICES

Prices paid for water vary widely, depending on the area and type of use. The estimated national average value of water was $135 per acre-foot, or 40 cents per 1,000 gallons. Conventional water costs ranged from 20 to 75 cents per 1,000 gallons. According to OSW the cost of converting sea water to fresh water in 1963 ranged from $1 to $1.50 per 1,000 gallons, compared with $4 to $5 in 1952. Two major factors in the cost of converting water are size of plant and cost of heat. Studies made by OSW indicated that the optimum plant size is about 25 to 30 million gallons per day and that using waste heat from an existing powerplant or building a combination powerplant and waterplant may

make this low-cost converted water competitive with high-cost conventional water in the near future.

Cost for new water at 14 mineral industry operations in Arizona, as reported (*14*) by the Bureau of Mines, ranged from 1.0 cent to 57.7 cents per 1,000 gallons, with an average of 12.5 cents, including power, labor, and supplies costs. Recirculation costs for power, labor, and supplies at three copper operations ranged from 1.0 cent to 1.8 cents per 1,000 gallons.

AEC operated the Savannah River heavy water plant, Aiken, S.C., at one-third capacity throughout 1964. Reevaluation of the service life of the plant's process equipment resulted in cost reductions that permitted a 12.5-percent decrease in the heavy water price to $24.50 per pound. Sales to U.S. customers during 1963 increased to over 4,000 pounds—about 1.5 times the 1962 sales. Foreign shipments totaled 54 tons of heavy water.

Heavy water was also available for leasing by foreign governments for 5-year periods or for the duration of bilateral agreements. Annual rental based on 4.75 percent of the purchase price of the water was charged.

RESEARCH

Salt water is more than 30 times as abundant as fresh water in the earth's hydrosphere and covers more than two-thirds of the earth's surface. Making use of the salt water to produce fresh water may be one of the means of satisfying the ever-increasing world's water demands. Many groups and organizations in the United States, governmental and otherwise, are interested in saline-water conversion research and development. The State of California has a sea-water conversion project, with the research being carried out at the University of California. Federal agencies having particular interest in saline-water conversion include the Departments of the Interior and Defense, AEC, and the Office of Emergency Planning. In addition, there is worldwide interest; extensive developments have been made in the Netherlands, Great Britain, and France. Some research on saline extraction has been reported in Spain and Italy. Saline-water research and development activity also has been reported in the U.S.S.R., Japan, Northern and Southern African countries, Australia, and Israel.

Scientific and technical activities in saline-water conversion range from basic research to demonstration and commercial plants. Now more than 25 mgd of fresh water is being produced from saline and brackish waters in large plants in various parts of the world. Most of it is produced from sea water, using several methods of distillation. The remainder is obtained by using electrodialysis processes on brackish waters. The largest sea-water distillation capacities are in Kuwait, on the Persian Gulf, and in Aruba and Curacao, in the Caribbean. Two of the newest plants, the largest saline-water distillation plants in the United States, are the OSW 1-mgd plants at Roswell, N. Mex., and Freeport, Tex. One other built at San Diego, Calif., was moved to the U.S. Naval Base at Guantanamo, Cuba, and placed on stream in the early summer of 1964 to supply fresh water after the Cuban Government had cut off the supply from Cuban sources. A new plant is being designed for the San Diego site. Large electrodialysis plants for brackish waters are at Bahrein in the Persian Gulf; Welkom, South Africa; Buckeye, Ariz.; and the OSW plant at Webster, S. Dak.

Fourteen scientific papers given at two symposia on saline-water conversion sponsored by the American Chemical Society, one in St. Louis, Mo., in 1961 and the other in Washington, D.C., in 1962, were published (*3*). This report is a sequel to a publication (*2*) by the same society in 1960 that was widely read and that reportedly stimulated new interest in the saline-water conversion program.

As part of its effort to promote and assist less developed countries towards self-sustaining growth and, more particularly, under its program for water resources development, the United Nations Secretariat surveyed the economic and technical aspects of salt-water conversion (*29*). While its survey showed that the known processes yield an expensive fresh-water product, it revealed many interesting possibilities of application even at present costs. Desalting, it appears, can already make a valuable contribution to economic development and may become an important feature of international cooperation.

The 1963 research and development programs on saline-water conversion conducted by OSW (*35*) took major steps toward lowering the cost of producing fresh water from salt water. OSW assumed a major role under the aegis of the International Atomic Energy Agency in worldwide efforts to use nuclear power as a source of heat for desalting. Important applied research facilities began operating at the new OSW Research and Development Test Station at Wrightsville Beach, N.C. Increased emphasis was placed on basic research on water. Favorable results were reported on two OSW preliminary appraisal studies, a nuclear-fired combination electric power and sea-water desalting plant to provide fresh water for the Florida Keys at an economically competitive price, and an oil-fired combination electric

power plant and desalting plant to serve municipal requirements at Tijuana, Mexico.

Five demonstration plants to convert saline water to fresh water have been completed by OSW to serve as pilot operations to test the various distillation processes. The first plant to be built by OSW is at Freeport, Tex., and uses the multiple-effect long-tube vertical-distillation process to produce 1 mgd of fresh water from sea water. It has 12 effects and the evaporators are of a falling-film type. A multistage flash-distillation process (36 flashing stages) with a capacity of 1 mgd of fresh water from sea water was the OSW second plant. It was built at San Diego, Calif., but was moved to the U.S. Naval Base, Guantanamo Bay, Cuba. A third plant, operating on brackish well water, using the electrodialysis membrane process, and having a fresh-water output of 250,000 gallons per day, was built by OSW at Webster, S. Dak. The fourth demonstration plant was completed in mid-1963 at Roswell, N. Mex., rated at 1 mgd of fresh water and using the force-circulation vapor-compression process for converting highly brackish water to fresh water. A fifth sea-water conversion pilot plant was completed by OSW in 1964 at Wrightsville Beach, N.C. It uses the freezing process and has a daily fresh-water output capacity of 200,000 gallons. The intended purpose of the plant is to supply fresh water to the city of Wrightsville Beach to augment its present limited sources of natural fresh water. Data obtained from the five OSW pilot operations are providing information that is being studied and evaluated to form the basis for the design of larger and more efficient plants.

In December 1964 a feasibility study was begun that was sponsored jointly by the Metropolitan Water District of Southern California, the U.S. Department of the Interior, and the AEC for a dual-purpose electric power and water-desalting plant capable of producing up to 150 mgd of pure water.

Flood-control, deep-well pumping, and drainage-alleviation projects relating to anthracite coal resources were continued in 1964 by the Bureau of Mines. The program, has implemented Federal and State anti-stream-pollution activities, assisted in conserving natural resources, and enhanced the economy of the anthracite-producing region. The problems and reports written on acid-mine drainage, which have been studied for the past 40 years, were summarized in two Bureau of Mines publications (*4*, *19*).

Acid-mine drainage control research projects in bituminous coal mines were continued by the Bureau of Mines in 1964. The projects comprised (1) a cooperative study with the Ohio River Valley Water Sanitation Commission on the assessment of the value of mine sealing as a means for reducing the efflux of acid mine water from abandoned above-drainage coal mines; (2) a cooperative pilot study with the U.S. Department of Health, Education, and Welfare, Public Health Service, on the application of the best known corrective measures to a watershed now being polluted by acid mine water; and (3) a laboratory study to determine the conditions required for the formation of acid in mine drainage, obtain more complete knowledge on the mechanism of the chemical and biochemical reactions that produce acid mine water, and explore physical, chemical, and biochemical process for its control.

Fundamental mine-hydrology studies are being made by the Bureau of Mines. These studies are intended to develop methods, techniques, instruments, and engineering principles for defining mine-drainage problems prior to the development of underground mines and for controlling the drainage of water in mines.

The Bureau of Mines has conducted extensive experimental work and research on hydraulic mining of both pitching and flat-lying bituminous coalbeds to determine the economics, practicability, safety, and productivity of this method of mining and on hydraulic transportation of coal. Numerous reports have been published giving results of such work.

Material, usually mill tailing, is extensively being hydraulically emplaced as stope fill in underground mines. Research is being conducted by the Bureau to develop the design principles for optimum use of hydraulic backfill as a means of ground support in mines under various conditions of geology, mining methods, and stresses acting upon the mining area.

Heavy water (D_2O), water incorporating deuterium instead of normal hydrogen, absorbs fewer neutrons than ordinary light water. Reactors moderated with heavy water can operate efficiently on natural or slightly enriched uranium fuel. Different types of heavy-water-moderated reactors have been studied in the United States for several years. Recent studies by du Pont and Combustion Engineering made for AEC have shown that the concept has good potential for reduction in unit-power costs in sizes of 500,000 electrical kilowatts or higher. The concept also has a potential application in the production of large amounts of heat for industrial processes such as desalting of sea water (*30*).

OUTLOOK

Continuing and expanded efforts will be required to develop and provide the United States with water in adequate quantity and of satisfactory quality from our finite limits of water supply to meet the ever-increasing needs. The demands of growing population, agriculture, and industry will press on the potential limits of the natural supply of water in certain areas.

The Nation's water resources are not uniformly distributed in all geographic regions. Substantial areas of the river basins in the western half of the United States already have a water shortage. Of the 22 water resources regions of the United States, full development of all of the available water resources in 5 of the western regions will be required by 1980 or earlier. By the year 2000, three more regions will be added to this list requiring full development of all available water resources. Continuation of growth of population and economic activities in these areas will pose many technical, legal, financial, and political problems involved in meeting future water needs. Solutions to such problems will require a major effort by Federal, State, and other agencies and the public, working in close cooperation.

As full development of water resources in a given area is approached, many changes in the utilization and management of water may be expected. Developing water resources to the fullest extent will be reflected in higher costs for water and in increased waste and sewage treatment. Control of pollution will become more stringent, and water conservation methods will be used more widely. Eventually it may be necessary to process all waste for disposal in streams so the effluent will meet rigid standards of purity.

Water will tend increasingly to be used where it will produce the greatest economic and social benefit. The value of manufactured goods produced with the use of 1,000 gallons of water is usually many times the value of agricultural products using the same quantity of water. On the other hand, the measurable values derived from water used in the maintenance of wetlands for wildlife habitat may be less than those derived from irrigating agricultural land.

Research will be continued to explore more of the physical and chemical properties of water in relation to its use, so that new sources of supply may be created from saline water and other sources. The problems of reuse of water will continue to be studied to the end that pollutants of all types can be controlled and safe standards of purity can be established and maintained.

National demands for water withdrawals for all uses were 300 bgd or 27 percent of the streamflow in 1954 and are projected to increase to 559 bgd or 51 percent of the streamflow by 1980 and to 888 bgd or 81 percent of the streamflow by 2000. However, most of the water is used and reused and returned to the stream and can be used by others, provided steps are taken to maintain the quality of the water returned to the streams.

Consumptive uses or depletion from streamflow, for the various purposes, range from about 60 percent of water withdrawn for irrigation down to a fraction of 1 percent of water diverted for steam-electric power cooling. Consumptive uses of 110 bgd or 10 percent of streamflow in 1954 are projected to 119 bgd or 11 percent of streamflow in 1980 and 156 bgd or 14 percent of streamflow by 2000. Additional consumptive losses from contemplated conservation practices for onsite water uses for watershed improvement and swamps and wetlands for wildlife programs raise the projected consumptive uses to 17 percent of the available streamflow by 1980 and 23 percent in 2000.

The principal factor responsible for the growing needs for water is the rapid gain in population and man's concurrent demand for an increased amount of goods and services requiring the use of water. The per capita use of municipal water, which has risen from an average of 108 gallons per day in 1950 to 134 gallons in 1960, is expected to reach 158 gallons per day by 1970. But of most importance is the increased water demand for steam-electric power cooling, manufacturing, irrigation, waste dilution, and the mineral industry.

The withdrawal of water for irrigation will continue to grow from 176 bgd of the 300 bgd total for all uses in 1954 to a projected 185 bgd of the 888 bgd total in 2000. However, from these figures it can be seen that irrigation is expected to represent a smaller part of the total withdrawal for all uses in the future, 59 percent of the total in 1954 compared with a projected 21 percent of the total in 2000. Steam-electric power cooling took 25 percent of the total in 1954 compared with a projected 48 percent of the total in 2000. Water withdrawals for manufacturing in 1954 were 11 percent of the total compared with a projected 26 percent by 2000.

Production of chemicals will take the largest share of the expected increase in future water requirements for the manufacturing industry. The manufacture of pulp and paper and food processing are also expected to take larger quantities of water as will the mineral-process-

ing industries of iron and steel, aluminum, and copper. Total water requirements for these six industries, which constituted 81 percent of the total water requirements for all of the manufacturing industries in 1959, are projected to 26,536 bgy in 1980 or three and one-half times that of 1959 and 61,585 bgy by 2000 or eight times the 1959 total.

The water requirements for the nonmanufacturing segments of the mineral industry, including metal and nonmetal mines, mills, and quarries, coal-preparation plants and associated mines, petroleum well-drilling and secondary recovery operations, and natural gas processing plants, are relatively small in comparison to the total water demand for the entire manufacturing industry. However, the requirements for new water by the mineral industry are expected to increase from 1,030 bgy in 1962 to more than 2,000 bgy (double that of 1962) in 1980 and more than 4,000 by the year 2000. To supply the total requirements of the mineral industry, a greater quantity of water will be recirculated or reused because the total water usage, which is the sum of new-water intake and water recirculated, is expected to be three times the 1962 figure of 3,594 bgy by 1980 and six times that of 1962 by 2000.

PROBLEMS

The primary and pressing problem for national water resource planners is one of providing an adequate quality and quantity of water at the time and place to meet the growing demands as the upper limit of potential supply from surface and ground sources is approached. Five major categories of effort are needed for meeting prospective demands on a long-range basis, so as not to inhibit national or regional growth, (*31*) as follows:

1. Regulating streamflow by the construction of surface reservoirs and watershed management.
2. Improving the quality of our streams by more adequate pollution-abatement programs.
3. Making better use of underground storage.
4. Increasing the efficiency with which water is used by elimination of wasteful practices, improved sewage-treatment methods, recirculation, increased irrigation efficiency, and substitution of air for water cooling.
5. Increasing the natural water yield by desalting, weather modification, and other artificial means.

The five demands listed above are complex, and solving the problems related to them is difficult and often creates other problems. Excess of water supply usually corresponds with cool rainy seasons, whereas the peak in water demand comes in hot, dry periods. Building reservoirs to store this excess water for use during the dry period creates other problems because the water may inundate towns, farmland, forests, mineral deposits, and historical and archeological sites. Evaporation from reservoirs is consumption and substantially reduces the benefits derived from such structures.

The most effective and economical methods for treating waterborne wastes, both organic and inorganic, must be determined so that the water will be suitable for reuse wthin a reasonably short period and the waste material will be converted into a usable or an inoffensive product. Under present practices biochemical action to remove organic wastes results in increasing concentrations of nitrates and phosphates. This in turn promotes the growth of algae blooms resulting in bad-tasting water and possible fish kills. If economical methods for recovering nitrates and phosphates from sewage-plant effluents were developed, not only would valuable fertilizer materials be produced but stream pollution would be reduced as well. Recent estimates are that by 1980 streamflow of satisfactory quality can only be maintained if the quantity of organic wastes removed from each gallon of municipal and industrial sewage is doubled. Chemical and radioactive waste removal also presents many problems. The cumulative effects on the potential water supply of certain chemical substances used as insecticides and herbicides is unknown, and standards for their removal remain to be formulated.

As the demand for water approaches the limit of supply, apportionment of water among the various users and for various purposes becomes very complex. An example of the complexity of water management is the fact that flood control requires an empty reservoir or one maintained at low level; hydroelectric power and municipal water supply require a reservoir maintained at high level, but with a water level that can be lowered as the water is needed; recreation and wildlife management require a reservoir with a relatively stable water level; and pollution abatement needs a reservoir that will stabilize streamflow in the various seasons of the year. Reconciliation of the demands for water for its many varied purposes requires careful evaluation in order to achieve the maximum benefits in the public interest.

Reuse of water tends to increase the concentration of pollutants. The effects of increased concentration of many pollutants and satisfactory control methods remain unknown. Temperature of the water may increase, causing

rapid growth of algae and other organisms which foul pipes and equipment and increase corrosion.

Large-scale pumping of water from aquifers often causes land subsidence which affects surface structures and may lead to compaction of aquifers, resulting in loss of their capacity for storing water. Lowering the water table by excess pumping near the ocean or other saline sources of water leads to contamination of the aquifer with salt water.

The water problems of the mining industries are varied. In water-short areas, obtaining an adequate supply of water of satisfactory quality for mining and metallurgical operations is a major problem. In other areas the flooding of mines by excess ground water and surface flow is equally serious. Disposal of oil-well brines and refinery wastes is a problem of the oil industry, and control of acid mine water from the coalfields is an important problem of the coal industry. Disposal of waterborne wastes resulting from metallurgical operations and from grinding, sizing, and cleaning minerals is a disposal problem of the mineral industry in general.

YTTRIUM

By John G. Parker [1]

YTTRIUM is always associated with the rare-earth elements in nature, but pure yttrium compounds have been available only since 1947. Production of yttrium and yttrium compounds has been developed as a small part of the rare-earth industry. Monazite, xenotime, and euxenite concentrates are digested with acid or sodium hydroxide, and the yttrium and rare-earth elements separated as mixed insoluble oxalates, precipitated by varying the pH, or loaded in solution onto ion-exchange resin beds. The products are converted to oxides, halides, and other salts. When needed, further separations or purifications are made by solvent extraction or ion-exchange methods. Yttrium metal is produced by electrolysis or by reduction of the fluoride or chloride with calcium, lithium, or sodium.

The major commercial application for yttrium to date has been in devices used in microwave electronics. Very recently certain advances in laser technology and particularly in color television have been shown to depend upon yttrium usage. A potential large-scale use of yttrium materials may be in the production of ductile cast iron.

The prices of yttrium metal and compounds vary with the producers, the purity or grade of the product, and the quantities purchased. Yttrium oxide prices range from $45 to $500 per pound for material of 99 percent to 99.9999 percent purity. Yttrium metal—99.9 percent pure—is quoted at $208 per pound; an yttrium misch metal is quoted at $38 per pound.

Production of and research programs on yttrium have been sponsored mainly by government agencies.

The problems of yttrium production include the development of uses and demand, disposal of surplus quantities of yttrium materials held by government agencies, and incomplete knowledge on abundance and location of domestic resources.

BACKGROUND

Johann Gadolin, a Russian chemist, isolated a new "earth" or metal oxide in 1794 from a mineral found at Ytterby, Sweden. The mineral from which the earth was extracted was later named gadolinite in his honor. In 1797 Ekeberg suggested the name yttria for this compound which both he and Gadolin considered as an oxide of a single element. Subsequently, several independent investigators discovered a second oxide, which was named ceria. Still later, it was found that these two oxides were composed of complex mixtures of the oxides of a number of unknown elements. The presence of a number of rare-earth- and yttrium-bearing minerals which were early subjected to intense study has immortalized the name of the area in the names yttrium, ytterbium, terbium, and erbium. The extremely complex riddle presented by the chemical and physical nature of yttrium and the 14 naturally occurring rare-earth elements required over a century to solve, being studied by eminent chemists such as Berzelius, Crookes, Klaproth, Marignac, and Mosander. Large-scale separation of pure yttrium was not possible until 1947, however, at which time an ion-exchange process was developed by F. H. Spedding and his associates at Iowa State College.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Producers extract small quantities of yttrium in the processing of monazite and other rare-earth minerals. The companies identified most closely with some phase of yttrium recovery include: Rare Earth Division, American Potash & Chemical Corp., West Chicago, Ill.; Michigan

[1] Commodity specialist.

Chemical Corp., St. Louis, Mich.; Research Chemicals Division of Nuclear Corp. of America, Phoenix, Ariz.; and Vitro Chemical Co., Chattanooga, Tenn. Lunex Co., Pleasant Valley, Iowa, produces yttrium metal.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Yttrium, Y, atomic number 39, occurs between the elements scandium and lanthanum in group III of the periodic table. It is homologous with the rare-earth metals, its chemical nature and occurrence being so nearly like these elements that it is difficult to separate from them. Yttrium metal has a hexagonal close-packed crystal structure of 4.48 density to 1,490° C, just below its melting point of 1,509° C. It boils at 2,927° C and has a thermal neutron cross section of 1.3 barns per atom. Pure yttrium metal is ductile and has good resistance to atmospheric corrosion. Its chemical reactivity in ordinary environments, however, is increased greatly by the presence of other metals, particularly some of the rare-earth metals. Small quantities of dissolved oxygen, nitrogen, and fluorine make yttrium brittle. Pure yttrium metal is not attacked by molten uranium-chromium eutectic at 900° C and is immiscible, or nearly so, with a number of other molten metals such as tantalum and vanadium (*1*).[2]

Yttrium oxide, Y_2O_3, or yttria, has a cubic crystal structure, a density of 4.84, a melting point of 2,410° C, and a boiling point of 4,300° C. It is a poor conductor of electricity, is fairly stable in air, and is not easily reduced.

Companies designate as high-purity metal yttrium of 99.9 percent quality which may be purchased as ingots, crystal sponge, lumps, and turnings. Distilled metal of greater than 99.9 percent purity is also available. Yttrium oxide, with a purity up to 99.9999 percent based on rare-earth oxide (REO) content, is produced by the industry.

Analytical determinations are difficult to perform on mixtures of the closely similar yttrium and elements of the rare-earth group. In evaluating ores and concentrates, yttrium and the rare-earth elements present are precipitated in a group as oxalates which are then ignited to the oxides, weighed, and reported as REO. More accurate analytical methods must be based on physical properties of the elements, such as the average atomic weight of the mixed elements, the magnetic susceptibility, and methods using arc, X-ray, or atomic absorption data. Neutron activation is used to determine extremely small quantities of contaminating materials, and the inert gas fusion method has been used to accurately determine oxygen in yttrium and yttrium fluoride. The type and distribution of inclusions present in the metal may be determined by metallographic inspection of the microstructure.

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

TECHNOLOGY

Geology

Although yttrium is always found in nature with the rare-earth elements, it is said to be concentrated predominantly in the earth's crust as pegmatitic differentiates from granitic magmas, whereas rare-earth elements of the cerium subgroup occur mostly in differentiates from syenitic magmas. Some of the syenites, however, were calculated to contain about 8 grams per ton yttrium, and certain aluminum-rich schists contained almost twice that quantity (*10*). Despite the fact that yttrium is sometimes concentrated in notable quantities in apatite and garnet, more common yttrium-bearing minerals include xenotime, gadolinite, members of the euxenite-polycrase and fergusonite-formanite series, samarskite, yttrotantalite, yttrofluorite, and doverite. Monazite, with rarely up to 5 percent yttria, and bastnaesite, with seldom more than 0.1 percent yttria, are discussed in the chapter on rare-earth metals. Although they are low grade sources of yttrium, they have served as the principal source of byproduct yttrium because of the large quantities of concentrate processed and the relatively limited demand for yttrium.

Xenotime, essentially yttrium phosphate with erbium and other heavy rare-earth elements, contains from 50 to 68 percent REO. It is found almost invariably in small quantities with monazite in granitic and gneissic rocks and in stream and beach placers. Gadolinite, a complex beryllium-iron-yttrium silicate found in granite pegmatites, theoretically can contain about 48 percent REO usually 60 percent of which (nearly 30 percent of the mineral) may be Y_2O_3. Thalenite and yttrialite are other rare silicates rich in yttria. Minerals of the euxenite-polycrase and fergusonite-formanite series are multiple oxides containing columbium, tantalum, and from 16 to over 45 percent yttrium and other heavy rare-earth metals. Usually minerals of the euxenite-formanite series contain significant quantities of uranium and thorium. A mineralogical phenomenon, called the metamict state, is often characteristic of these multiple oxide minerals which have their crystalline structures disarranged by alpha radiation from the uranium, thorium, and other decay products.

Samarskite, yttrotantalite, and yttrofluorite are uncommon minerals containing from 6 to 17 percent yttria. Doverite, an yttrium fluocarbonate with about 45 percent REO, first reported from a Morris County, N.J. iron mine, has been considered by some researchers as an yttrian synchisite. This material may contain as much as 35 percent heavy REO, most of which is yttrium, with lesser quantities of the light REO. Apatite may contain significant quantities of yttrium and rare-earth elements substituted for calcium, a notable occurrence being its association with magnetic iron ore at Mineville, N.Y. Here the heavy subgroup is less than half the combined REO content, and Y_2O_3 may total several percent of the mineral.

Minerals containing yttrium and rare-earth elements are found disseminated and in veins in alkalic rocks, granites and syenites, granitic and syenitic pegmatites, gneisses, carbonatites, and contact metamorphic rocks. Some are concentrated in basic rocks, notably associated with magnetite. Fluvial and beach placer deposits, derived from primary deposits, are the main economic sources of yttrium. For example, monazite is now processed in Florida and xenotime was formerly extracted from a placer deposit at Aiken, S.C. Large placers in Idaho and Montana formerly were worked for their rare-earth and thorium contents. In Bear Valley, Idaho, alluvium washed down by streams from a deep regolith was deposited in placers worked for columbite, tantalite, and euxenite in the late 1950's.

In the United States, in addition to the rare-earth-bearing magnetite ores in New York and New Jersey, other notable bedrock occurrences are with thorite in mineralized shear zones in Precambrian metamorphic rocks of the Powderhorn district, and with thorium deposits in a Precambrian complex in the Wet Mountains area of Colorado. In Canada, yttrium has been derived as a byproduct from brannerite-uraninite ore found in the conglomerate type deposit of the Blind River, Ontario, area.

Mining and Beneficiation

Conventional methods employing suction and bucketline dredges are used to recover monazite, xenotime, and euxenite from beach sands and river gravels. Jigs are used to separate gravels and coarser materials and Humphrey spirals, sands. The bulk concentrate, called "black sand," is sent to a plant where it is subjected to magnetic and electrostatic separation to obtain the individual minerals. Wet magnetic separation is used to remove most of the magnetite and part of the ilmenite. After the residue is dried, it is passed over magnetic separators, using magnetic fields of varying strengths, to remove successively the remaining magnetite, ilmenite, and garnet.

It was reported that flotation with oleic acid was used for production of concentrate from the vein monazite deposit at Van Rhynsdorp, Republic of South Africa (*11*).

Processing

The recovery of yttrium requires complex chemical processing. Most rare-earth and yttrium concentrates are processed commercially by one of two methods, as described fully in the chapter on rare-earth metals. The general plan is to treat finely ground mineral concentrate with sulfuric acid or sodium hydroxide, separate rare-earth elements and yttrium from uranium and thorium, and then separate rare-earth elements from yttrium.

The most commonly used breakdown method for acid leachable minerals such as monazite and xenotime is digestion with hot concentrated sulfuric acid. More refractory minerals such as euxenite, fergusonite, and samarskite are fused first with sodium hydroxide to make them more soluble. Treatment by the sulfuric acid process entails reacting finely ground concentrate with hot sulfuric acid, dilution with cold water, and then any one of several methods to separate rare-earth elements and yttrium from thorium and uranium. For example, thorium, uranium, and a small part of the rare-earth elements are separated by neutralizing the solution to a pH of 1.0, most of the remainder of the rare-earth elements and yttrium are precipitated at pH 2.3, and the uranium and the rest of the rare-earth elements are precipitated from the filtrate at about pH 6. Another method entails precipitating thorium and rare-earth elements from diluted solution with sodium oxalate and converting the oxalate to hydroxide by treating with hot caustic soda (*11*). The hydroxides are heated to form oxides which are then dissolved in nitric acid, and the rare-earth and yttrium values are removed from thorium and cerium by solvent extraction with tributyl phosphate (TBP).

In the sodium hydroxide digestion of monazite, the reaction mixture is diluted and the sodium hydroxide-sodium phosphate solution filtered from the hydrous yttrium and rare-earth oxides, the hydrous oxide cake is dissolved in hydrochloric acid, and the thorium and uranium precipitated from the solution by raising the pH (*11*). After the crude thorium hydroxide is separated, the rare-earth metals and yttrium are precipitated from the filtrate by raising the pH further. In another method, developed for the treatment of xenotime, the

mineral concentrate is digested with hot sulfuric acid (*5*). The leachate from the digestion is then loaded onto cation exchange resin beds and eluted with ammonia-buffered ethylenediaminetetraacetic acid (EDTA) solution containing cupric ion which prevents precipitation of the insoluble EDTA on the resin bed. The yttrium and rare-earth metals are separated in different fractions of the eluant, precipitated as their oxalates, and then ignited to their oxides.

In the separation of yttrium and elements of the yttrium subgroup by large-scale ion exchange with EDTA and nitrilotriacetic acid (NTA), the use of Cu^{2+} and Zn^{2+} retaining ions facilitated redeposition of rare-earth ions on the resin bed in the column after they had been dislodged by the eluant from the resin phase (*9*). Ammonium and ammonium-hydrogen ions have been used alone or added to the copper retaining ion when separating yttrium under less acid conditions.

A hydroxyethyl EDTA, called HEDTA, used with a hydrogen-state resin bed, avoids the need for a heavy-metal retaining ion, is easily recovered from an aqueous solution, and can be recycled (*9*). Diethylenetriaminepentaacetic acid (DTPA) has been used at elevated temperatures to isolate yttrium in a pure state.

Solvent extraction is being used increasingly by industry. Its applications and advantages are mentioned in the chapter on rare-earth metals, but it can be used to isolate yttrium from rare-earth elements by employing two different solvent extraction systems (*7*). Yttrium and heavy rare-earth values are extracted from an acidified aqueous solution with dialkyl phosphoric acid (*8*). The resulting organic phase, rich in yttrium, was stripped by an aqueous mineral acid, and the yttrium subsequently was left in this aqueous strip solution after the other heavy rare-earth metal values were removed by a solvent such as trialkyl phosphate. Bureau of Mines researchers have recovered yttrium oxide from siliceous thorite ores of the Powderhorn area in Colorado by acid curing, baking, leaching, and solvent extraction with di-2-ethylhexyl phosphoric acid (D2EHPA) (*2*).

The fluoride and chloride of yttrium, from which the metal is won by metallothermic reduction, are usually prepared by reacting yttrium oxide with ammonium hydrogen fluoride or anhydrous hydrogen fluoride at elevated temperatures, or by mixing yttrium oxide, ammonium chloride, and hydroxylamine hydrochloride together and heating (*5*). Before employing metallothermic reduction, Bureau of Mines investigators purified yttrium halides by vacuum distillation. In laboratory-scale work, use of high-purity lithium or sodium as a reductant permitted 95 percent recovery of an yttrium sponge metal which was more than 99.8 percent pure (*6*). Massive yttrium metal has been produced on a commercial scale by the direct reduction of yttrium fluoride (YF_3) with calcium at high temperature in an inert atmosphere. More recently, in metallothermic reduction of the chloride with lithium or sodium, it was not necessary to heat the reactants as much as when using the fluoride. (*4*). Yttrium metal also has been produced on a large scale by reducing the fluoride with calcium, in excess, in the presence of magnesium. The resulting yttrium-magnesium alloy was heated in a vacuum to sublime the magnesium and residual calcium, leaving a metal sponge which was arc melted into ingots. Electrolysis may be used to electrowin yttrium metal from the oxide in a bath of fused alkali halide.

Recently the Bureau of Mines has electrowon yttrium from Y_2O_3 on an iron cathode using a fluoride electrolyte, thereby preparing a low melting alloy. Efforts were being made to coreduce iron-yttrium oxides to the alloy in a fluoride electrolyte. Yttrium was electrorefined and vacuum distilled, using a $LiCl\text{-}YCl_3$ electrolyte; solid state electrolysis was used to remove significant nickel, iron, and oxygen from yttrium metal bars.

Other refining methods include consumable electrode arc melting under vacuum and purification by high temperature distillation.

USES

The major and probably only commercial use of yttrium is in yttrium-iron garnets, called "yigs" in the electronics industry. These crystals, having the general composition $3Re_2O_3.5Fe_2O_3$ where Re is rare-earth elements or yttrium, serve as filters for selecting or tuning microwaves. Recently yttrium-aluminum garnets (yags), with low lasing thresholds and needing little cooling, have been used in lasers. Yttrium orthovanadate and yttrium oxide, both activated by europium, are two superior red phosphors said to provide high luminosity in color television tubes.

Other potentially important uses of yttrium, upon which significant research has been conducted, are as a structural metal in nuclear reactors because of its low thermal neutron cross section and relatively high melting point; as a hydride with superior thermal stability which makes it of value as a neutron moderator in nuclear reactors; as a scavenger and grain refiner in vanadium, and as a preventor of nitride formation and promoter of high temperature oxidation resistance in chromium; as corrosion-resistant metal pipe in fluoride processing; as a refractory oxide coating with good thermal

shock resistance; and, probably most significant, as an additive promoting the formation of nodular graphite in ductile cast iron.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Monazite and euxenite are usually recovered as byproducts from the processing of beach sands and river gravels for titanium minerals, zircon, columbite, gold, or tin. Since the Atomic Energy Commission (AEC) thorium procurement program ceased in 1959, the rare-earth elements and yttrium extractable from monazite have become more important to the industry than has the thorium. Euxenite, formerly processed primarily for its columbium-tantalum content and secondarily for uranium, thorium, and the heavy or yttrium subgroup elements, has not been mined domestically since the late 1950's.

ALTERNATE MATERIALS

Although research on yttrium has shown the potential value of the metal and its compounds for various applications, its most important use to date has been in components of microwave equipment. In this electronic field, especially as yttrium-iron garnets which have low electrical and low eddy-current losses, it has competed successfully with other cheaper, more plentiful materials such as the spinel-type of ferrite compounds. Yttrium oxide has been suggested as a refractory coating, but thorium oxide is a cheaper stable refractory oxide which, however, has poor resistance to thermal shock. Yttrium hydride, as a neutron moderator, must compete with standard moderators such as graphite, beryllium, and heavy water. Due to its low neutron cross section yttrium metal has received attention as a structural metal in nuclear reactors along with columbium and tantalum but zirconium, aluminum, and stainless steel are cheaper and are commonly used. The large scale usage of yttrium in the production of ductile iron is hindered at this time by the lack of satisfactory yttrium materials at generally acceptable low prices competitive with the commonly used nodularizers such as ferrosilicon-magnesium misch metal alloy or nickel-magnesium alloy.

RESOURCES

The consideration of yttrium as a mineral commodity separate from the rare-earth elements, with which it is always associated, has taken place only in the past 5 or 6 years. The most common rare-earth mineral, monazite, is a primary source of yttrium, and it may be considered as a byproduct of the recovery of cerium group metals which have had greater usage. Although the yttrium oxide contents of monazite from various localities sometimes differ greatly, the yttrium contents of 15 domestic monazites showed an average of about 2.5 percent of the total rare-earth elements present. Reference to domestic resources of monazite and their rare-earth oxide contents, described in the chapter on rare-earth metals, indicates the presence of a substantial domestic supply of yttrium in monazite.

Xenotime, found in small quantities with monazite, has been processed very little for its yttrium content, and, although the yttrium oxide content of the mineral is substantial, the yttrium resources estimates for this mineral are included with monazite. In addition, although the yttria content of bastnaesite is lower than the lowest noted for monazite—0.2 percent or lower—the large California bastnaesite deposit contains about 10,000 tons of yttrium oxide. The euxenite deposit in Idaho, formerly mined primarily for its columbium, tantalum, and uranium content, was estimated to contain 7,500 tons of the mineral with about 20 percent, or 1,500 tons, of yttrium oxide.

It is possible that nearly 30,000 tons of yttrium oxide is present in the various domestic ores. This conforms closely with estimates that the supply of yttrium from these sources is no more than 10 percent of the available cerium (*13*). Not included in these estimates are large quantities of yttrium in apatite contained in tailings from magnetic iron ore processing.

PRODUCTION, CONSUMPTION, AND TRADE

Practically all of the more recent production of yttrium metal and compounds for research purposes was sponsored by Government agencies, principally by the AEC. During the period 1957 through 1959 two organizations made about 15 tons of production-grade metal and sponge (*4*) and over 30 tons of yttrium fluoride was produced for use in the preparation of the metal (*3*). At times during this period total yttrium oxide production reached peaks of over 2 tons per month. Since then, however, yttrium production has dropped considerably and most of the current small demand has been for high-purity materials in electronics and in metallurgical research. Metal production since 1960 probably has not amounted to much more than 200 pounds; oxide production for 1962 and 1963 has averaged about 5 tons a year. Tariff rates on yttrium metal and alloys are included in those for processed rare-earth materials.

STRATEGIC CONSIDERATIONS

Despite the low yttrium content in bastnaesite, any conceivable emergency demand could be met by the processing of domestic bastnaesite and monazite or by the reactivation of additional monazite and the Northwest euxenite operations.

Yttrium is not on the Government list of strategic materials for stockpiling but is associated with rare-earth materials in various Government stockpiles. A considerable quantity of REO, and yttrium, will be in excess because of the new, lower objective of 3,000 short tons of REO for the strategic stockpile announced early in 1964. In addition, industrial stocks are large, and the AEC holds in inventory large quantities of yttrium metal, alloys, fluorides, and oxides. Well dispersed plants, now operating below capacity, easily could handle raw materials coming from amplified or reactivated mining operations.

PRICES

Monazite, prices of which are shown in the chapter on rare-earth metals, is the only yttrium-bearing ore or concentrate which is quoted on the open market. Sales contracts are written on large quantities, or purchases are directly negotiated between buyer and seller on small lots of ore or concentrate. No sales have been noted on any ores except monazite and bastnaesite since 1959, at which time contained yttrium brought from 50 cents to $1 per pound, depending on grade.

Recently, production chemical grades of yttrium oxalate and oxide of 70 to 85 percent purity sold for $18 and $36 in from 1- to 49-pound lots. In contrast, research quantities of anhydrous yttrium chloride and fluoride, from the same company, were $73 and $80 per pound package, respectively.

In 1963 one major producer raised prices substantially on its highest purity grades of yttrium oxide while another dropped prices on a number of grades. Nevertheless, prices on 99 percent to 99.9999 percent pure yttrium oxide ranged from $45 to $500 per pound in lots of 2 to 99 pounds. Low-oxygen yttrium metal ingots or lumps, of 99.9 percent purity, sold for $350 per pound in lots from 1 to 25 pounds; other yttrium metal of various purities, forms, and lot sizes, available from four companies, sold from $125 to $340 per pound. An 80 percent yttrium-magnesium alloy, in ingot or lump form, was $90 per pound in 1 to 25 pound lots; an yttrium misch metal was $38 per pound in 2 to 10 pound lots.

TAXES

With the exception of monazite, a 15-percent depletion allowance can be obtained on the gross incomes from the mining of domestic and foreign rare-earth and yttrium-bearing minerals. Monazite, because it contains thorium, is eligible for a 23-percent depletion allowance when it is mined domestically, and 15 percent, when it is mined from foreign deposits.

RESEARCH

Investigations on yttrium have always been included in research by the rare-earth industry and by other organizations and laboratories conducting studies on the processing, properties, and uses of the rare-earth elements. At the four rare-earth research conferences held in the United States from 1960 through 1964, yttrium phase studies were discussed, metal production and fabrication described, and geochemical abundance data presented.

Research has been sponsored by the AEC and the Department of Defense at university, industrial, and government laboratories. The separation of yttrium and the individual rare-earth elements by ion exchange at Iowa State College (now Iowa State University) and at Oak Ridge National Laboratory (ORNL) was sponsored by AEC. More recently experiments have been conducted at Ames Laboratory (Iowa State University) on the extrusion of seamless yttrium tubing from recrystallized billets (*12*). Geochemical abundance data have become available through programs financed by National Aeronautics and Space Administration (NASA). Research Chemicals, a division of Nuclear Corporation of America, conducted research on the properties and phase relationships of yttrium metal and alloys for the U.S. Air Force.

The Federal Bureau of Mines has conducted research on the extraction, production, refining, and properties of yttrium at its Albany (Oreg.) and Reno (Nev.) Metallurgy Research Centers.

OUTLOOK

Most of the yttrium raw material should be obtained as a byproduct of monazite and bastnaesite operations but, if demand should increase sharply, the outlook is promising for developing additional supplies from yttrium mineral deposits or from other mineral operations. Typical of this is the possible recovery of substantial quantities of yttrium and yttrium subgroup elements from apatite in Adirondack magnetic iron ore tailings. In addition, a substantial quantity of yttrium metal and compounds, remnants of experimental work on nuclear reactor materials used in such projects as the discontinued Aircraft Nuclear Propulsion (ANP) program, will probably be available to industry from the surplus inventory held by the AEC.

Most of the yttrium consumed is used in electronic equipment, with lesser quantities being used in alloys. Continually expanding usage in microwave devices such as yttrium-iron garnets will not require any additional sources of yttrium than those mentioned. However, newer potentially large requirements for yttrium and its compounds for alloy or ceramic applications may ultimately require the exploitation of or possible exploration for yttrium mineral deposits. To date, yttrium materials have been too expensive and too controversial to be considered seriously by industry for such large-scale uses as in nodularizing cast iron.

PROBLEMS

Similarities exist between the resource problems of yttrium and those of the rare-earth elements with which it is associated. The complex relationship between all these elements manifests itself in their production, separation, and marketing. Their association creates supply problems due to the accumulation of large quantities of certain less needed or unused rare-earth elements. This problem is not as acute with yttrium, principally because of its low content in the common rare-earth ore minerals. On the other hand, the supply of yttrium now in the possession of industry exceeds the demand. Furthermore, there are excess stocks of yttrium metal, alloys, compounds, and concentrates held by the AEC. As stated previously, it is almost certain that this total quantity will suffice for most of the current uses, even considering their expansion in the near future.

Much of the difficulty encountered in developing newer uses, such as that of yttrium nodular iron, stems from the high cost of the material needed. Lower cost material would become available if larger quantities were available. Conversely, only if there were a demand for much larger quantities of yttrium, for a reason such as the commercial production of yttrium-bearing alloys, will there be the need for exploring for yttrium-group rare-earth minerals or recovering these elements as byproducts from other current operations.

New exploration techniques or detection methods would be a boon to prospectors searching for yttrium and rare-earth elements. Collection of complete geochemical and mineralogical occurrence data would assist in evaluating byproduct and coproduct sources.

At this time, the problems of extraction and separation technology are not as critical as those of developing large-scale or newer uses. However, clean-cut separation of yttrium from certain rare-earth elements is difficult. Purification techniques also need improvement so that larger quantities of extremely pure yttrium would become available at lower cost for utilization research. Concurrently, extraordinary analytical methods are needed to test for minute quantities of impurities.

Some results of yttrium research and data accumulation are not yet available to the public. This is due largely to restrictions placed by both government and producers on the publication of certain information concerning potential fields of use.

ZINC

By Harold J. Schroeder [1]

ZINC is a relatively soft, metallic element with a bluish-white color when freshly fractured. Although it has been used as a component of brass for 2,000 years, it was not until the middle of the 18th century that the metal was produced commercially in Europe. Thereafter new uses and increased demand for old uses multiplied the demand for zinc greatly. World smelter production now approximates 3.8 million tons annually, a quantity exceeded only by steel, aluminum, and copper production.

About 300 firms mine, smelt, import, or market zinc in the United States. Eleven firms operate 15 primary zinc smelters accounting for 98 percent of slab zinc output. Seven of the smelting companies operate mines which produced about 64 percent of domestic mine output.

For nearly all of the last 50 years the United States has led the world in producing and consuming zinc ores and metal. During 1925–53, U.S. mines produced one-third of world mine output, its smelters reduced 40 percent of all refined zinc, and its industries consumed 40 percent of world supply. In recent years world mine and smelter production have increased relative to that of the United States and in 1959–63 domestic mines and smelters produced but 13 and 26 percent of the world output, respectively. During 1963 the United States consumed 1.1 million tons of slab zinc, or about 29 percent of world consumption.

World War II marked the beginning of U.S. dependence on imports for an appreciable part of its needs. For many years the United States had been a net exporter of zinc, but beginning in 1940 and continuing thereafter greatly increased domestic requirements and domestic mine output below wartime levels necessitated importation of large tonnages of foreign metal, ores, and concentrates to augment supplies. Return to self-sufficiency is unlikely in the near future because large reserves of high-grade ores combined in some cases with lower labor cost permits foreign production at costs lower than can be attained for many domestic deposits. Average annual imports for 1959–63 of slab zinc or recoverable as slab zinc was 541,000 tons. Canada and Mexico, the second and fifth largest producers of mined zinc in recent years, are historically the chief sources of U.S. imports.

The major producers of zinc on a mine basis in order of output in 1963, were the United States, Canada, the U.S.S.R., Australia, Mexico, Japan, Peru, Poland, Italy, and the Congo (Leopoldville). The leading four countries furnished 47 percent of the 4.0 million tons of mine output in 1963. Estimated world smelter output in 1963 was 3.8 million tons of which 58 percent was produced by 5 countries—the United States, the U.S.S.R., Japan, Canada, and Belgium in ranked order.

World reserves of zinc in measured and indicated ore classifications are estimated to contain 85.0 million tons of zinc. Canada with 19.0 million tons has the largest reserve, followed by the United States with 12.2 million tons. The Western Hemisphere contains about 48 percent of the total reserve. Estimates of zinc in inferred ore are not available, but past experience indicates such quantities may be expected to exceed the sum of measured and indicated reserves.

The outlook for future zinc demand in the United States is for continued growth with little change in present use patterns. Requirements are expected to approximate 1.3 million tons annually by 1970 and 1.6 million tons by 1980. Domestic mine output will continue to be a substantial part of supply, and imports will probably increase providing that the import quota restrictions imposed in 1958 are relaxed. The 1.6 million tons of surplus zinc in the national stockpile is an additional potential supply source that must be taken into account.

BACKGROUND

Zinc, as a component of brass, was used in China and Rome 2,000 years ago, long before it became known as an element. The first commercial metal production is credited to the Chinese in the 14th century A.D., but the events were poorly recorded. Zinc was smelted in Bristol, England about 1740, and the first continental European smelter was erected at Liege in 1807. As the demand for zinc increased, new ore sources and smelters were developed in Germany and Russia.

Commercial production of zinc in the United States began in 1860 when smelters were constructed at Friedensville, Pa., and La Salle, Ill. Thereafter, as demand increased, additional ore bodies and new smelting works were developed and by 1880, 13 smelters were producing about 23,000 tons of refined zinc annually. Statistics of smelter production show a strong, growing industry yielding 64,000 tons of zinc in 1890, 124,000 tons in 1900, and 256,000 tons in 1909 when the United States became established as the leading producer. The smelter growth rate of the United States was maintained during World War I when most continental European sources of refined zinc were unavailable to the Allies; by 1917 output was 686,000 tons, a quantity not exceeded until 1940. In 1943, the peak year of World War II, U.S. smelter output was 991,000 tons. Postwar demand for zinc remained high and an alltime output of 1,058,000 tons was attained in 1957. After a slump to 828,000 tons the following year there was a slow upward trend to 953,000 tons by 1963.

During the period of rapid growth, the industry was stimulated by tremendous industrial expansion, the discovery of numerous ore bodies, and the development of many new techniques in mining, milling, and smelting. These new techniques included high-speed drilling equipment, improved explosives, power loading devices, electrically powered pumps, fans, and haulage motors, and rubber-tired ore loading and transporting equipment powered by internal combustion engines. Developments in the flotation process about 1918 permitted economic use of large reserves of complex and fine grained ores, formerly marginal because of high metallurgical losses and treatment charges. In smelting, the introduction of electrolytic zinc reduction plants about 1915 and later The New Jersey Zinc Co.'s continuous distillation process and rectification column provided new methods of producing high-purity zinc suitable to a wider range of uses than grades formerly produced.

Demand for zinc in the United States has outstripped domestic supply, and since 1940 the Nation has become a large importer of zinc ore and metal.

Acquisition of 1.6 million tons of zinc metal by the U.S. Government between 1946 and 1960 for a national stockpile has been a significant factor in the zinc industry. The stockpile was substantially completed early in 1958 and in October 1958 import quotas were imposed to curtail further build up of industrial stocks and alleviate injury to the domestic industry.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Zinc is one of the four metals produced and used in greatest quantity by industrialized nations. In the United States it ranked fourth in tonnage of metals produced and consumed in 1963, following iron, aluminum, and copper. The United States has been the world's foremost producer of zinc in ore and refined form for 50 years except for 1958 when Canada surpassed the United States in mine output. Over the 5-year period 1959–63 the United States produced 13 and 26 percent of world mine and smelter production, respectively. Other leading producers of zinc ore in 1963, ranked in order of output, were Canada, the U.S.S.R., Australia, Mexico, Japan, Peru, Poland, Italy, and the Congo (Leopoldville). Other principal smelting countries were the U.S.S.R., Japan, Canada, Belgium, Australia, Poland, France, and West Germany. The smelter output of the five leading nations including the United States was about 58 percent of the world total; that of the Western Hemisphere about 34 percent.

The U.S. zinc industry is made up of about 300 units which mine domestic ores, import foreign ores, purchase scrap, or smelt or otherwise process these raw materials into slab zinc, zinc pigments, dust, alloys, or other zinc products.

Eleven firms operate 15 primary zinc smelters. These firms listed in descending order of slab zinc output for the period 1961–63 are St. Joseph Lead Co., New Jersey Zinc Co., American Smelting and Refining Co., The Anaconda Company, American Zinc, Lead and Smelting Co., The Bunker Hill Co., Blackwell Zinc Co., The Eagle-Picher Co., The National Zinc Co., Matthiessen & Hegeler Zinc Co., and Athletic Mining & Smelting Co. The leading four companies accounted for 57 percent of output and the total for all primary producers was about 98 percent. Ten companies with secondary smelters produced the remaining 2 percent of slab zinc. Smelter data are shown in table 1.

TABLE 1.—*U.S. primary and secondary zinc plants, their location and capacity for slab zinc in 1963*

Type of plant and company	Plant location	Slab zinc capacity (short tons)
Primary plants:		
Electrolytic:		
American Smelting and Refining Company	Corpus Christi, Tex	507,500
American Zinc Co. of Illinois	Monsanto, Ill	
The Anaconda Company	Anaconda, Mont	
Do	Great Falls, Mont	
The Bunker Hill Co	Kellogg, Idaho	
Horizontal-retort:		718,800
American Smelting and Refining Company	Amarillo, Tex	
American Zinc Co. of Illinois	Dumas, Tex	
Athletic Mining & Smelting Co	Fort Smith, Ark.[1]	
Blackwell Zinc Co., Division of American Metal Climax, Inc.	Blackwell, Okla	
The Eagle-Picher Co	Henryetta, Okla	
Matthiessen & Hegeler Zinc Co	LaSalle, Ill [2]	
National Zinc Co	Bartlesville, Okla	
Vertical-retort:		
Matthiessen & Hegeler Zinc Co	Meadowbrook, W. Va	
The New Jersey Zinc Co	Depue, Ill	
Do	Palmerton, Pa	
St. Joseph Lead Co	Herculaneum, Mo [3]	
Do	Josephtown, Pa	
Secondary plants:		63,500
American Smelting and Refining Company	Beckemeyer, Ill	
Do	Sand Springs, Okla	
Do	Trenton, N.J

[2] Plant closed July 1, 1961.
[3] Electrothermic slag-fuming unit, yielding a slab zinc product.

Seven of the smelting companies also own and operate zinc mines in the United States. These seven in 1961 accounted for 64 percent of zinc mine output and the four largest accounted for 56 percent. Listed in descending order of production the companies were New Jersey Zinc Co., St. Joseph Lead Co., American Zinc, Lead and Smelting Co., The Bunker Hill Co., The Eagle-Picher Co., American Smelting and Refining Co., and The Anaconda Company.

Companies reporting mine production of zinc in the same year and not integrated with smelters numbered about 240. The leading 15 companies accounted for 31 percent of domestic mine output. The next 28 companies accounted for 4 percent and the remaining 197 for only 1 percent. The leading 15 listed in descending order of output are United States Smelting, Refining and Mining Co.; Tri-State Zinc, Inc.; Shattuck Denn Mining Corp.; United States Steel Corp., Tennessee Coal & Iron Division; Pend Oreille Mines and Metals Co.; Idarado Mining Co.; Hydrometals, Inc. (American Peru Mining Co.); Tennessee Copper Co.; United Park City Mines Co.; Cyprus Mines Corp.; Ozark-Mahoning Co.; Minerva Co.; McFarland & Hullinger Co.; New Park Mining Co.; and Camp Bird Colorado, Inc.

Some of the companies prominent in the U.S. zinc mining or smelting industry have substantial investments or control of important zinc mines in Canada, Mexico, Argentina, Peru, Australia, South-West Africa, and Morocco. Among these are American Metals Climax Co., American Smelting and Refining Co., Pend Oreille Mines and Metals Co., and St. Joseph Lead Co. Other important foreign zinc operations controlled or substantially owned by American corporations are Peruvian mines and smelters by Cerro de Pasco, Mexican Mines by the Fresnillo Co. and diversified investments by Newmont Mining Corp.

There are many large and small mines and more than 60 smelters abroad which produce about two-thirds of the world's zinc. Major foreign mining and smelting companies include Consolidated Mining and Smelting Co. and Hudson Bay Mining and Smelting Co. in Canada; Cia Royale Asturienne De Mines, Societe des Mines et Fonderies de Zinc de la Vieille-Montagne, and Societe Miniere et Metallurgique de Penarroya in North Africa, Spain, Belgium, or France; Union Miniere du Haut Katanga and its subsidiary Metalkat with mines and smelter in the Congo (Leopoldville); Rhodesian Broken Hill Development Co., Ltd., with mine and smelter in Northern Rhodesia; Rio Tinto-Zinc Corp. owner of the Zinc Corp., Ltd. and other interests in the Broken Hill district of New South Wales, Australia, as well as zinc and other smelters in the United Kingdom; E Z Co. of Australia; Mitsui Mining & Smelting Co., Ltd., Mitsubishi Metal Mining Co., Ltd., and Toho Zinc Co. in Japan; as well as numerous others in the same countries as well as elsewhere.

U.S. mine production of 529,000 tons of zinc in 1963 came from approximately 250 mines in 22 States. The 25 leading zinc-producing mines yielded 81 percent of domestic output and the leading 4 mines supplied 25 percent of the total. States east of the Mississippi River produced 51 percent of the total output; Western States, 46 percent; and West Central States, 3 percent.

Concentration mills are at all the principal mines. Some operate as customs mills to process ores from mines without mills.

Zinc is smelted and refined at 17 primary and 11 secondary reduction plants in 12 States. The same plants also produce zinc oxide, zinc dust, zinc-base alloys or zinc pigments and salts.

Although it is desirable for a smelter to be near its source of raw material, the governing factors in location of a smelter are availability of skilled labor, fuel, and power, and nearness to markets for sulfuric acid and refined zinc (*5*).[2] Only the Anaconda, Mont., Kellogg, Idaho, and Palmerton, Pa. smelters are situated within 30 miles of any zinc mine and both Kellogg and Palmerton rely on ores shipped many hundreds of miles for capacity operation. The location of the retort plants in Illinois, Oklahoma, and Texas were originally chosen because the site offered natural gas or coal and possibly retort clays also.

DEFINITIONS OF TERMS, GRADES, AND SPECIFICATIONS (*4*)

Zinc is a bluish-white metal with atomic weight of 65.38. Characteristic properties are specific gravity of 7.13 grams per cm at 20° C, melting point of 419.5° C, and boiling point of 906° C. The properties of being chemically active and alloying readily with other metals is utilized industrially in a large number of zinc containing alloys and compounds. The relatively high position of zinc in the electromotive series largely accounts for the extensive use of the metal to protect iron and steel products against corrosion. Commercial zinc cast in various smelter shapes and sizes is termed *slab* zinc in the United States; the older term *spelter* is now rarely used in this country.

Slab zinc is produced in six standard grades which range from about 98.3 to more than 99.99 percent zinc.

The specifications (ASTM designation: B 6–61) for primary slab zinc provide that the zinc be made from ore or other material by distillation or electrolysis, and not by "sweating" or remelting of scrap. The grades and maximum impurities are shown in table 2.

TABLE 2.—*Grades of slab zinc*

Name	Maximum, percent [1]				Minimum percent zinc [2]
	Lead	Iron	Cadmium	Total	
Special High Grade	0.006	0.005	0.004	0.010	99.99
High Grade	.07	.02	.07	.10	99.90
Intermediate	.20	.03	.50	.50	99.50
Brass Special	.60	.03	.50	1.0	99.00
Selected	.80	.04	.75	1.25	98.75
Prime Western	1.60	.08			98.3

[1] ASTM Standards, 1961, part 2, p. 636.
[2] Difference, by deduction of listed allowable impurities.
NOTE.—Analysis shall not regularly be made for tin but when used for die castings, if found, by the purchaser, tin shall not exceed 0.003 percent. Greater amounts may constitute cause for rejection.
Where it is specified by the purchaser at the time of purchase that the special high-grade zinc is to be used for the manufacture of zinc-base, die-casting alloy ingot, the maximum permissible tin content shall be 0.002 percent and the maximum permissible lead content shall be 0.005 percent.
Analysis shall not regularly be made for aluminum. When used for the manufacture of rolled zinc or brass, aluminum, if found by the purchaser, shall not exceed 0.005 percent. Greater amounts may constitute cause for rejection.

The refined zinc is cast into slabs typically weighing 55 pounds, each of which is identified as to grade and producer by the registered brand name cast into the metal. The slab metal is commonly loaded and strapped onto pallets designed for fork-lift handling. Such zinc pallet loads weigh 2,000 to 2,500 pounds each.

Zinc produced from newly mined ores is termed primary or virgin zinc. When zinc is produced from scrap or residues, it is termed secondary *redistilled* or *remelt* zinc dependent upon the process utilized for recovery. Primary zinc is referred to as *electrolytic* or *distilled* zinc according to the reduction process used. Refined zinc refers to an upgraded distilled zinc sometimes accomplished by repeating the original process when it is designated as redistilled zinc. All of the above terms are mainly descriptive of source of material or process of produc-

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

tion and only generally denotes grade, thus certain brands classed as refined zinc are lower in purity than others simply classed as distilled zinc.

Zinc die casting alloys are any of several zinc-base alloys in which aluminum and copper are the principal alloying elements. The most widely used of these alloys have compositions described by ASTM Specification B 86, Alloys AG40A and AC41A. These alloys contain from 3.5 to 4.3 percent aluminum and from 0.03 to 0.08 percent magnesium. The aluminum imparts desirable mechanical properties to the alloy, and the magnesium counteracts subsurface corrosion caused by certain impurities. Alloy AC41A contains 0.75 to 1.25 percent copper and AG40A up to 0.25 percent copper to improve tensile strength, hardness, and other physical properties.

Copper-base alloys in which zinc is the principal alloying element and ranges from about 5 to 40 percent by weight is called *brass*. Some bronzes whose principal alloying materials are copper and tin also contain up to 4.5 percent zinc.

Zinc burns in air with a brilliant green-blue light to form the white powdery *zinc oxide* used widely in pigments and rubber. Table 3 presents ASTM Specifications (D–79–44) for American and French process zinc oxide.

Zinc is available as a semimanufactured product in the form of dust. Although standard specifications have not been adopted by the industry, chemical purity and particle sizes are closely controlled to particular customer requirements. Commercial zinc dust produced ranges from 95 to 99.8 percent zinc with the balance principally oxidized zinc and also as impurities of lead and iron. A representative particle size gradation would be 100 percent minus 100-mesh and 25 percent minus 325-mesh although some specifications call for more than 97 percent passing a 325-mesh screen.

TABLE 3.—*ASTM specifications for American and French process zinc oxide*

	American process	French process
Zinc oxide, minimum percent	98.0	99.0
Sulfur, maximum percent	.2	.1
Moisture and other volatiles, do	.5	.5
Total impurities, do	2.0	1.0
Retained on 325-mesh (44-micron) sieve, do	1.0	1.0

TECHNOLOGY (*1, 9*)

Geology

Numerous minerals contain zinc but the principal ore mineral is the sulfide, sphalerite, sometimes called "blende". An exception is the unique and very important deposit found at Ogdensburg, N.J. composed of zincite (ZnO), willemite (Zn_2SiO_4), and franklinite (Fe,Zn,Mn)O. $(Fe,Mn)_2O_3$. Zinc sulfide oxidizes readily to the common minerals smithsonite ($ZnCO_3$) and hemimorphite ($H_2Zn_2SiO_5$). These oxidized zinc ores used to be mined extensively but are now treated only a few places in the world because of poor metallurgical recoveries and economic considerations.

Sphalerite is commonly associated with lead and iron sulfides and to a lesser degree with copper sulfides and gold and silver minerals. The zinc ores of the Mississippi Valley and Eastern United States are characterized by simple mineralization, the zinc being present with relatively minor quantities of lead and little or no copper, gold, and silver. Most sphalerite has associated cadmium as a coating or solid solution in quantities from traces to 2 percent. Other metallic elements commonly associated with sphalerite in small quantities include germanium, gallium, indium, and thallium.

Most economic deposits of zinc are cavity fillings, replacements, or combinations believed to have been deposited by mineral-bearing solutions of magmatic origin. Cavity fillings include the fissure veins in San Juan and San Miguel Counties, Colo., the breccia ores in the Jefferson City-Mascot area of Tennessee and the Austinville area of Virginia, and the cave and fracture fillings ("pitches and flats") of the upper Mississippi Valley area. Replacements also play a part in these same deposits. The extensive replacement deposits in limestones are typified by deposits at Leadville, Colo.; Bingham and Tintic, Utah; eastern Tennessee; and Metaline area of Washington. Fissure fillings with wall rock replacement form the lode deposits of Butte, Mont.; the Coeur d'Alene district, Idaho; and Park City, Utah.

Important foreign mines based on fissure veins and wall rock replacement include the Cerro de Pasco in Peru; the Fresnillo, San Francisco del Oro, Parral, Santa Barbara, and Pachuca in Mexico. The ore bodies at the Sullivan and Flin Flon mines in Canada and the Mt. Isa and Broken Hill mines in Australia are massive sulfide replacements in metamorphosed sediments or igneous rocks.

Grades of ore mined vary widely throughout the world depending on the natural resource, technologic, and economic factors. A 1960 study of ores mined and milled in the United States showed that for 25 operations classed as lead-zinc ores the average grade was 3.45 percent zinc and 0.95 percent lead; for 29 operations classed as copper-lead-zinc ores the average grade was 3.26 percent zinc, 2.51 percent lead, 0.50 percent copper, 3.45 ounces of silver per ton, and 0.017

ounces of gold per ton. Variations between mining districts are great as shown by table 4.

TABLE 4.—*Selected examples of approximate ore grades*

District	Zinc, percent	Lead, percent	Silver, ounces per ton
Coeur d'Alene	4.3	5.8	4.0
St. Lawrence County, N.Y.	9.0	.15	
Upper Mississippi Valley	3–7	0.5–1.0	
Kansas and Oklahoma [1] [2]	2.0	.3	
East Tennessee	2–6		

[1] Portion of Tri-State district.
[2] Grades in earlier years were commonly about 10 percent of combined lead and zinc.

For comparison some of the ore grades of important zinc producing mines in Canada are the Sullivan mine, about 10 percent combined lead and zinc plus values in gold and silver; the Flin Flon mine, 4.7 percent zinc and 2.25 percent copper; Mattagami Lake district mines, 12.5 percent zinc, 0.7 percent copper, and 1.3 ounces of silver per ton; and the Geco mine, 4.6 percent zinc, 2.1 percent copper, and 2.3 ounces of silver per ton.

The Fresnillo and Naica mines in Mexico average about 5.0 percent zinc, 5.3 percent lead, and 5.4 ounces of silver per ton. In Australia mines in the Broken Hill district average about 11.2 percent zinc, 12.6 percent lead, and 5.0 ounces of silver per ton. The Mount Isa mine in Queensland, Australia has reserves estimated to contain 7.8 percent lead, 5.5 percent zinc, and 5.6 ounces of silver per ton.

Prospecting and Exploration

During the last half of the 19th century when the U.S. demand for zinc ores began, reserves were primarily developed coincident with the exploration and mining of lead, copper, gold, and silver ores.

Most of the important zinc producing mines of the United States except those of eastern Tennessee, St. Lawrence County, N.Y., Sussex County, N.J., and the Picher portion of the Tri-State district began as lead or lead-silver mines discovered on the basis of outcrops. As the easily discovered ore bodies were depleted, prospecting techniques were developed involving geologic mapping of rock units and structures to evaluate the structural conditions, mineralizing solutions, reactive gangue, and other control factors.

In the period since World War II geophysics and geochemistry have been used increasingly in mineral exploration. Geophysical exploration is a highly specialized field of engineering requiring a thorough knowledge of physics, mathematics, geology, and their related field application to make careful measurements of physical properties such as magnetic susceptibility, density, electrical conductivity, and radio-activity. Airborne magnetic surveys in southeast Missouri in 1948 and airborne electromagnetic measurements in New Brunswick and Ontario in 1953 were instrumental in the discovery of large reserves of base metals, including zinc. Geochemistry has been widely used in Tennessee, Virginia, and elsewhere to determine favorable areas for drilling on the basis of anomalous quantities of zinc in the soil or vegetation (*6*).

The final step in the prospecting and the most important part of the exploration phase is to obtain actual samples and some direct knowledge of the deposit. Where the deposit outcrops at or near the surface, trenches or pits provide a simple means of exposing the mineralized zones. Boreholes, shafts, and adits are used to explore deeper portions of a mineral deposit. Drilling is the most universal method employed to obtain samples. Churn, rotary, and percussion are drilling methods used. Diamond drilling, one of the rotary methods, has attained widespread use since it permits orientation of the hole in any direction, penetrates to depths of several thousand feet, and provides a solid core of the mineral formations for study and analysis. Descriptions of drill equipment and their operation is not included here since this information is readily available in general texts on mining.

The pattern, spacing, and sampling of openings is designed to obtain adequate knowledge of the deposit to determine reserve figures and for initial planning of subsequent mining operations. Preliminary determination of amenability of the ore to beneficiation is also usually a part of the exploration work.

Mining

Most zinc is mined using underground mining methods, principally classed as open, shrinkage, cut-and-fill, or square set stoping methods. A few mines, particularly in their early stages of operation, mine zinc by open pit methods. Open stopes with pillars (breast stopes) are employed exclusively in mining the near-flat lying ores of the Metaline, Tri-State, Upper Mississippi Valley, Tennessee, and Virginia mining districts. The rock structure overlying the ore deposit being mined is supported by the walls of the stope and such pillars as are necessary to assure safe working conditions. If the width of the ore body is such that the roof-span will stand without pillar supports, the entire ore body may be extracted. Ore bodies having large horizontal extent require a system of pillars to support the roof, with the position and size of

the pillars dependent on mass rock mechanics of the pillars, walls, roof, and floor. Optimum roof conditions compatible with allowable costs often require that some ore be left as part of the roof, or that waste-rock be shot down. As mining progresses to new areas, some pillars may be removed and others reduced in size. Despite such pillar recovery ore remaining as ground support commonly ranges up to 30 percent of the ore shoot, and may average about 15 percent.

Owing to the shape, size, and position relative to the surface and the frequently fractured, altered nature of the ore and surrounding wall rocks, most stopes in mines in the Western States require artificial support. The mining method employed is usually some form of filled stope such as cut-and-fill, filled square set, or by shrinkage stopes which are subsequently filled.

Top slicing and caving methods are little used as primary stoping methods, but find some use in combined methods in which stoping is by square-setting or shrinkage, and the stope pillars are mined by top slicing or caving.

Mechanization during the past 50 years has progressively lessened the hand labor of mining and led to greatly increased output per man-shift. The rate of ore breakage has been increased by the introduction of light-weight rock drills using drill steel with detachable alloy or carbide bits. Hand loading in drifts, crosscuts, and shafts has been replaced by loading machines of various types, and in many instances chute loading has been replaced by machine loading from drawpoints in the stope floor. Increasing mining depth has brought many additional problems. These include the necessity of supporting increasingly heavy ground or devising methods adapted to it. Added depth has also increased the burden of pumping, ventilating, hoisting, and securing mine fill.

The large, single-level, open stopes of the Tri-State, Tennessee, and Metaline districts have adopted "trackless" mining in which jumbos, power loading equipment, and haulage units are mounted on crawler-type tread or pneumatic-tire vehicles. The working speed and facility of movement from work face to work face gives greater capacity with lower mining costs which in some cases permit mining ore containing as little as 2 percent zinc.

Milling

Milling consists of separating the desirable mineral constituents in an ore from the unwanted impurities (gangue) by various mechanical processes. Terms used somewhat interchangeably for milling include concentration, ore beneficiation, ore dressing, and mineral dressing. Liberation of the minerals by crushing and grinding is followed by subjecting the discrete particles to forces of gravity, magnetism, or solid-liquid-gas surface phenomenon relations (flotation process). The upgraded mineral products are termed concentrates, the rejects are called tailings, and poorly separated intermediate products destined for additional milling are termed middlings.

Compelling reasons for milling an ore include large savings in shipment costs by not transporting worthless waste material long distances from mine to smelter; efficient utilization of fuel and facilities in the metal reduction or other treatment process; and improved metallurgical results when using a relatively clean, high-grade concentrate.

The particular combination of ore-dressing equipment used differs with the quantities and kinds of ore minerals present, their values, the character of the gangue minerals, and the mineral particle sizes. Simple ores, such as coarsely disseminated zinc or zinc-lead minerals occurring with a low specific gravity gangue, are readily treated in heavy-medium cones, jigs, and tables after being crushed and rolled in closed circuit with vibrating or trommel screens and classifiers to give properly sized feed. Selective or differential flotation to the slime products or of a reground middling product completes the flowsheet. Ores of this kind are common in the mines of the Mississippi Valley and Eastern United States. In some instances the ores are concentrated wholly by flotation.

The more complex sulfide ores, such as those in the Western United States, consist of disseminated mixtures of fine-grained lead and zinc sulfide, usually accompanied by pyrite, some copper sulfides, and some gold and silver in a country rock, quartz, or quartz-calcite gangue. Concentration of such ores may be complicated by partial oxidation of the sulfides and the presence of high-density gangue minerals such as barite, siderite, or rhodochrosite. Such complex ores are crushed and fine-ground in closed circuit to a size at which the ore minerals are freed from the gangue. The ore is then selectively floated to yield lead, zinc, and copper or copper-pyrite concentrates; middling products are reground and recycled to complete the recovery.

The low capital and operating costs of the heavy-medium plant make it very effective for producing a rough zinc concentrate and eliminating a large fraction of the gangue minerals in simple ores. Such units, using ferrosilicon as the heavy medium, have been used extensively in eastern Tennessee and the Tri-State area to treat ore.

A 1960 milling study in the United States showed that for 25 operations classed as treating lead-zinc ores, 14 used flotation, 11 used

gravity plus flotation, and 14 used flotation alone to produce zinc concentrates. The combined operating results showed production of zinc concentrate averaging 59.85 percent zinc and achieving a 92 percent recovery of the zinc in the ore. For 29 operations classed as treating copper-lead-zinc ore, the zinc concentrate averaged 53.43 percent zinc and recovered 86 percent of the zinc. An additional 6 and 1 percent of the zinc was recovered with the lead and copper concentrates, respectively.

In recent years no oxidized ores have been treated in the United States. Data available for a foreign plant operating on oxidized ore shows the following results: Feed—5.0 percent zinc, 2.5 percent lead; zinc concentrate—39.5 percent zinc, 2.5 percent lead; lead concentrate—68.7 percent lead, 3.9 percent zinc; and recovery of zinc—54.7 percent.

Smelting and Refining (*1, 7*)

The reduction of zinc ores and concentrates to zinc is accomplished by electrolytic deposition from a solution (electrowinning or hydrometallurgy of zinc) or by distillation in retorts or furnaces. For either method the zinc concentrate is roasted to eliminate most of the sulfur and for conversion to impure zinc oxide called roasted concentrates or "calcines".

At electrolytic zinc plants the roasted zinc concentrate is leached with dilute sulfuric acid to form a zinc sulfate solution. The pregnant solution is then purified to remove contained copper, cadmium, cobalt, iron, etc., and piped to electrolytic cells, where the zinc is electrodeposited on aluminum cathodes. This zinc is either Special High Grade or High Grade. At intervals the cathodes are lifted from the tanks and stripped of the zinc, which is then melted in a furnace and cast into slab form. The electrolysis of the solution regenerates sulfuric acid, which is used in a succeeding cycle of leaching. Inasmuch as zinc concentrates shipped to electrolytic plants commonly contain lead, gold, and silver, the leach and electrolytic tank residues become enriched in these metals by the extraction of the zinc, and are usually shipped to a lead smelter. There the lead, gold, and silver content is recovered in lead bullion. Zinc reports with the lead furnace slag and is subsequently removed as an impure oxide by a fuming operation. The zinc fume, after de-leading and densifying in a kiln, forms a suitable feed for return to a zinc reduction plant.

Distillation retort plants are classified as batch horizontal retorts, continuous vertical retorts externally heated by fuel, and continuous vertical retorts heated electrothermally. All employ coal or coke as a reducing agent, quantities required range from about 0.5 to 0.8 tons per ton of slab zinc output. The zinc vapor and carbon monoxide from the retorts pass into condensers of various types where the zinc is collected as liquid metal ready for casting into slab form. Zinc produced by distillation are normally the lower commercial grades but may be upgraded by refining to reduce the quantities of the common impurities of lead, cadmium, and iron; also the lesser impurities such as copper, tin, and arsenic. Simple liquation removes lead down to the maximum solubility in zinc at its freezing temperature (1.2 percent lead) and also removes iron to a limited degree to produce a product conforming to the specifications for Prime Western grade zinc. Refining by redistillation is accomplished by vertical fractionating columns which separates the impurities contained in the feed zinc and can produce zinc of 99.995 plus purity.

The residues from distillation are shipped to a lead smelter for further processing when they contain economic quantities of lead, gold, or silver or are processed in a Waelz kiln when economic quantities of zinc with or without lead remain. The Waelzing operation consists of charging a mixture of residues and 10 to 15 percent coal or coke to a large oil-or-gas-fired rotary (Waelz) furnace. The high temperature (1,100° to 1,150° C) in combination with the carbon of the fuel causes volatilization of the lead and zinc which are collected as a fume product in a Cottrell precipitator or bag-house.

The blast furnace process of producing zinc, also known as the Imperial vertical-type smelter process, was introduced commercially in 1950 by Imperial Smelting Corp., Ltd., Avonmouth, England. Installations have been completed or are being built in England, France, Australia, Northern Rhodesia, and Canada. The normal blast furnace practice of burning carbonaceous matter in intimate association with the ore to be reduced is followed. However, as in other zinc distillation processes, the zinc is released as a vapor and must be condensed. An important advantage to the process is the ability to treat a mixed zinc-lead concentrate and recover both metals as well as any gold or silver present with no extra coke consumption and little extra labor. Metal produced by the blast furnace conforms to Prime Western grade, containing about 1.2 percent lead and 0.02 percent iron.

High-purity zinc for specialized uses has been made by zone refining. Zone refining is a process in which a short molten zone moves slowly but repeatedly through a bar of the material to be refined, redistributing the solutes or impurities through the mechanism of fractional crystallization as the molten zone travels from one end to the other. The molten zone contains a

melting liquid-solid interface and a freezing liquid-solid interface. At the melting interface all solid materials become mobile. At the freezing interface, the concentration of each impurity differs from that in the liquid phase. If the impurity is one which lowers the melting point of the zinc, it concentrates in the liquid phase and moves with it. If the impurity is one which raises the melting point of zinc, it tends to concentrate in free zinc solid and the liquid becomes depleted in that impurity. Experimental work by the Consolidated Mining & Smelting Co. of Canada, Ltd. at Trail, British Columbia, has produced zinc with lead and cadmium contents of but one part per million each. Thallium and bismuth also can be effectively removed by zone refining.

Metallurgical recoveries at zinc-reduction plants range from 89 to 97.5 percent, the range in recovery being governed by the nature of the smelter feed, the treatment process, and the economics of recovery.

USES

A large part of the world's zinc supply is used for protective coatings on steel and iron, principally by the hot-dip galvanizing process; zinc-base alloys for die-cast products; alloying constituent of brass; production of zinc oxide; and wrought or rolled zinc products.

Domestic consumption of zinc has normally been in the order listed when the comparison includes the direct production of zinc oxide from ore and scrap zinc. However, zinc consumed in diecasting has in some years exceeded the use for galvanizing and these two together account for approximately 65 percent of the total consumption of zinc from slab, direct consumption of ores, and zinc scrap.

TABLE 5.—*Slab zinc use pattern*

Slab zinc used in	Percent of total		
	1961	1962	1963
Zinc-base alloy for die castings	36	40	42
Galvanizing of sheet and strip	23	21	22
Galvanizing tubes and pipe	6	5	5
Galvanizing wire and wire rope	4	4	4
Rolled zinc	4	4	4
Sheet, strip, and plate	7	6	5
Rod and wire	4	4	4
Zinc oxide	2	2	1
Other	14	14	13
Total	100	100	100

The widespread use of zinc as a protective coating on iron and steel products is due mainly to (1) excellent resistance of zinc to normal weathering processes, (2) sacrificial nature of the zinc relative to iron (galvanic action), thus affording some protection to the iron exposed by cuts and scratches in the coating, and (3) economy of application.

Principal classes of material galvanized are sheet and strip, tubes and pipe, wire and wire rope, structural shapes, and a multitude of hardware fittings. Galvanized products are used in large quantities by the construction, agriculture, appliance manufacturing, and automotive industries. Specific applications of galvanized iron and steel products number in the thousands and include such well known articles as roofing and siding sheets, wire and wire products, water tanks, pipe, pails and cans, nails, screws, bolts, and hinges.

Most of the galvanizing is accomplished by immersion of the iron or steel article in molten zinc, a process known as hot-dip galvanizing. Much of the hot-dip galvanizing is now accomplished on high-speed continuous galvanizing lines, a process which gives improved and uniform zinc adherence and ductility as well as economical production. Electro-deposited zinc coatings are also used as this method of coating provides a product with properties that are particularly useful for sign work, lighting fixtures, cabinet applications, wire, and small or intricately shaped articles. Coatings are also applied by spraying, sherardizing, and painting.

Cathodic protection of underground and underwater structures, such as pipelines, storage tanks, ships' hulls, and steel piers, also depends on galvanic protection. Corrosion of steel is caused by the passage of an electric current from the steel to the surrounding soil or liquid. Zinc anodes bonded to the steel structure generate a countercurrent which stops the corrosive outflow of current and establishes a slight flow to the steel with accompanying long-term controlled corrosion of the zinc anode. Cathodic protection at 100 Naval shore installations between 1958 and 1968 is expected to reduce maintenance costs by $40 million, at a total cost of less than $500,000.

Zinc-base alloys for diecasting purposes has in recent years used approximately 40 percent of domestic slab zinc and 85 percent of Special High Grade zinc consumption. In the diecasting processes, castings are produced in quantity by forcing molten alloy into steel dies at temperatures up to 900° F and at pressures up to 2,500 pounds per square inch. Diecasting permits production of intricate parts within close limits of accuracy and yields extremely smooth surfaces that are easily plated with nickel-chrome finishes. Automobile hardware such as door handles, window cranks, horn rings, instrument panel parts, hood ornaments, and radiator grilles as well as fuel pumps, carburetors, parts for windshield wiper motors, heaters, and hydraulic brakes are commonly zinc diecastings. Zinc diecastings are also used

in electrical appliances, business machines, tools, building hardware, toys, and novelties. Another use of zinc-base alloys is to make forming, stretching, and drawing dies used by the aircraft and automobile industries in forming metal shapes from aluminum and low-carbon and stainless steels.

Zinc in brass ranges from 3 to 45 percent with the average brass containing about 30 percent zinc. Red brass pipe, 15 percent zinc, is widely used for water and other piping. Brass finds extensive use in the automobile industry for radiator cores and lamp reflectors. Other important uses include lamp fixtures, brass screws, bolts, locks and hinges, watch and clock parts, cartridge cases, and numerous parts for the radio, television, telephone, and telegraph industries.

Zinc oxide which is used in rubber, paints, ceramics, cosmetics, pharmaceuticals, textiles, and floor coverings requires about 20,000 tons of slab zinc, 90,000 tons of zinc in ore, and 25,000 tons of zinc in scrap. All rubber, natural and synthetic, contains an average of about 5 percent zinc oxide, natural rubbers more, synthetics less. Heavy duty tires use larger quantities because zinc oxide not only aids the curing process but reduces heat generation, dissipates heat rapidly, and adds reinforcement to the rubber bond (*2*).

Other important quantities of zinc are consumed as rolled zinc which is used in the popular battery dry cells, as extruded cans for radio condensers and tube shields, and to make weather stripping, photoengraving plates, and anodes to protect hot water tanks, boilers, ship hulls, and pipelines. In Europe, rolled zinc is widely used as a long-lived roofing material. Smaller, but still important, quantities of zinc are consumed as zinc dust (chiefly from scrap), in the manufacture of lithopone, zinc chloride, zinc ammonium chloride, zinc sulfate, zinc chromate, other chemicals, and light-metal alloys, and in the desilverizing of lead.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

The sources of zinc production, classified according to types of ore in 1963 were 44.7 percent from zinc ores; 43.6 percent from lead-zinc ores; 0.4 percent from lead ore; 6.0 percent from copper-lead, copper-zinc, and copper-lead-zinc ores; and 5.3 percent from all other classifications. These sources include ores with substantial gold and silver output. Manganese is a coproduct of zinc-lead manganese-silver ores at Butte, Mont. and zinc-manganese ores at Ogdensburg, N.J. In the Tri-State area tailings (chats), which are mostly flint and chert, are sold for railway ballast, roadstone, concrete aggregate, roofing granules, and sand for sand blasting. The Tennessee, Virginia, and upper Mississippi Valley product is limestone or dolomite which is almost all sold for use as agricultural limestone or as crushed stone.

In addition, the zinc smelters produced 862,000 tons of byproduct sulfuric acid from zinc concentrates in 1963. The smelters also recovered on the order of 9 pounds of cadmium for each ton of slab zinc produced from zinc concentrates. In addition smaller quantities of germanium, thallium, indium, and gallium were recovered from flue dusts and residues of zinc smelting operations.

Byproduct antimony, bismuth, and tellurium occur with the lead minerals in many of the zinc-lead ores from the Western States.

ALTERNATE MATERIALS

For galvanizing iron and steel products, one of the major uses of zinc, there is no adequate substitute. Ceramic and plastic coatings are now employed in a narrow field that may gain in future importance. Cadmium is used for electroplating, but its cost and the quantity available limit it as a substitute for zinc in galvanizing. Other metals, particularly aluminum, may be substituted for zinc coating on steel in some instances, but the cost to date has inhibited extensive use. Sheet aluminum is a strong competitor of galvanized steel, although it has poorer structural qualities and its cost in the same gage sheets is higher.

Aluminum alloys and stainless steel have replaced part of the brass formerly consumed by the building industry and thus have reduced the zinc market in the brass mills.

Aluminum competes with zinc in certain diecasting applications, the competition between the two metals being influenced in part by metal prices, but for the most part selection of an alloy depends upon the properties desired in the finished casting. In addition, where the use of electrodeposited coatings is desired, zinc has a great advantage because of the ease with which finishes can be applied over diecastings of zinc alloy. Acetate plastic moldings and steel stampings are strongly competitive with diecastings.

The competition of substitute materials is keenly felt in chemical and pigment uses. Aluminum and magnesium could replace zinc to some extent as reducing agents in chemical reactions. In the paint industry lead and titanium pigments are used instead of zinc pigments in many instances. Titanium pigments have almost wholly replaced lithopone, but supplement rather than compete with zinc oxide in most paint formulations. Titanium dioxide

has made inroads on the use of zinc oxide in porcelain enamels, and in opacifiers, zirconium compounds have partly replaced zinc oxide. Zinc oxide consumption per unit of rubber consumption has declined in recent years, not because of substitution of an alternate product but rather because the synthetic rubbers require little or no zinc oxide in the vulcanizing process.

Substitute materials exist for many zinc uses. Which material is used and in what amount depends upon cost factors, relative technologic advantage, and availability and stability of supply.

SECONDARY SOURCES AND RECOVERY

Secondary zinc is the total zinc in all forms recovered from old scrap and from such new scrap as enters trade for processing. Combined old and new scrap containing zinc, annually yields 250,000 to 300,000 tons of recoverable zinc as slab zinc, zinc dust, various alloys and pigments, and chemicals. Table 6 shows the kinds of scrap processed and the quantity of zinc recovered by product.

Zinc-base scrap is divided into new and old scrap. New scrap is defined as that generated in manufacturing processes and consumed at plants other than where generated. Old scrap consists of zinc, zinc products, or alloys which have been discarded because of wear, damage, or obsolescence.

Zinc dross, ashes, and skimmings produced in hot-dip galvanizing and continuous galvanizing lines account for about 50 percent of the zinc recovered from zinc-base scrap sources. Dross is a mixture of zinc-iron alloys which form in the galvanizing kettles through the interaction of hot zinc and steel or iron. The quantity of dross which settles out, differs with the type of work and the process. About 15 percent of total zinc consumed by job galvanizers is lost as dross, but individual plant losses range from 10 to 50 percent (*10*).

Zinc ashes, the zinc oxide which forms at the surface of the hot-dip galvanizing kettle accounts for losses ranging from about 3 to 20 percent depending on operating temperatures and percentage of standby time. Zinc losses in "sal" or flux skimmings range from about 2 to 5 percent of zinc put in the galvanizing kettle.

Sheet and strip continuous galvanizing lines introduced since World War II have eliminated a large part of the zinc losses in dross, ashes, and skimmings through the use of carefully controlled scale-free strip, use of aluminum in the galvanizing bath which minimizes formation of zinc-iron alloys, and by maintenance of nonoxidizing atmospheres which eliminates the necessity for flux and the formation of zinc oxide at the surface of the bath. Zinc losses as dross and skimmings in the continuous strip galvanizing mills are about 5 percent.

Other new zinc scrap includes die-cast skimmings, flue dust, and chemical residues. Chemical residues are generated as a byproduct

TABLE 6.—*Zinc recovered from scrap processed in the United States, by kind of scrap and form of recovery*

[Short tons]

Kind of scrap	1962	1963
New scrap:		
Zinc-base	109, 324	110, 886
Copper-base	87, 893	91, 592
Aluminum-base	2, 994	3, 144
Magnesium-base	53	69
Total	200, 264	205, 691
Old scrap:		
Zinc-base	33, 588	32, 572
Copper-base	25, 929	27, 634
Aluminum-base	2, 192	2, 302
Magnesium-base	44	56
Total	61, 753	62, 564
Grand total	262, 017	268, 255

Form of recovery	1962	1963
As metal:		
By distillation:		
Slab zinc [1]	58, 217	59, 540
Zinc dust	24, 497	23, 417
By remelting	3, 892	4, 317
Total	86, 606	87, 274
In zinc-base alloys	15, 183	14, 940
In brass and bronze	118, 487	125, 087
In aluminum-base alloys	5, 256	5, 543
In magnesium-base alloys	154	201
In chemical products:		
Zinc oxide (lead-free)	18, 985	18, 591
Zinc sulfate	(2)	(2)
Zinc chloride	11, 753	10, 768
Miscellaneous	5, 593	5, 851
Total	175, 411	180, 981
Grand total	262, 017	268, 255

[1] Includes zinc content of redistilled slab made from remelt die-cast slab.
[2] Included with "Miscellaneous."

in the manufacture of sodium dithionate (sodium hydrosulfite) used by the textile industry as a bleach and are high-grade scrap used in making high-quality zinc oxide. Sal skimmings, on the other hand, are frequently generated at a rate in excess of the market for the zinc chloride and zinc ammonium chloride made from the skimmings.

Zinc dust, redistilled zinc and to a lesser extent zinc oxide, are made from galvanizers' dross. Redistilled zinc, remelted die-cast slab, and zinc oxide are the principal products made from die-cast skimmings, die-cast scrap, and zinc flue dust. Distillations are usually made in clay or graphite vertical retorts.

The second and almost equally important source of secondary zinc is the copper-base alloys, brass and bronze. The contained zinc is almost wholly recovered in brass and bronze ingot and brass mill products, though a small part which accumulates as flue dusts may be recovered in other products.

Minor quantities of zinc are recovered in the utilization of scrap aluminum and magnesium-base alloys at light-metal foundries.

RESERVES

Zinc ore reserves are widely distributed throughout the world. Countries with important productive deposits include Algeria, Argentina, Australia, Bulgaria, Canada, the Congo (Leopoldville), Finland, West Germany, Italy, Japan, North Korea, Mexico, Morocco, Peru, Poland, Northern Rhodesia, Spain, Sweden, the United States, the U.S.S.R., and Yugoslavia.

Table 7 lists the measured and indicated reserves of zinc in ores inventoried or estimated, based on available data, existing prices and technologies as of January 1962. Reserves of inferred zinc are judged to be at least equal to the sum of measured and indicated reserves. Extraction of zinc using current mining, milling, and smelting practices would recover about 75 percent of the contained zinc.

TABLE 7.—*Estimate of world reserves of zinc in measured and indicated ore, January 1962* [1]

Country	Zinc content (thousand short tons)	Percent of total
North America:		
Canada [2]	19,000	22.3
Mexico	4,000	4.7
United States	12,200	14.4
South America: Argentina, Bolivia, Brazil, and Peru	6,000	7.1
Europe:		
Free world countries	13,000	15.3
Soviet-bloc countries	13,000	15.3
Africa: Algeria, Congo (Leopoldville), Egypt, Kenya, Morocco, Nigeria, Northern Rhodesia, South-West Africa, and Tunisia	4,500	5.3
Asia: Burma, China, India, Iran, Japan, North Korea, North Viet-Nam, Turkey	8,000	9.4
Australia [3]	5,300	6.2
Total	85,000	100.0

CONSERVATION

Utilization of zinc resources in the production of zinc has been promoted by relevant research and application of the findings to the several phases of zinc production. Cutoff grades in mines are constantly adjusted to permit extraction of the lowest economic ore grade, and access to marginal grades of ore is maintained to the degree practical. Improved mining practice, particularly in ore bodies amenable to greater mechanization, has served to make large tonnages of lower grade ore profitable.

Continuing technologic advances in milling have had a tremendous impact in extending the world's economic resources in zinc. Chief among these was the development of selective flotation which made possible the production of high-grade concentrates with good recoveries. Another important development has been the introduction of heavy-medium concentration, which reduced overall treatment costs by rejection of a large part of the gangue fraction of the ore prior to grinding and beneficiation.

Conservation is also practiced in smelting. Sulfur dioxide gases from the roasting-sintering units are converted to sulfuric acid, and cadmium once marketed with slab zinc is recovered for its specialized uses. Residues containing zinc, lead, and other metal values are either treated for additional recoveries or are stocked for future processing. At present almost 10 percent of domestic slab zinc is produced from zinc-bearing slags at lead smelting plants.

Much of the zinc entering brass, bronze, and zinc- or light-metal casting alloys is ultimately recovered as secondary metal. That going into industry as galvanized steel or zinc oxide becomes so dispersed that no recovery is possible. The new scrap generated in the production of all zinc-bearing products is held at minimum levels by competition and is recycled to the secondary recovery plants for reclamation.

SOURCES OF STATISTICAL INFORMATION

The Bureau of Mines canvasses mine output of the principal mines, consumption of zinc-base scrap, and production of secondary zinc products, the output of zinc oxide, the consumption of slab zinc, and stocks of zinc held by consumers on a monthly basis. These data with smelter output and producers' stocks obtained

from the American Zinc Institute, import-export statistics from the Bureau of Census, and market information from the Engineering and Mining Journal Metal and Mineral Markets form the bases of comprehensive and adequate monthly statistics on the zinc industry.

Annual statistics are based on the same data, supplemented by annual reports covering mine, smelter, and rolling mill output, recovery of zinc from copper-, aluminum-, and magnesium-base scrap, and raw materials used and items produced by manufacturers of zinc pigments and salts. The annual statistics are further supplemented by world mine and smelter production by countries, the data being compiled by the Bureau of Mines from State Department dispatches, reports of foreign governments, and other sources.

The Mineral Census of the United States made in 1958 and 1962 provides valuable general information on productivity and costs. Special studies by the Tariff Commission in 1954, 1958, 1960, and 1962 have further added to available statistical information.

The Yearbook of the American Bureau of Metal Statistics contains tables of world zinc consumption by country and slab zinc capacity of individual smelters. The monthly bulletin of the International Lead and Zinc Study Group includes data on world metal stocks and trade movements of concentrates and metals. Publications such as the World Non Ferrous Metal Statistics (London), The Non Ferrous Metal Industry (Paris), and Metallgeselschaft (Frankfurt) gives the consumption of slab zinc by detailed use and other detailed data for a number of countries.

PRODUCTION, CONSUMPTION, AND TRADE

World mine and smelter production of zinc have increased almost without interruption since the end of World War II and in 1963 were 3.97 and 3.83 million short tons, respectively. These quantities are more than 50 percent above wartime outputs and more than double the production rates of 1945 and 1946.

Mine production of zinc in the United States reached 768,000 tons in 1942. After the war production ranged from 681,000 tons in 1951 to 412,000 tons in 1958, followed by a rising trend to 529,000 tons in 1963. Domestic smelters reached a record high of 991,000 tons in 1943 and 1,058,000 tons in 1957. After a slump to 828,000 tons the next year, a slow upward trend began with output reaching 953,000 tons in 1963.

In 1963 zinc mine production was recorded for 42 countries of which 26 had ouptut in excess of 10,000 tons of contained zinc. The four leading countries ranked in order were the United States, Canada, the U.S.S.R., and Australia; they had a combined output of 1,871,000 tons, 47 percent of the total. The United States exceeds all other countries in smelter output of zinc accounting for 23 percent in 1963. The U.S.S.R., Japan, Canada, and Belgium followed with 13, 8, 7, and 6 percent of the total, respectively. Twenty other countries supply the remaining 43 percent.

The United States in 1963 consumed 1.1 million tons of slab zinc, 29 percent of the world total. The U.S.S.R. consumed an estimated 410,000 tons. Other nations consuming in excess of 100,000 tons annually in order of demand are Japan, West Germany, United Kingdom, France, Belgium, Italy, and Australia.

In addition to consumption of slab zinc the United States annually consumes about 200,000 tons of recoverable zinc in scrap to produce zinc dust, pigments, chemicals, and alloys as shown in table 6. Yet another 100,000 to 110,000 tons of zinc in ore is used directly in making American process zinc oxide, lithopone, or chemicals. The sum of such consumption is the total consumption on figure 1, while consumption reported by industry products in table 10 is slab zinc only.

Domestic slab zinc consumption since World War II has fluctuated appreciably, but the trend shows an average annual increase of about 20,000 tons. Consumption was 801,000 tons in 1946, dropped to 712,000 tons by 1949, rose to a record 1,120,000 tons in 1955, slumped to 868,000 tons by 1958 and then rose to a new record of approximately 1,200,000 tons in 1964. Most of the growth is due to the increased consumption for zinc-base alloys from 212,000 tons in 1946 to 463,000 tons in 1963. Zinc consumed in galvanizing rose from 320,000 tons in 1946 to 451,000 tons in 1955, declined to 361,000 tons in 1954, and then increased to 420,000 tons by 1963. In brass products zinc consumption declined from 149,000 tons in 1946 to 130,000 tons in 1963 and in rolled zinc for the same period the decline was from 92,000 to 42,000 tons.

Before 1939, domestic mines provided most U.S. needs for zinc ore, and at times the United States exported substantial quantities of ore to other countries. After 1939, the United States became a large net importer of zinc ores and concentrates amounting to one-third of the ore supply between 1940 and 1949 and about one-half of the ore supply between 1954 and 1958. The trade in zinc metal followed a similar pattern except that a period of reversals between a net importing or exporting position occurred between 1938 and 1948 after which imports became increasingly important. By 1957 metal imports were equivalent to one-half of the quantity of zinc produced from domestic ore.

TABLE 8.—*Supply and distribution of slab zinc in the United States*

[Thousand short tons]

Year	Supply						Distribution		
	Primary production		Redistilled secondary	Total	General imports of slab zinc	Total	Consumption of slab zinc [1]	Exports of slab zinc	Total
	Domestic materials	Foreign materials

[1] Data derived in part from the Yearbook of the American Bureau of Metal Statistics, the United Nations Statistical Yearbook, and the Statistical Summary of the Mineral Industry (Overseas Geological Surveys, London).

[2] Recoverable.

[3] Smelter production.

[4] Czechoslovakia and Rumania also produce zinc, but production data are not available; estimates are included in totals.

Depressed conditions in the domestic zinc industry led to imposition of import quotas, effective October 1958, on zinc metal and ore. The annual quotas were set at 80 percent of the U.S. average annual commercial import rate from 1953 through 1957—379,840 tons of zinc in ore (concentrates) and 141,120 tons of zinc in metal. At the start of 1965 the quotas remained in effect and the Tariff Commission was preparing a report following an investigation on the condition of the zinc industry with particular reference to the quota system.

Of the 2,248,000 tons of zinc imported from 1960 through 1963, 76 percent has been as concentrates and 24 percent as metal. Mexico, Canada, and Peru supplied 40, 33, and 18 percent, respectively, of the zinc as concentrates. Canada, Belgium-Luxembourg, and Mexico supplied 55, 12, and 8 percent, respectively, of the zinc as metal.

Exports of zinc metal were 107,000 tons in 1947, but declined thereafter to 2,000 tons in 1958. After imposition of quotas a practice of smelting ex-quota ore in bond for export developed, and in 1960 exports were 75,000 tons followed by a decline to 34,000 tons in 1963. Much of the exports have been to Latin American countries, India, and the Republic of Korea.

Zinc is also exported as scrap, as sheets, plates, and strips, as zinc dust, and in pigments and salts as well as in fabricated metal products.

Imported zinc has been subject to tariff regulation since 1846 (*14*). The highest rates were in effect from 1930 to 1939 when the duties on slab zinc and ores and concentrates (zinc content) were 1.75 and 1.50 cents per pound, respectively. Since that time the duties on slab and zinc in ore have been progressively reduced so that by June 6, 1951, import duties on slab and ore were 0.7 and 0.6 cent per pound, respectively. These rates were suspended during the period of February 12 through July 23, 1952.

New tariff schedules which went into effect August 31, 1963, revised the method of computing duties on zinc ores and concentrates. Under the new schedules the rate of duty became 0.67 cents per pound imposed on the zinc content after certain allowable deductions for processing losses. For a given importation the net result was a total duty approximately the same as under the previous method.

[1] Data derived in part from the Yearbook of the American Bureau of Metal Statistics, the United Nations Statistical Yearbook, and the Statistical Summary of the Mineral Industry (Overseas Geological Surveys, London).

[2] Average annual production 1955–58.

[3] Includes production from reclaimed scrap.

[4] Average annual production 1957–58.

[5] Czechoslovakia and Rumania also produce, but production data not available; estimates in total.

In terms of an equivalent ad valorem base the duty on zinc in concentrate has been reduced from approximately 56 percent in 1930 to 10 percent in 1963; that on slab zinc in the same period declined from 38 to 6 percent.

On September 22, 1958, the President acting on recommendations of the Tariff Commission proclaimed imposition of import quotas on zinc (and lead) effective October 1. The quotas established were 80 percent of the average dutiable imports into the United States during the base period, 1953–57, and duty rates remained at then existing levels (*15*).

STRATEGIC CONSIDERATIONS

The United States was fully self-sufficient in zinc supplies until about 1940. Since then increased consumption, decreased mine production, and diversion of substantial quantities to build a national stockpile in the period 1949–59 brought about partial dependence on imports. Between 1942 and 1958, 35 percent of all supply was from imports. In the period 1954–58 about 45 percent of the U.S. supply was imported. These quantities exceeded requirements by a large margin which was added to industry and government stocks. Imports needed to balance consumer requirements in the 5 years, 1954–58, averaged 500,000 short tons. Average annual imports for the period were 702,000 tons of which 653,000 tons was slab zinc, or recoverable as such, or an annual excess of 153,000 tons. Imports needed to balance consumer requirements in the 5 years 1959–63, averaged 544,000 tons. Average annual imports were 581,000 tons of which 541,000 tons was slab zinc, or recoverable as such, a quantity approximately equal to reported requirements.

Mining and smelting capacities to produce zinc, imports expected from strategically accessible foreign sources, and the zinc in the Nation's stockpile are calculated to be adequate to meet any anticipated wartime requirements. Primary and secondary zinc producing plants and stockpiled zinc are well dispersed. Furthermore, the chief source of imports, neighboring Canada and Mexico, produce large quantities of zinc in excess of their requirement and both are accessible by rail, as well as ocean freight. Imports from Western Hemisphere countries in 1959 through 1963 amounted to about 85 percent of the import requirements for consumption.

GOVERNMENT PROGRAMS

The defense program of the United States relating to zinc was authorized by the Strategic and Critical Materials Stockpiling Act of 1946 (Public Law 520, 79th Cong.) and the Defense Production Act (DPA) of 1950, as amended.

TABLE 14.—*Zinc tariffs under the Tariff Act of 1930 and the Reciprocal Trade Agreements Act*

[Cents per pound]

	Tariff Act of 1930	Canadian Agreement, Jan. 1, 1939	Geneva Agreement, Jan. 1, 1948	Torquay Agreement, June 6, 1951
Zinc-bearing ores, except pyrites containing not more than 3 percent zinc (rates apply on zinc content)	$1.50	$1.20	$0.75	[1] $0.60
Zinc in blocks or slabs	1.75	1.40	.87½	.70
Zinc sheets	2.00	2.00	1.00	1.00
Zinc oxide and leaded zinc oxides containing not more than 25 percent lead	1.75	1.75	.60	.60
Lithopone containing less than 30 percent of zinc sulfide	1.75	[2] 1.50	.87½	.87½

[1] New tariff schedules, effective Aug. 31, 1963, changed rate to .67 cents on assay zinc content less certain allowable deductions to remain approximately equivalent to the previous rate.
[2] Netherlands Agreement, Feb. 1, 1936.

The stockpiling act authorized and directed the determination of an acquisition of quantities of metals deemed necessary to the public defense, and under its provisions stocks held by the Metals Reserve Co. were transferred to the national stockpile in 1948. DPA purchases in substantial quantities began in 1949. The 1.5 million tons of zinc initially established as an objective was revised downward to 700,000 tons in 1951. Upward revisions in 1954 and 1956 brought the objective to 1.2 million tons, but objectives were reduced to 178,000 tons in 1958 and eliminated in 1963. On June 30, 1964, government inventories totaled 1.6 million tons, of which 1.3 million was in the national (strategic) stockpile and 0.3 million in the supplemental stockpile.

Under authority of Public Law 480 (1954) and Office of Defense Mobilization (ODM) authorization of May 1956, The Department of Agriculture, through its agent, the Commodity Credit Corporation, traded perishable surplus agricultural products for zinc of foreign origin. The 327,000 tons of zinc acquired from 1956 through 1960 under this program was placed in the supplementary stockpile.

Under the Defense Production Act of 1950, as amended, the Defense Minerals Exploration Administration (DMEA) was authorized to grant loans up to 50 percent of approved costs on exploration of zinc. Public Law 85–701 (1958) established the Office of Minerals Exploration (OME) in the Department of the Interior as the successor to the DMEA. Zinc was removed effective July 1, 1962, from the list of metals eligible for exploration assistance under the program. Through 1963, DMEA and OME had entered into 290 contracts for exploration of zinc and/or lead. The total estimated cost was $27.4 million of which the Government's share was $13.7 million. Exploration was judged to be successful on 86 properties. ore discoveries ranging from several hundred tons of ore to one of 35 million tons in eastern Tennessee.

PRICES AND COSTS

Market prices of zinc are established by the producer and most commonly quoted in cents per pound for Prime Western Grade, f.o.b., East St. Louis, although relatively little zinc is delivered there; Brass Special and Intermediate grades are normally quoted ¼ and ½ cents, respectively, above the Prime Western Grade. These grades of zinc are also quoted on a delivered basis that is ½ cent above the East St. Louis price. High Grade and Special High Grade are quoted on a delivered basis at approximately 1¼ and 1½ cents per pound above the East St. Louis price of Prime Western.

The London Metal Exchange (LME), founded in 1881, is another important market pricing center. Although relatively small quantities of zinc are sold on the exchange, the quotations are widely used as a basis for pricing large quantities of zinc and zinc ores sold outside the exchange. In 1964 many producers outside the United States have also established a producer price.

Since 1951 various supply and demand factors have caused the price to decline from a high of 19.5 cents in May 1952 to 9.25 cents a pound in 1954. Following the 1954 low, prices advanced to 13.5 cents in 1955, declined to 10.0 cents in 1957, and then upward to 14.5 cents in October 1964.

The price data given in table 15 permit comparison of the price of Joplin concentrate with refined common zinc in St. Louis, New York,

TABLE 15.—*Prices of zinc*

	1959	1960	1961	1962	1963
Joplin 60-percent zinc concentrate: [1] Price per short ton, dollars	67.53	79.67	68.42	69.00	72.01
Average price common zinc at:					
St. Louis (spot) [1] cents per pound	11.46	12.95	11.55	11.63	12.01
New York [1] do	11.96	13.45	12.05	12.13	12.51
London [2] do	10.27	11.05	9.78	8.43	9.60

[2] E&MJ Metal and Mineral Markets English quotations converted into American money on basis of average rates of exchange recorded by Federal Reserve Board.

and London. Evaluation of the tabulation reveals the substantial increase in the percent of metal price paid for the zinc contained in concentrate as the metal price increases. The table also shows that the LME price has generally been about 2 to 3 cents below the New York price, the difference largely representing the added costs of duty, ocean freight, and insurance for delivery to the United States.

TAXES

The zinc mining industry receives the maximum depletion allowance for metallic minerals of 23 percent on domestic production and 15 percent on foreign production.

TRANSPORTATION

Zinc ore is usually concentrated at mills situated in close proximity to the mines. Exceptions are or have been the Butte-Anaconda, Montana operation where ore is hauled by rail about 26 miles to the concentration plant at Anaconda; the Midvale mill at Midvale, Utah; the Eagle-Picher Central mill at Cardin, Okla.; and the Eagle-Picher mill north of Galena, Ill. Concentrate of domestic and foreign origin is transported by rail, truck, or boat to smelters. In 1961, examples of the freight rate per ton of concentrate shipped by rail to the smelter were $0.50 from the Summit Valley district to Anaconda, Mont.; $1.08 from Coeur d'Alene, Idaho to Kellogg, Idaho; $6.61 from Lawrence County, N.Y. to Josephtown, Pa.; $8.42 from eastern Tennessee to East St. Louis, Ill.; and $20.74 from Central, N. Mex. to Palmerton, Pa.

RESEARCH

Research plays a vital role in maintaining zinc in a competitive position with alternate materials. These research efforts by individual companies, trade associations, and government agencies are directed towards all phases of the zinc industry—ore discovery, production, and product utilization.

Exploration efficiency has been advanced by studies of the geological controls involved in the process of ore deposition and by developing improved methods such as the use of photogeology, geochemistry, and various geophysical techniques. These methods have been successful in discovering new mineral districts as well as extending old districts.

Research in mining has emphasized development of equipment to mechanize operations or otherwise increase labor productivity to offset rising prices of wages and supplies. Bureau of Mines mining research includes studies of hydraulic stope filling, roof-control, rock mechanics, rock drilling, and statistical analysis for operational control.

In minerals beneficiation much of the research has been directed towards improvement of equipment and operating practices. Notable advances are in progress to monitor or control milling processes by automatic systems such as sound measuring instruments for grinding mill loads, gamma-ray density meters for pulp density, torque measurements for classifier sand return, and fluorescent X-ray spectrometry for reagent control in flotation. The Bureau of Mines ore beneficiation studies include the use of radioactive tracers in mill processes and recovery of zinc concentrates from complex ores, slimes, and mill tailings by flotation.

In zinc production research, the Imperial Smelting Corp., Ltd. achieved reduction of zinc in 1950 by use of a blast furnace with a number of attendant efficiencies. This type of furnace has since been built or scheduled for construction in eight countries. Other improvements have been made in roasting, sintering, and furnace design. The Bureau of Mines extractive studies include leaching with chemical solutions and microorganisms; reduction of sulfide minerals with atomic hydrogen; and use of vacuum and carrier gas distillation to improve separation and purification of metals.

Research on utilization of zinc has been carried on by many producers and some of the larger consumers of zinc. Development of diecasting alloys by The New Jersey Zinc Co. was a notable example. Beginning in 1958 many major zinc producers in the world working through the American Zinc Institute began a unified research program on zinc utilization. This research group changed its name July 1, 1963 from the Expanded Research Program of the American Zinc Institute and the Lead Industries Association to the International Lead-Zinc Research Organization (ILZRO). Included in the many research projects sponsored by ILZRO are new diecasting alloys, use of powder metal materials, welding of galvanized sheets, effect of temperature on properties of galvanized steel, cathodic protection of installations with zinc anodes, improved zinc-rich paints, and anodized finishes on zinc products.

Both zinc and zinc oxide readily form crystals that exhibit a wide spectrum of solid-state properties and have therefore received much attention by investigators of the fundamental properties of all substances.

An extensive library and information service is maintained by the American Zinc Institute. This association and the Zinc Development Association (London) jointly publishes Zinc Abstracts monthly giving a comprehensive coverage of zinc technology reported in the scientific and technical press.

OUTLOOK

The long-term upward trend of domestic slab zinc consumption should continue with an increase from the 1.1 million tons recorded in 1963 to 1.3 million tons by 1970 and 1.6 million tons by 1980. The forecast growth rate is somewhat more optimistic than a straight projection of zinc consumption data but is below a projection of the gross national product index.

Free world slab zinc consumption should increase approximately parallel to the United States, advancing from 3 million tons in 1963 to about 4 million tons by 1970. The Asian countries of India and Japan and a number of African countries are expected to experience significantly higher than average percentage increases, but their combined total consumption will still represent only about 15 percent of the free world total by 1970.

The use pattern of zinc in the United States should remain unchanged, except that the consumption of slab zinc for galvanizing and for diecasting will likely increase at a somewhat faster rate than for the other remaining use categories. An important factor in the long-term demand for zinc is the growing recognition of the value of protecting iron and steel products from corrosion by using a zinc coating. In the rapidly expanding die-cast and molded products field, zinc-base alloys can be expected to participate in the increase despite strong competition from other materials. The new alloy developments for rolled zinc may promote an upward trend of zinc consumption for this category. Increased use of zinc oxide for photocopying and other electronic applications utilizing the property of electro-luminescence also could add to the relatively stable older applications. The other numerous products consuming zinc do not have developments indicating any substantial future changes to their consumption pattern.

The increasing supply requirements will be met in part by an increase in domestic mine output from 530,000 tons of recoverable zinc in 1963 to a forecasted 620,000 to 650,000 tons by 1970 and probably somewhat in excess of this level thereafter. Relaxation of the import quota restrictions would undoubtedly result in larger imports of both concentrates and metal, particularly from Canada. There are substantial quantities of zinc in the national stockpile declared surplus to defense needs that must be taken into account as a significant factor in potential sources of supply for future years.

States east of the Mississippi River are expected to expand their zinc mine output from 51 percent of the total in 1963 to around 55 percent by 1970. The remaining production will be derived largely from the Western States with only a minor quantity from the West Central States. Replacement ore bodies, like those of east Tennessee and the Metaline area in Washington which are amendable to mechanized mining methods, and ore bodies with significant quantities of gold, silver, and copper will continue to compete successfully with foreign deposits. The trend toward vertical integration of domestic mining, smelting, and manufacturing companies will continue.

Domestic smelters will modestly increase slab zinc output to the extent practicable by available concentrates. Larger quantities of die-cast scrap should become available and be a larger factor in the production of slab zinc, zinc oxide, and other zinc products. There is a decided trend toward the higher grades of zinc making up a larger proportion of total output.

PROBLEMS

Producers, and indirectly the consumers, of zinc are confronted with technical and economic problems related to the discovery of new deposits, mining, milling, and smelting operations, and the marketing of zinc. Problems also occur because changes in policy by governments of major zinc producing countries require adjustments by the zinc industries in all affected countries.

The trend towards establishment of zinc reduction plants in countries previously only mining zinc causes disruption in trade patterns, especially in the supply of concentrates to the United States and Europe. New import sources of concentrate must then be found or greater effort directed toward replenishment of depleted domestic reserves, to supply the domestic smelters.

Better knowledge of geological ore depositional controls is required to aid in selecting areas for conducting exploration. Techniques are not adequate to utilize fully the exploration data and determine characteristics of the deposit important to future mining activity such as ease of drilling and breaking the rock, water flow expected, and stability of the mine structure.

Output at current and projected rates requires operation of some mines at increasing depths resulting in conditions of high rock pressures and temperatures, and the removal of water under a large pumping head. The lack of

knowledge of earth physics impedes solution of the problems of rock bursts, ground control, and water control. The shallow replacement-type deposits have similar, albeit not as dramatic problems. Additionally, breaking, loading, and hauling costs per ton of ore must be kept down since the average metal content of these latter deposits is usually low.

Loss of zinc through the combined steps of mining, milling, and processing is too high from the standpoint of both operating efficiency and conservation of resources. More knowledge of the physicochemical nature of complex mineral assemblages and of the ore beneficiating processes used would make possible an improved separation. In reduction of zinc concentrate to metal both basic and applied research is needed to reduce the processing cost.

The character of zinc scrap being generated is changing, requiring new types of treatment. The zinc dross from the continuous galvanizing lines has a higher aluminum content and possibly different physical properties than dross from previous processes, causing problems for secondary metal producers. Scrap zinc die-castings will be available in increasing quantities with attendant technologic and marketing problems.

As a counterpart to the supply side of the equation, there is an equal need to investigate the properties of zinc to assure full and wise utilization of the material. Although zinc has been in use for many centuries, voids remain in the knowledge regarding its physical and chemical properties. For example, zinc exhibits low creep resistance and also a low ductility at or below room temperature, both poor qualities for wrought-metal use. Little is known about the basic mechanism or the means of changing these properties by alloying.

Increased understanding of zinc for corrosion protection is needed. In the hot-dip galvanizing process, the effect on corrosion or weldability characteristics of the iron-zinc intermetallic substrate underlying the zinc coating is not clearly understood. On the atmosphere side of the coating, there is a need to minimize corrosion of the zinc.

Threshold knowledge indicates zinc oxide and other zinc compounds may be extremely useful in applications involving electroluminescence, photoconductivity, semiconductivity, or other electronic uses. However, much additional knowledge is needed on the thermodynamic, physical, and electronic properties of the compounds.

Other areas in which information is incomplete include the corrosion properties of zinc in various media; the energy requirements for rolling, extruding, joining, or other fabricating techniques; the function of zinc oxide in ceramics and glasses; and the utilization of zinc compounds in preventing mildew and in agricultural soil additives.

Continuing efforts are required to achieve orderly zinc marketing and price stability so that both producers and consumers can make plans with a reasonable assurance of future conditions. A major problem exists in determination of the zinc price at which substitution of alternate competitive materials is not a serious threat to zinc consumption and yet is sufficient to provide incentive for sustained output to meet the demand. Evaluation of the many world supply and demand factors is required for determination of the best commercial and government policies to attain this marketing goal.

ZIRCONIUM

By Donald E. Eilertsen [1]

DUCTILE ZIRCONIUM, developed only about 10 years ago, is used in nuclear reactors and to resist attack by acid and alkaline solutions in industry.

Zirconium was discovered in 1789, and approximately 150 years later the zirconium industry emerged as a commercial enterprise in the United States. Zirconium was wanted for testing in nuclear reactors. The Bureau of Mines in cooperation with the Atomic Energy Commission (AEC) developed a large-scale production procedure for zirconium and shortly thereafter industry adopted the method. Zirconium sponge output reached a record 1,700 tons in 1961.

Zircon, dredged from sand deposits, is used commercially to produce zirconium metal, alloys, and compounds, but the largest use of zircon is in refractories, particularly foundry sand, and in abrasives and ceramics.

In the United States, three firms produce zircon, four firms process zircon to zirconium, and several firms produce zirconium alloys. Zircon and zirconia refractories are produced by approximately 12 firms. Numerous foundries use zircon as foundry sand.

Large quantities of zircon are consumed in the United States; much of this is imported, particularly from Australia. U.S. zircon resources are large but most would be expensive to recover.

The principal problem of the zirconium industry is: How can larger markets be developed for the metal?

BACKGROUND

Zirconium was prepared in elemental form in 1824, produced in relatively pure form in 1914, and made into high-purity grade in 1925 by the deBoer-van Arkel procedure. This procedure later was used for the first commercial zirconium production in the United States.

The Bureau of Mines began research on producing high-purity zirconium on a commercial scale in 1944 under the direction of W. J. Kroll. A method was developed and tested commercially to produce high-purity zirconium by the magnesium reduction of zirconium tetrachloride in an inert atmosphere. Private industry adopted this process in 1953, and soon afterwards the zirconium industry expanded and was able to produce large quantities of high-purity and commercial-grade zirconium. The AEC contracted for most of this zirconium for nuclear reactor testing and application. These contracts terminated in 1963, leaving the industry with idle capacity since zirconium's largest use is in nuclear reactors.

[1] Commodity specialist.

SIZE, ORGANIZATION, AND GEOGRAPHIC DISTRIBUTION OF THE INDUSTRY

Three firms in the United States produce zircon as a coproduct in mining heavy mineral sands for ilmenite and rutile. These companies are E. I. du Pont de Nemours & Co., Inc., at its Trail Ridge and Highland mines near Starke, Fla.; Titanium Alloy Manufacturing Division of National Lead Co. at the Skinner mine near Jacksonville, Fla.; and Florida Mineral Co. at its Vero mine at Vero Beach, Fla. Figures on zircon output are withheld because they are company confidential data.

Four firms produce zirconium sponge: U.S. Industrial Chemicals Co., Division of National Distillers & Chemical Corp., Ashtabula, Ohio; The Wah Chang Corp., Albany Division, Albany, Oreg.; The Carborundum Metals Co. Division, The Carborundum Co., Parkersburg, W. Va., and Akron, N.Y.; and Columbia-National Division, Pittsburgh Plate Glass Co.,

Pace, Fla. The latter firm placed its zirconium production facilities in a standby condition in mid-1963 for an indefinite period. Annual output of zirconium sponge in recent years has been in excess of 1,000 tons.

Zirconium sponge is converted to ingot by The Carborundum Metals Co. Division, The Carborundum Metals Co., Parkersburg, W. Va., and Akron, N.Y.; The Wah Chang Corp., Albany, Oreg.; Bridgeport Brass Co., Niles, Ohio, and U.S. Industrial Chemicals Co., Ashtabula, Ohio (divisions of National Distillers and Chemical Corp.); Harvey Aluminum, Inc., Torrance, Calif.; and Oregon Metallurgical Corp., Albany, Oreg. Annual production of zirconium ingot has been about 1,000 tons.

The principal producers of zirconium alloys are Union Carbide Corp., Metals Division, Alloy, W. Va., and Niagara Falls, N.Y.; Titanium Alloy Manufacturing Division of National Lead Co., Niagara Falls, N.Y.; and Vanadium Corporation of America, Cambridge, Ohio.

Titanium Alloy Manufacturing Division of National Lead Co., Niagara Falls, N.Y.; the Norton Co., Huntsville, Ala.; Harbison-Carborundum Co., Falconer, N.Y.; Zirconium Corporation of America, Solon, Ohio; and Tizon Chemical Corp., Flemington, N.J., process zircon to zirconium chemicals, principally zirconia. Annual zirconium oxide output, excluding that produced for zirconium metal production, has averaged about 5,000 tons in recent years.

Twelve firms processed zircon to refractories in 1963. The largest producers of refractories were Corhart Refractories Co. at Louisville, Ky., and Buckhannon, W. Va.; Harbison-Carborundum Corp., Falconer, N.Y.; The Charles Taylor Sons Co., Cincinnati, Ohio, and South Shore, Ky.; Walsh Refractories, St. Louis, Mo.; and Remmey Division of A. P. Green Fire Brick Co., Philadelphia, Pa. Annual zircon and zirconia refractory production has been between 21,000 and 37,000 tons in recent years.

Approximately 20 dealers in the United States sell domestic and imported zircon to consumers, the largest quantity going to the foundries.

DEFINITION OF TERMS, GRADES, AND SPECIFICATIONS

Domestic zircon ($ZrSiO_4$) is quoted on a minimum basis of 66 percent ZrO_2 content (98.2 percent pure zircon), while imported zircon is quoted on a minimum basis of 65 percent ZrO_2 (96.7 percent pure zircon).

Zirkite is a trade name for a mixture of zircon and baddeleyite.

Typical spectrographic analyses of the maximum impurities in nuclear-reactor-grade and commercial-grade zirconium sponge and zirconium oxide produced by The Wah Chang Corp. follow:

Impurities	Maximum impurities, parts per million		
	Nuclear-grade zirconium sponge	Commercial-grade zirconium sponge	Zirconium oxide
Aluminum	50	300	100
Boron	<.2	<.2	2
Cadmium	<.2	<.2	----
Calcium	<50	<50	----
Carbon	100	100	----
Chlorine	500	500	----

Vanadium	<20	<20	<20

Zircaloy-1 is an alloy of sponge zirconium containing, by weight, 2.5 percent tin.

Zircaloy-2 is an alloy of sponge zirconium containing, by weight, 1.2 to 1.7 percent tin, 0.7 to 0.20 percent iron, 0.05 to 0.15 percent chromium, and 0.03 to 0.08 percent nickel (*5*).[2]

TECHNOLOGY

Geology

Zirconium and hafnium are always found together in minerals. The earth's crust has been estimated to contain 220 parts per million of zirconium, compared with 4.5 parts per million of hafnium.

Zirconium is a fundamental constituent of a number of minerals and an occasional constituent of others. The well known zirconium minerals are zircon ($ZrSiO_4$) and baddeleyite (ZrO_2). Zircon and baddeleyite are marketed commercially, but zircon is practically the lone zirconium mineral in use.

Zircon is often a minor constituent of granites, pegmatites, and granodiorites, and sometimes a minor constitutent in diabase, basalt, limestone, sandstone, conglomerate, slate, schist and gneiss. Zircon is rarely found in rock in economically minable concentrations. However, weathering and erosion, particularly of granitic rocks, have led to deposition in minable concentrations of heavy-mineral sand along rivers and ocean beaches and in dunes. Heavy-mineral

[2] Italicized numbers in parentheses refer to items in the list of references at the end of this chapter.

sands are found in many parts of the world. Australia is a large supplier of zircon.

Mining and Concentration

Zircon and minor quantities of baddeleyite are recovered commerically from heavy-mineral beach sands or river gravels as coproducts and byproducts of ilmenite and rutile, and occasionally gold, cassiterite, and monazite.

Heavy-mineral sands are usually mined by conventional dredging methods using bucketline, suction, or dragline dredges. The heavy-mineral rougher concentrator may be on the dredge, on one or more barges attached to the dredge or on land. The mineral constituents are usually separated from the rougher heavy-mineral concentrate in a mill on land. Spiral concentrators and electrostatic and magnetic separators are extensively employed in the recovery and separation of zircon.

Numerous flowsheets are in use for separating zircon and other valuable minerals from heavy-mineral sands. Procedures used by the Trail Ridge, Fla., plant of Du Pont to separate zircon from sand containing zircon, ilmenite, rutile, leucoxene, staurolite, sillimanite, kyanite, and other minerals are described briefly as follows (*3*):

Feed from the dredge is pumped to 704 rougher spirals which produce a concentrate for further treatment, middlings for recirculation and retreatment, and tailing reject. The concentrate continues on to 264 cleaner spirals which produce a concentrate for further treatment and middling and tailing for recirculation and retreatment. The concentrate continues to 132 recleaner spirals which produce a concentrate for further treatment and tailing for recirculation and retreatment. The concentrate is scrubbed, dried, and passed through rougher electrostatic separators which produce a concentrate, middling, and tailing. The concentrate is redirected for recovery of titanium minerals, the middling is recirculated for retreatment, and the tailing goes to scavenger electrostatic separators which produce concentrate, middling, and tailing, the latter two being recirculated for retreatment. The concentrate goes to a magnetic separator to remove staurolite and then to spirals to remove sillimanite and kyanite and to produce a zircon concentrate which undergoes electrostatic and magnetic separation, the products of which are titanium-rich reject and zircon.

Metal Production

The deBoer-van Arkel process, first described in 1925, is essentially a refining process, and was adopted by the Foote Mineral Co. in 1945. Using impure zirconium as a raw material, zirconium tetraiodide is formed by reaction with iodine vapor at 200° C. This halide, which is gaseous at this temperature, is transferred to a connecting vessel, leaving behind most impurities in a solid state. At 1,300° C the reaction is reversed, depositing elemental zirconium on a heated filament and regenerating iodine vapor to return to the head of the process (*5*).

A procedure to produce commercial-grade zirconium containing about 2 percent hafnium and nuclear-grade low-hafnium zirconium is described briefly as follows (*2*):

Zircon sand and coke, blended together, are melted in an electric-arc furnace to produce zirconium carbonitride containing about 85 percent zirconium. The carbonitride is chlorinated to crude zirconium tetrachloride for Kroll process reduction to commercial zirconium which contains about 2 percent hafnium, or to nuclear-grade low-hafnium zirconium.

For nuclear-grade zirconium, the crude zirconium tetrachloride is dissolved with a complexing agent and put through solvent extraction, which strips hafnium from the solution. The zirconium component is precipitated and calcined to oxide which is rechlorinated to high-purity zirconium tetrachloride. The zirconium tetrachloride is reduced with magnesium in an inert atmosphere in a Kroll furnace, forming a mixture of zirconium and magnesium chloride for distillation. Magnesium chloride is distilled off while zirconium sponge remains behind. The zirconium sponge is crushed, compacted into consumable electrodes, and vacuum melted in an inert atmosphere into ingot. The ingot is used as consumable electrode to produce second-melt ingot, which is machined and readied for fabrication.

Metal Fabrication

A zirconium ingot weighing 1,000 to 2,500 pounds is forged or cogged at approximately 790° to 970° C on standard equipment into a billet. The billet is conditioned by grinding or by grit blasting and is then hot- or cold-rolled to zirconium plate, sheet, or bars. Hot-rolled products are annealed in a neutral or slightly oxidizing atmosphere at about 790° C for 20 minutes. The hot-rolled products are grit-blasted to remove oxide and acid-pickled to brighten surfaces. The cold-rolled product is vacuum-annealed to regain ductility without oxidizing the surface of the metal.

Zirconium Hydride Production

Zirconium hydride is prepared by exposing zirconium sponge in the ½- to 2-inch size range

to hydrogen at 800° C. Commercial hydrogen is used but must be carefully purified. The product is brittle and is ground dry in an inert atmosphere to the desired particle size.

Processing of Zircon as an Industrial Mineral

Zircon intended for use as foundry facings or refractories is graded and sized, and in many cases wet- or dry-ground; it is then marketed as technical, ceramic, or electrical zircon.

Zirconium oxide is prepared by pelletizing zircon with dolomite and reacting it in a rotary kiln at 1,427° C. The kiln product is a mixture of zirconia and artificial monticellite ($CaMgSiO_4$). The latter is leached with acid to leave a final zirconia product. This product may be stabilized with alkaline-earth oxides, or may be unstabilized (monoclinic) zirconia of high purity; either can be made by using suitable charge proportions.

Other zirconium chemicals—the hydrous or carbonated oxide, the acetate, sulfate, fluorides, zirconyl chloride, organic zirconium complexes, and various zirconates—are usually prepared from the unstabilized oxide.

USES

More than half of the zircon is utilized in its mineral form; the remainder is used to produce zirconium metal, alloys, and compounds.

Zircon has extensive use as refractories, particularly as foundry molds and cores. Other applications are in chemically resistant ware, enamels, electrical insulators and resistors, glazes, glass polish, pigments, heat transfer pebbles, porcelains (*1*), and abrasives.

Zirconium's very low absorption cross section, excellent corrosion resistance at moderately elevated temperatures, good strength, good ductility, ease of fabrication, low radioactivity after reactor exposure (*5*), and very large mineral-resource supply have led to extensive use in nuclear reactors. Powerplants of the first atomic-powered submarine, *Nautilus*, and a number of other naval vessels contain zirconium.

Zirconium's corrosive resistance has led to the development of many applications, particularly in the chemical industry, such as components of heat exchangers and acid concentrators, tanks, shafts, valves, pump housings, fanwheels, high-speed agitators, electrode assemblies, steam-jet exhausters, tubing, pipe and pipe fittings (*6*), spinnerettes used in the textile industry (*5*), and crucibles. Zirconium foil is used in photo flashbulbs.

Numerous zirconium alloy systems have been developed; those commonly known in industry are Zircaloys and ferroalloys. Zircaloys also are used in nuclear reactors. Columbium-zirconium alloy magnets have use in scientific instruments.

Numerous uses have been developed for zirconium compounds (*1*). Besides being used in the production of zirconium metal and alloys, zirconium oxide is used in refractories and abrasives. Other uses developed for zirconia include such applications as hardener for metals; opacifier for glazes, enamels, and X-ray photography; phosphor activation; prolonging life of cathodes of fluorescent lamps; retarding recrystallization of electric-lamp filaments; decreasing the coefficient of thermal expansion, increasing chemical resistance, and absorbing infrared and ultraviolet radiation in certain glasses; electrical insulators and wire-insulating compositions; and removing tellurium and mercury from crude selenium.

Zirconium alkoxides are added to paint to inhibit rust, used as catalysts, as a flexible film coating on stainless steel, as ink stabilizer to promote drying and prevent smearing, and as water repellent for leather and textiles.

In addition to its use in producing zirconium metal, zirconium tetrachloride has applications in catalysis, but most of these uses are trade secrets. Sulfatozirconate is used as a tanning agent to produce high-quality "plump" leather.

Some floor waxes contain zirconium.

BYPRODUCTS AND COPRODUCT RELATIONSHIPS

Zircon is recovered commercially while dredging heavy-mineral sands primarily for ilmenite and rutile; it usually is a coproduct but sometimes is a byproduct. Other merchantable products of these sands include monazite, kyanite, staurolite, and garnet. Placer deposits rarely are worked for zircon alone; each product bears a share of the operating cost.

In the production of reactor-grade zirconium, hafnium is removed as a valuable impurity. High-hafnium zircon such as that from Nigeria increases the yield of hafnium.

ALTERNATE MATERIALS

Stainless steel is an alternate material for nuclear structural applications, whereas aluminum, columbium, and vanadium may be used in place of zirconium for fuel containers. Stainless steel and titanium are substituted for zirconium in many corrosion-resistant industrial applications.

In ferrous metal applications, manganese, vanadium, and several other elements may be

substituted as deoxidants; titanium is a slightly better denitrifier; aluminum and titanium inhibit grain growth as well as zirconium; vanadium and chromium may be substituted to improve low-temperature impact strength (*4*).

Alumina holds promise as a mold aggregate, but is more expensive than zircon. Zircon is an acid refractory. In some instances it can be replaced by silica and olivine.

Titanium oxide and tin oxide may be substituted as opacifiers in ceramic glazes and enamels.

SECONDARY SOURCES AND RECOVERY

Scrap developed from fabricating zirconium is usually remelted into ingot. Very little zirconium and Zircaloy scrap is obtained through scrap dealers for remelting.

RESERVES

The U.S. resource of zircon concentrate containing approximately 66 percent ZrO_2 was estimated in 1961 at 12.6 million tons. The free world resource of zirconium minerals has been estimated at 23 million tons.

The U.S. resource of zircon is in sand deposits associated with titanium minerals except that of New Mexico, Utah, and Wyoming which is in zirconiferous sandstone.

The distribution of the U.S. zircon resource is shown in table 1.

TABLE 1.—*Resource of zircon in the United States, by States*

State	Thousand tons
California	1,500
Florida	7,155
Georgia	345
Idaho	82
Maryland	162
New Jersey	1,520
New Mexico, Utah, Wyoming	290
Oregon	90
South Carolina	1,350
Other States	87
Total	12,581

The free world resource of zirconium minerals is shown in table 2. In addition, there are important deposits in Egypt, the Republic of Senegal, Western Australia, and the Bihar and Orissa provinces of India, but quantitative data are lacking.

TABLE 2.—*Free world resource of zirconium minerals, by countries*

Country	Thousand tons
Australia	2,882
Brazil	2,552
Ceylon	1,000
India	3,360
South Africa, Republic of	564
United States	12,581
Other countries [1]	404
Total	23,343

[1] Includes Republic of Ivory Coast, Republic of Korea, Malagasy Republic, Nigeria, and Uruguay.

SOURCES OF STATISTICAL INFORMATION

Domestic producers, dealers, and primary consumers of zircon are canvassed annually by the Bureau of Mines. Stocks, receipts, production, shipments, and consumption of zircon and of zirconium metal, alloys, and compounds are reported. Foundries are not canvassed for data on zircon.

PRODUCTION, CONSUMPTION, AND TRADE

Production and consumption data on various zirconium products are shown in table 3.

TABLE 3.—*Production and consumption of various zirconium products in the United States*

[Short tons]

Item	1954–58 average	1959	1960	1961	1962	1963
Production:						
Zircon	35,497	(1)	(1)	(1)	(1)	(1)
Zirconium sponge	(2)	1,404	1,423	1,697	1,272	1,022
Zirconium oxide [3]	(2)	(2)	6,907	5,732	4,495	5,283
Zircon and zirconia refractories	(2)	16,500	24,862	20,737	37,100	21,000
Consumption:						
Apparent, zircon	(2)	81,500	89,000	92,100	89,000	[4] 37,500

[1] Figure withheld to avoid disclosing individual company confidential data.
[2] Data not available.
[3] Excluding zirconia used for metal production.
[4] Excludes foundries.

Imports and exports of various zirconium products are shown in table 5. Zirconium ore and concentrate are imported duty free. Unwrought zirconium is dutiable at 12.5 percent, ad valorem.

Imports of zircon are shown in table 4.

TABLE 4.—*U.S. imports for consumption of zircon, by countries*

[Short tons]

Country	1954–58 (average)	1959	1960	1961	1962	1963
Australia [1]	27,195	53,650	29,183	31,225	27,001	50,004
Austria						11

Zirconium and zirconium alloys, semifabricated	2	5	35	45	37	38

[1] Less than 1 ton.

STRATEGIC CONSIDERATIONS

The United States is self-sufficient in zirconium metal, alloys, and compounds and could be self-sufficient in domestic zircon if required, but at higher prices.

Zircon is recovered commercially in Florida which has more than half of the total U.S. zircon resource.

Zirconium sponge is produced in Oregon, Ohio, West Virginia, and Florida. Zirconium ingot is produced in Oregon, Ohio, West Virginia, and California. Most of the zirconium alloy production is in New York, West Virginia, and Ohio.

Zirconia output, excluding that produced for zirconium metal production, is mostly in New York, Alabama, and Ohio.

Large quantities of zircon are imported for commercial use, particularly from Australia, but zircon output in Florida could probably be increased substantially if needed.

GOVERNMENT PROGRAMS

Zirconium mineral concentrate is not being bought by the Government for the national strategic and supplemental stockpiles. Stocks, on December 31, 1964 totaled 1,920 tons of zircon and 16,533 tons of baddeleyite, both destined for disposal.

Zirconium is not acquired for the national strategic stockpile.

PRICES

Quoted prices for zircon concentrate and zirconium in December 1964 follows:

	Price
Zircon:	
Domestic, containing 66 percent zirconia, f.o.b. Starke, Fla., per short ton	$47.25
Imported, containing 65 percent zirconia, c.i.f. Atlantic ports, per long ton	61.00
Zirconium:	
Flash-grade powder, per pound	10.00
Sponge, per pound	4.25–5.00
Sheets, strip, and bars, per pound	10.00–14.00

TAXES

The domestic depletion allowance is 23 percent, whereas the foreign depletion allowance is 15 percent.

TRANSPORTATION

Domestic zircon is shipped in bags or in covered hopper cars; imported material comes in 112-pound bags or bulk.

Zirconium combines readily with oxygen and nitrogen and is quite combustible; in its finely divided state it is even explosive. Burning zirconium is not extinguished by water, carbon tetrachloride, or carbon dioxide; dry chemicals are used to cover and isolate the burning material. Interstate Commerce Commission regulations exist for shipping some forms of zirconium.

RESEARCH

Zirconium has undergone extensive research and development since its emergence as a very desirable metal for nuclear reactor applications.

Much of the work on zirconium has been published by the Government, industry, and various organizations.

Principal features of the Bureau of Mines program on zirconium and hafnium in 1963 were research on extraction, separation, and purification of zirconium and hafnium, and studies on alloys and refractory compounds.

OUTLOOK

The demand for zirconium in nuclear reactors will depend on the future demand for new reactors and how well zirconium outperforms its competitors such as stainless steel and aluminum. Moderate use of zirconium in reactors is predicted, but this market will be relatively small compared with outputs during the early 1960's when, in addition to normal usage, AEC-acquired large quantities of zirconium for testing and stocking.

Modest increases in the demand for zirconium alloys and chemicals are predicted.

Market expansion, especially for zirconium metal, will be stressed. New uses and larger markets in established uses will be sought.

Research will continue on zirconium's basic properties, improvements in processing technology, development of new uses, and testing the metal under duress.

Competition among zirconium producers will be keen, and occasional price reductions of zirconium may result.

There may be greater international competition for zirconium products as industries in other countries continue to develop.

Zircon mining, both domestic and foreign, will continue to expand and modernize to compete for increasing markets, particularly in foundry and refractory applications. No large decrease in the price of zircon is anticipated.

PROBLEMS

Zircon output is not always controllable because zircon is recovered as a byproduct in mining and milling for titanium minerals. Mining and beneficiation problems include sampling procedure, special concentrating methods, tailing disposal, land reclamation, and water pollution control.

Ductile zirconium has only been available for slightly more than a decade. The most pressing problem for zirconium is: How can large markets be developed for the metal? Zirconium metal output has largely been purchased by AEC for limited nuclear-energy applications. This market is in the development stage; consequently some zirconium producers curtail or suspend operations from time to time.

The problem of increasing the demand for zirconium may require solutions to numerous individual problems such as price reductions, lowering high costs of extraction and fabrication, expanding the technology, and testing the performance of zirconium in many diversified applications in industry.

Additional information is needed on the properties of zirconium compounds and production of these materials.

More than half of the zircon consumed in the United States is used in foundries for molding. The zirconium goes to waste since no attempt is made to recover it. Conservation of the zirconium is therefore a problem.

INDEX AND INFORMATION FINDING GUIDE

The 89 commodity chapters in Bulletin 630 are arranged alphabetically by commodity and conform to a standard outline, but with some deviations and omissions as required for particular commodities. The generalized outline is as follows:

Summary
Background
- Size and organization of the industry
- Geographic distribution of the industry
- Definition of terms, grades, and specifications
- Technology—geology, mining, processing
- Uses
- Byproducts and coproduct relationships
- Alternate materials
- Secondary sources and recovery
- Reserves (domestic and foreign)
- Conservation
- Sources of statistical information
- Production, consumption, and trade
- Strategic considerations
- Government programs
- Prices and costs
- Taxes
- Employment and productivity
- Transportation
- Research

Outlook
Problems
Bibliography

The commodity index has two main purposes. First it is a guide to the title of the main chapter in which a particular mineral or mineral commodity is reviewed. For example a glance at the commodity index will show that amosite is reviewed in the Asbestos chapter and rutile is reported in the Titanium chapter. As a second purpose the commodity index serves as a guide to any substantial reference to a mineral commodity in a chapter dealing principally with some other commodity. As an example, while most information on copper is in the Copper chapter, the index lists several substantial references to copper in other chapters.
